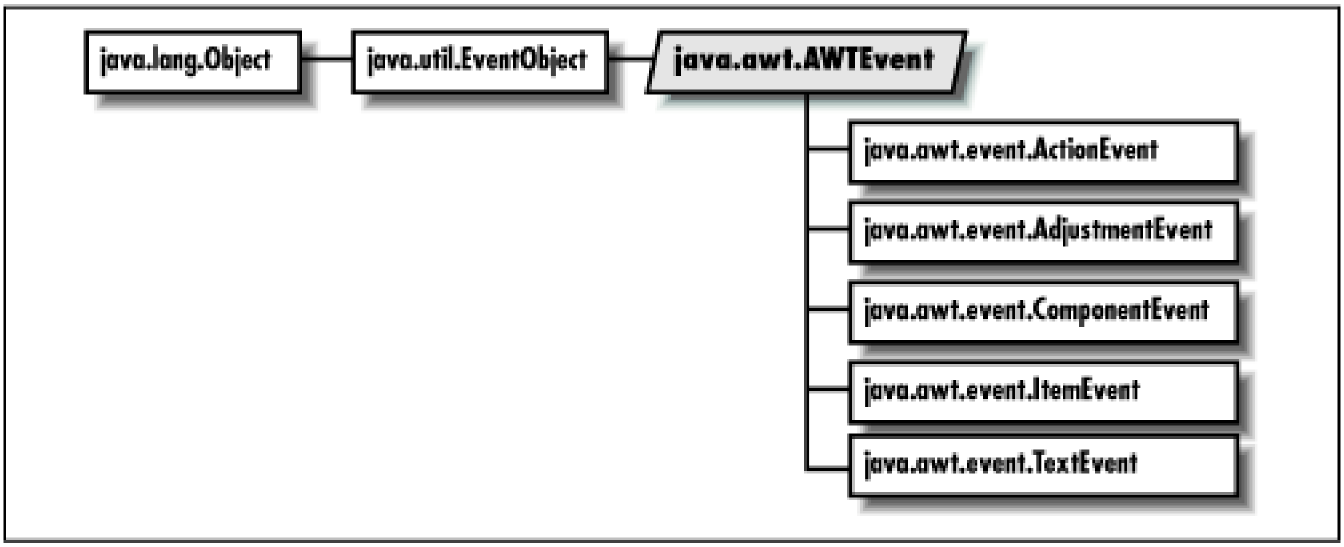
JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

AWTEvent ★

Name

AWTEvent ★



Description

The root class of all AWT events. Subclasses of this class are the replacement for `java.awt.Event`, which is only used for the Java 1.0.2 event model. In Java 1.1, event objects are passed from event source components to objects implementing a corresponding listener interface. Some event sources have a corresponding interface, too. For example, `AdjustmentEvent`s are passed from `Adjustable` objects to `AdjustmentListener`s. Some event types do not have corresponding interfaces; for example, `ActionEvent`s are passed from `Button`s to `ActionListener`s, but there is no "Actionable" interface that `Button` implements.

Class Definition

```
public abstract class java.awt.AWTEvent
    extends java.util.EventObject {
  // Constants
  public final static long ACTION_EVENT_MASK;
  public final static long ADJUSTMENT_EVENT_MASK;
  public final static long COMPONENT_EVENT_MASK;
  public final static long CONTAINER_EVENT_MASK;
  public final static long FOCUS_EVENT_MASK;
  public final static long ITEM_EVENT_MASK;
  public final static long KEY_EVENT_MASK;
  public final static long MOUSE_EVENT_MASK;
  public final static long MOUSE_MOTION_EVENT_MASK;
  public final static long RESERVED_ID_MAX;
  public final static long TEXT_EVENT_MASK;
  public final static long WINDOW_EVENT_MASK;
  // Variables
  protected boolean consumed;
  protected int id;
  // Constructors
  public AWTEvent (Event event);
  public AWTEvent (Object source, int id);
  // Instance Methods
  public int getID();
  public String paramString();
  public String toString();
  // Protected Instance Methods
  protected void consume();
  protected boolean isConsumed();
}
```

Constants

ACTION_EVENT_MASK

public static final long ACTION_EVENT_MASK

The mask for action events.

ADJUSTMENT_EVENT_MASK

public static final long ADJUSTMENT_EVENT_MASK

The mask for adjustment events.

COMPONENT_EVENT_MASK

public static final long COMPONENT_EVENT_MASK

The mask for component events.

CONTAINER_EVENT_MASK

public static final long CONTAINER_EVENT_MASK

The mask for container events.

FOCUS_EVENT_MASK

public static final long FOCUS_EVENT_MASK

The mask for focus events.

ITEM_EVENT_MASK

public static final long ITEM_EVENT_MASK

The mask for item events.

KEY_EVENT_MASK

public static final long KEY_EVENT_MASK

The mask for key events.

MOUSE_EVENT_MASK

public static final long MOUSE_EVENT_MASK

The mask for mouse events.

MOUSE_MOTION_EVENT_MASK

public static final long MOUSE_MOTION_EVENT_MASK

The mask for mouse motion events.

RESERVED_ID_MAX

public static final int

The maximum reserved event id.

TEXT_EVENT_MASK

public static final long TEXT_EVENT_MASK

The mask for text events.

WINDOW_EVENT_MASK

public static final long WINDOW_EVENT_MASK

The mask for window events.

Variables

consumed

protected boolean consumed

If `consumed` is `true`, the event will not be sent back to the peer. Semantic events will never be sent back to a peer; thus `consumed` is always `true` for semantic events.

id

protected int id

The type ID of this event.

Constructors

AWTEvent

public AWTEvent (Event event)

Parameters

> *event*
>
> > A version 1.0.2 `java.awt.Event` object.

Description

> Constructs a 1.1 `java.awt.AWTEvent` derived from a 1.0.2 `java.awt.Event` object.

public AWTEvent (Object source, int id)

Parameters

> *source*
>
> > The object that the event originated from.
>
> *id*
>
> > An event type ID.

Description

> Constructs an `AWTEvent` object.

Instance Methods

getID

public int getID()

Returns

> The type ID of the event.

paramString

public String paramString()

Returns

> A string with the current settings of `AWTEvent`.

Description

> Helper method for `toString()` that generates a string of current settings.

toString

public String toString()

Returns

> A string representation of the `AWTEvent` object.

Overrides

> `Object.toString()`

Protected Instance Methods

consume

protected void consume()

Description

Consumes the event so it is not sent back to its source.

isConsumed

public boolean isConsumed()

Returns

A flag indicating whether this event has been consumed.

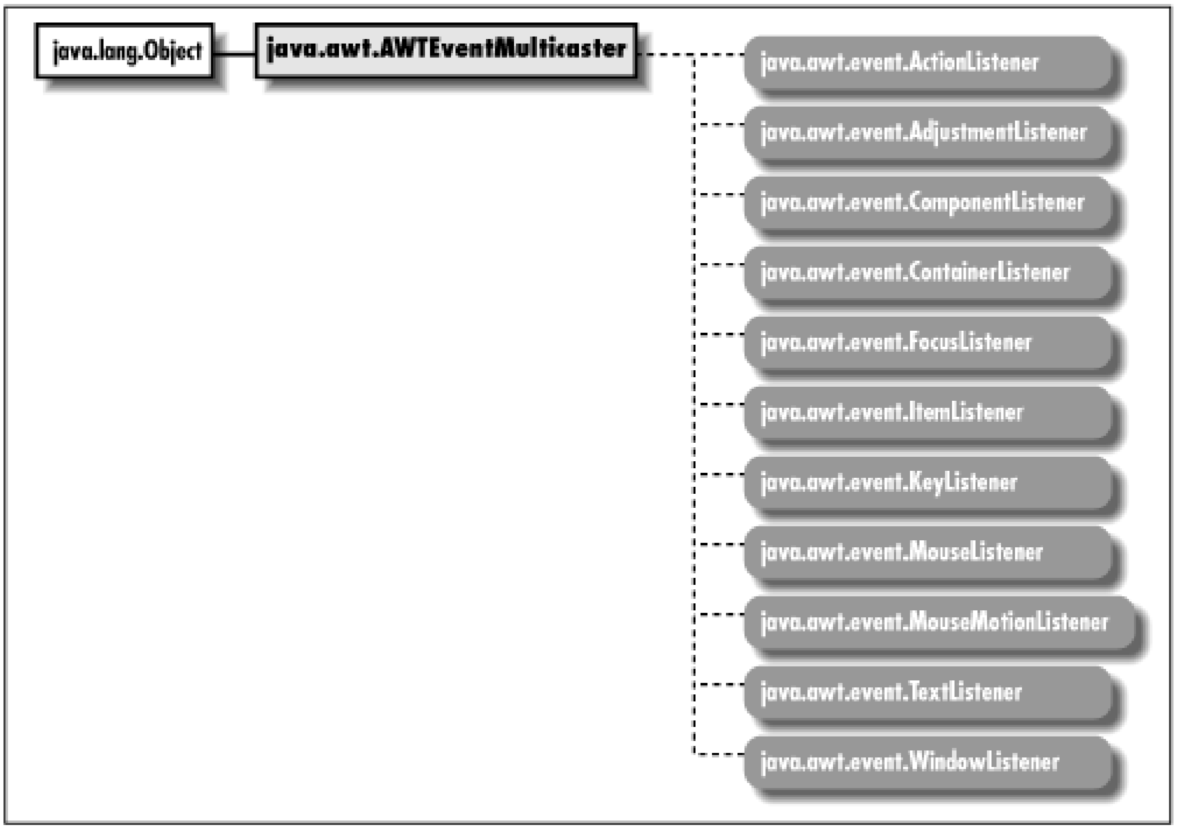
AWTEventMulticaster ★

Name

AWTEventMulticaster ★



java.lang.Object
java.awt.AWTEventMulticaster
java.awt.event.ActionListener
java.awt.event.AdjustmentListener
java.awt.event.ComponentListener
java.awt.event.ContainerListener
java.awt.event.FocusListener
java.awt.event.ItemListener
java.awt.event.KeyListener
java.awt.event.MouseListener
java.awt.event.MouseMotionListener
java.awt.event.TextListener
java.awt.event.WindowListener

Description

This class multicasts events to event listeners. Each multicaster has two listeners, cunningly named `a` and `b`. When an event source calls one of the listener methods of the multicaster, the multicaster calls the same listener method on both `a` and `b`. Multicasters are built into trees using the static `add()` and `remove()` methods. In this way a single event can be sent to many listeners.

Static methods make it easy to implement event multicasting in component subclasses. Each time an `add<type>Listener()` function is called in the component subclass, call the corresponding `AWTEventMulticaster.add()` method to chain together (or "tree up") listeners. Similarly, when a `remove<type>Listener()` function is called, `AWTEventMulticaster.remove()` can be called to remove a chained listener.

Class Definition

```
public class java.awt.AWTEventMulticaster
  extends java.lang.Object
  implements java.awt.event.ActionListener, java.awt.event.AdjustmentListener,
             java.awt.event.ComponentListener, java.awt.event.ContainerListener,
             java.awt.event.FocusListener, java.awt.event.ItemListener,
             java.awt.event.KeyListener, java.awt.event.MouseListener,
             java.awt.event.MouseMotionListener, java.awt.event.TextListener,
             java.awt.event.WindowListener {
  // Variables

  public void windowOpened(WindowEvent e);
  // Protected Instance Methods
  protected EventListener remove(EventListener oldl);
  protected void saveInternal(ObjectOutputStream s, String k) throws IOException;
}
```

Variables

a

protected EventListener a

One of the `EventListener`s this `AWTEventMulticaster` sends events to.

b

protected EventListener b

One of the `EventListener`s this `AWTEventMulticaster` sends events to.

Constructors

AWTEventMulticaster

protected AWTEventMulticaster (EventListener a, EventListener b)

Parameters

a

A listener that receives events.

b

A listener that receives events.

Description

Constructs an `AWTEventMulticaster` that sends events it receives to the supplied listeners. The constructor is protected because it is only the class methods of `AWTEventMulticaster` that ever instantiate this class.

Class Methods

add

public static ActionListener add (ActionListener a, ActionListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to a and b.

public static AdjustmentListener add (AdjustmentListener a, AdjustmentListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to a and b.

public static ComponentListener add (ComponentListener a, ComponentListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to a and b.

public static ContainerListener add (ContainerListener a, ContainerListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to a and b.

public static FocusListener add (FocusListener a, FocusListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to a and b.

public static ItemListener add (ItemListener a, ItemListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to a and b.

public static KeyListener add (KeyListener a, KeyListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to `a` and `b`.

public static MouseListener add (MouseListener a, MouseListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to `a` and `b`.

public static MouseMotionListener add (MouseMotionListener a, MouseMotionListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to `a` and `b`.

public static TextListener add (TextListener a, TextListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to `a` and `b`.

public static WindowListener add (WindowListener a, WindowListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to `a` and `b`.

addInternal

public static EventListener addInternal (EventListener a, EventListener b)

Parameters

a

An event listener.

b

An event listener.

Returns

A listener object that passes events to `a` and `b`.

Description

This method is a helper for the `add()` methods.

remove

public static ActionListener remove (ActionListener l, ActionListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static AdjustmentListener remove (AdjustmentListener l, AdjustmentListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static ComponentListener remove (ComponentListener l, ComponentListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static ContainerListener remove (ContainerListener l, ContainerListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static FocusListener remove (FocusListener l, FocusListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static ItemListener remove (ItemListener l, ItemListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static KeyListener remove (KeyListener l, KeyListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static MouseListener remove (MouseListener l, MouseListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static MouseMotionListener remove (MouseMotionListener l, MouseMotionListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static TextListener remove (TextListener l, TextListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static WindowListener remove (WindowListener l, WindowListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

public static WindowListener remove (WindowListener l, WindowListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

removeInternal

public static EventListener removeInternal (EventListener l, EventListener oldl)

Parameters

l

An event listener.

oldl

An event listener.

Returns

A listener object that multicasts to `l` but not `oldl`.

Description

This method is a helper for the `remove()` methods.

Instance Methods

actionPerformed

public void actionPerformed (ActionEvent e)

Parameters

e

The action event that occurred.

Description

Handles the event by passing it on to listeners `a` and `b`.

adjustmentValueChanged

public void adjustmentValueChanged (AdjustmentEvent e)

Parameters

e

The adjustment event that occurred.

Description

Handles the event by passing it on to listeners a and b.

componentAdded

public void componentAdded (ContainerEvent e)

Parameters

e

The container event that occurred.

Description

Handles the event by passing it on to listeners a and b.

componentHidden

public void componentHidden (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Handles the event by passing it on to listeners a and b.

componentMoved

public void componentMoved (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Handles the event by passing it on to listeners a and b.

componentRemoved

public void componentRemoved (ContainerEvent e)

Parameters

e

The container event that occurred.

Description

Handles the event by passing it on to listeners a and b.

componentResized

public void componentResized (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Handles the event by passing it on to listeners a and b.

componentShown

public void componentShown (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Handles the event by passing it on to listeners a and b.

focusGained

public void focusGained (FocusEvent e)

Parameters

e

The focus event that occurred.

Description

Handles the event by passing it on to listeners a and b.

focusLost

public void focusLost (FocusEvent e)

Parameters

e

The focus event that occurred.

Description

Handles the event by passing it on to listeners a and b.

itemStateChanged

public void itemStateChanged (ItemEvent e)

Parameters

e

The item event that occurred.

Description

Handles the event by passing it on to listeners a and b.

keyPressed

public void keyPressed (KeyEvent e)

Parameters

e

The key event that occurred.

Description

Handles the event by passing it on to listeners a and b.

keyReleased

public void keyReleased (KeyEvent e)

Parameters

e

The key event that occurred.

Description

Handles the event by passing it on to listeners a and b.

keyTyped

public void keyTyped (KeyEvent e)

Parameters

e

The key event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mouseClicked

public void mouseClicked (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mouseDragged

public void mouseDragged (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mouseEntered

public void mouseEntered (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mouseExited

public void mouseExited (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mouseMoved

public void mouseMoved (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mousePressed

public void mousePressed (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

mouseReleased

public void mouseReleased (MouseEvent e)

Parameters

e

The mouse event that occurred.

Description

Handles the event by passing it on to listeners a and b.

textValueChanged

public void textValueChanged (TextEvent e)

Parameters

e

The text event that occurred.

Description

Handles the event by passing it on to listeners a and b.

windowActivated

public void windowActivated (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners a and b.

windowClosed

public void windowClosed (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners a and b.

windowClosing

public void windowClosing (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners a and b.

windowDeactivated

public void windowDeactivated (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners a and b.

windowDeiconified

public void windowDeiconified (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners a and b.

windowIconified

public void windowIconified (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners `a` and `b`.

windowOpened

public void windowOpened (WindowEvent e)

Parameters

e

The window event that occurred.

Description

Handles the event by passing it on to listeners `a` and `b`.

Protected Instance Methods

remove

protected EventListener remove(EventListener oldl)

Parameters

oldl

The listener to remove.

Returns

The resulting `EventListener`.

Description

This method removes `oldl` from the `AWTEventMulticaster` and returns the resulting listener.

AWTException

Name

AWTException

[Graphic: Figure from the text]

Description

An `AWTException`; thrown to indicate an exceptional condition; must be caught or declared in a `throws` clause.

Class Definition

```
public class java.awt.AWTException
    extends java.lang.Exception {

  // Constructors
  public AWTException (String message);
}
```

Constructors

AWTException

public AWTException (String message)

Parameters

message

Detailed message.

See Also

`Exception`, `String`

AWTEventMulticaster ★ | BOOK INDEX | Adjustable ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Adjustable ★

Name

Adjustable ★

[Graphic: Figure from the text]

Description

The `Adjustable` interface is useful for scrollbars, sliders, dials, and other components that have an adjustable numeric value. Classes that implement the `Adjustable` interface should send `AdjustmentEvent` objects to listeners that have registered via `addAdjustmentListener(AdjustmentListener)`.

Interface Definition

```
public abstract interface java.awt.Adjustable {
  // Constants
  public final static int HORIZONTAL = 0;
  public final static int VERTICAL = 1;

  // Interface Methods
  public abstract void addAdjustmentListener (AdjustmentListener l);
  public abstract int getBlockIncrement();
  public abstract int getMaximum();
  public abstract int getMinimum();
  public abstract int getOrientation();
  public abstract int getUnitIncrement();
  public abstract int getValue();
  public abstract int getVisibleAmount();
  public abstract void removeAdjustmentListener (AdjustmentListener l);
  public abstract void setBlockIncrement (int b);
  public abstract void setMaximum (int max);
  public abstract void setMinimum (int min);
  public abstract void setUnitIncrement (int u);
  public abstract void setValue (int v);
  public abstract void setVisibleAmount (int v);
}
```

Constants

HORIZONTAL

public static final int HORIZONTAL

A constant representing horizontal orientation.

VERTICAL

public static final int VERTICAL

A constant representing vertical orientation.

Interface Methods

addAdjustmentListener

public abstract void addAdjustmentListener (ActionListener l)

Parameters

l

An object that implements the `AdjustmentListener` interface.

Description

Add a listener for adjustment event.

getBlockIncrement

public abstract int getBlockIncrement()

Returns

The amount to scroll when a paging area is selected.

getMaximum

public abstract int getMaximum()

Returns

The maximum value that the `Adjustable` object can take.

getMinimum

public abstract int getMinimum()

Returns

The minimum value that the `Adjustable` object can take.

getOrientation

public abstract int getOrientation()

Returns

A value representing the direction of the `Adjustable` object.

getUnitIncrement

public abstract int getUnitIncrement()

Returns

The unit amount to scroll.

getValue

public abstract int getValue()

Returns

The current setting for the `Adjustable` object.

getVisibleAmount

public abstract int getVisibleAmount()

Returns

The current visible setting (i.e., size) for the `Adjustable` object.

removeAdjustmentListener

public abstract void removeAdjustmentListener (AdjustmentListener l)

Parameters

l

One of the object's `AdjustmentListener`s.

Description

Remove an adjustment event listener.

setBlockIncrement

public abstract void setBlockIncrement (int b)

Parameters

b

New block increment amount.

Description

Changes the block increment amount for the `Adjustable` object.

setMaximum

public abstract void setMaximum (int max)

Parameters

max

New maximum value.

Description

Changes the maximum value for the `Adjustable` object.

setMinimum

public abstract void setMinimum (int min)

Parameters

min

New minimum value.

Description

Changes the minimum value for the `Adjustable` object.

setUnitIncrement

public abstract void setUnitIncrement (int u)

Parameters

u

New unit increment amount.

Description

Changes the unit increment amount for the `Adjustable` object.

setValue

public abstract void setValue (int v)

Parameters

v

New value.

Description

Changes the current value of the `Adjustable` object.

setVisibleAmount

public abstract void setVisibleAmount (int v)

Parameters

v

New amount visible.

Description

Changes the current visible amount of the `Adjustable` object.

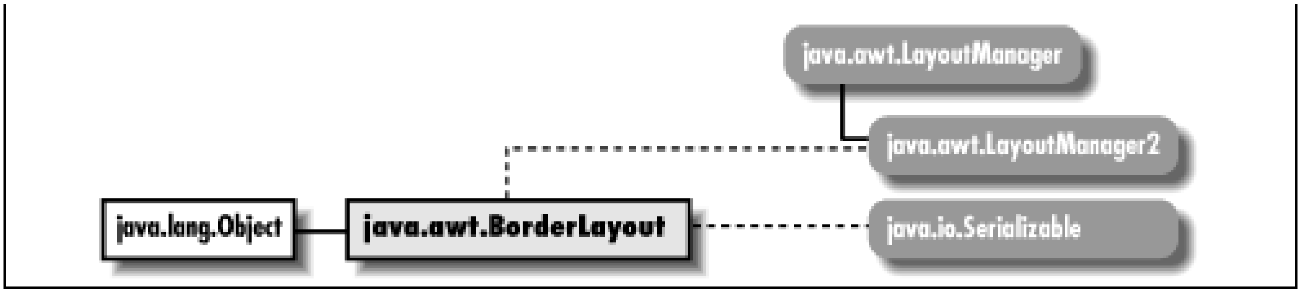
See Also

`AdjustmentEvent`, `AdjustmentListener`, `Scrollbar`

BorderLayout

Name

BorderLayout



Description

`BorderLayout` is a `LayoutManager` that provides the means to lay out components along the edges of a container. It divides the container into five regions, named North, East, South, West, and Center. Normally you won't call the `LayoutManager`'s methods yourself. When you `add()` a `Component` to a `Container`, the `Container` calls the `addLayoutComponent()` method of its `LayoutManager`.

Class Definition

```
public class java.awt.BorderLayout
    extends java.lang.Object
    implements java.awt.LayoutManager2, java.io.Serializable {
  // Constants
  public final static String CENTER; ★
  public final static String EAST; ★
  public final static String NORTH; ★
  public final static String SOUTH; ★
  public final static String WEST; ★

  // Constructors
  public BorderLayout();
  public BorderLayout (int hgap, int vgap);

  // Instance Methods
  public void addLayoutComponent (Component comp, Object constraints); ★
  public void addLayoutComponent (String name, Component component); ☆
  public int getHgap(); ★
  public abstract float getLayoutAlignmentX(Container target); ★
  public abstract float getLayoutAlignmentY(Container target); ★
  public int getVgap(); ★
  public abstract void invalidateLayout(Container target); ★

  public void layoutContainer (Container target);
  public abstract Dimension maximumLayoutSize(Container target); ★
  public Dimension minimumLayoutSize (Container target);
  public Dimension preferredLayoutSize (Container target);
  public void removeLayoutComponent (Component component);
  public void setHgap (int hgap); ★
  public void setVgap (int vgap); ★
  public String toString();
}
```

Constants

CENTER

public final static String CENTER

A constant representing center orientation.

EAST

public final static String EAST

A constant representing east orientation.

NORTH

public final static String NORTH

A constant representing north orientation.

SOUTH

public final static String SOUTH

A constant representing south orientation.

WEST

public final static String WEST

A constant representing west orientation.

Constructors

BorderLayout

public BorderLayout()

Description

> Constructs a `BorderLayout` object.

public BorderLayout (int hgap, int vgap)

Parameters

> *hgap*
>
> > Horizontal space between each component in the container.
>
> *vgap*
>
> > Vertical space between each component in the container.

Description

Constructs a `BorderLayout` object with the values specified as the gaps between each component in the container managed by this instance of `BorderLayout`.

Instance Methods

addLayoutComponent

public void addLayoutComponent (Component comp, Object constraints) ★

Parameters

comp

The component being added.

constraints

An object describing the constraints on this component.

Implements

`LayoutManager2.addLayoutComponent()`

Description

Adds the component `comp` to a container subject to the given `constraints`. This is a more general version of `addLayoutComponent(String, Component)` method. It corresponds to `java.awt.Container`'s `add(Component, Object)` method. In practice, it is used the same in version 1.1 as in Java 1.0.2, except with the parameters swapped:

```
Panel p = new Panel(new BorderLayout());
p.add(new Button("OK"), BorderLayout.SOUTH);
```

addLayoutComponent

public void addLayoutComponent (String name, Component component) ☆

Parameters

name

Name of region to add component to.

component

Actual component being added.

Implements

`LayoutManager.addLayoutComponent()`

Description

Adds a `component` to a container in region `name`. This has been replaced in version 1.1 with the more general `addLayoutComponent(Component, Object)`.

getHgap

public int getHgap() ★

Returns

The horizontal gap for this `BorderLayout` instance.

getLayoutAlignmentX

public abstract float getLayoutAlignmentX (Container target) ★

Parameters

target

The container to inspect.

Returns

The value .5 for all containers.

Description

This method returns the preferred alignment of the given container `target`. A return value of 0 is left aligned, .5 is centered, and 1 is right aligned.

getLayoutAlignmentY

public abstract float getLayoutAlignmentY (Container target) ★

Parameters

target

The container to inspect.

Returns

The value .5 for all containers.

Description

This method returns the preferred alignment of the given container `target`. A return value of 0 is top aligned, .5 is centered, and 1 is bottom aligned.

getVgap

public int getVgap() ★

Returns

The vertical gap for this `BorderLayout` instance.

invalidateLayout

public abstract void invalidateLayout (Container target) ★

Parameters

target

The container to invalidate.

Description

Does nothing.

layoutContainer

public void layoutContainer (Container target)

Parameters

target

The container that needs to be redrawn.

Implements

`LayoutManager.layoutContainer()`

Description

Draws components contained within `target`.

maximumLayoutSize

public abstract Dimension maximumLayoutSize (Container target) ★

Parameters

target

The container to inspect.

Returns

A `Dimension` whose horizontal and vertical components are `Integer.MAX_VALUE`.

Description

For `BorderLayout`, a maximal `Dimension` is always returned.

minimumLayoutSize

public Dimension minimumLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Minimum `Dimension` of the container `target`.

Implements

`LayoutManager.minimumLayoutSize()`

Description

Calculates minimum size of `target`. container.

preferredLayoutSize

public Dimension preferredLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Preferred `Dimension` of the container `target`.

Implements

`LayoutManager.preferredLayoutSize()`

Description

Calculates preferred size of `target` container.

removeLayoutComponent

public void removeLayoutComponent (Component component)

Parameters

component

Component to stop tracking.

Implements

`LayoutManager.removeLayoutComponent()`

Description

Removes `component` from any internal tracking systems.

setHgap

public void setHgap (int hgap) ★

Parameters

hgap

The horizontal gap value.

Description

Sets the horizontal gap between components.

setVgap

public void setVgap (int vgap) ★

Parameters

vgap

The vertical gap value.

Description

Sets the vertical gap between components.

toString

public String toString()

Returns

A string representation of the `BorderLayout` object.

Overrides

`Object.toString()`

See Also

`Component`, `Container`, `Dimension`, `LayoutManager`, `LayoutManager2`, `Object`, `String`

PREVIOUS HOME NEXT
Adjustable ★ BOOK INDEX Button

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Button

Name

Button

[Graphic: Figure from the text]

Description

The `Button` is the familiar labeled button object. It inherits most of its functionality from `Component`. For example, to change the font of the `Button`, you would use `Component`'s `setFont()` method. The `Button` sends `java.awt.event.ActionEvent` objects to its listeners when it is pressed.

Class Definition

```
public class java.awt.Button
    extends java.awt.Component {

  // Constructors
  public Button();
  public Button (String label);

  // Instance Methods
  public void addActionListener (ActionListener l); ★
  public void addNotify();
  public String getActionCommand(); ★
  public String getLabel();
  public void removeActionListener (ActionListener l); ★
  public void setActionCommand (String command); ★
  public synchronized void setLabel (String label);

  // Protected Instance Methods
  protected String paramString();
  protected void processActionEvent (ActionEvent e); ★
  protected void processEvent (AWTEvent e); ★
}
```

Constructors

Button

public Button()

Description

> Constructs a `Button` object with no label.

public Button (String label)

Parameters

> *label*
>
> > The text for the label on the button

Description

> Constructs a `Button` object with text of `label`.

Instance Methods

addActionListener

public void addActionListener (ActionListener l) ★

Parameters

l

An object that implements the `ActionListener` interface.

Description

Add a listener for the action event.

addNotify

public void addNotify()

Overrides

`Component.addNotify()`

Description

Creates `Button`'s peer.

getActionCommand

public String getActionCommand() ★

Returns

Current action command string.

Description

Returns the string used for the action command.

getLabel

public String getLabel()

Returns

Text of the `Button`'s label.

removeActionListener

public void removeActionListener (ActionListener l) ★

Parameters

l

One of this `Button`'s `ActionListener`s.

Description

Remove an action event listener.

setActionCommand

public void setActionCommand (String command) ★

Parameters

command

New action command string.

Description

Specify the string used for the action command.

setLabel

public synchronized void setLabel (String label)

Parameters

label

New text for label of `Button`.

Description

Changes the `Button`'s label to `label`.

Protected Instance Methods

paramString

protected String paramString()

Returns

String with current settings of `Button`.

Overrides

`Component.paramString()`

Description

Helper method for `toString()` used to generate a string of current settings.

processActionEvent

protected void processActionEvent (ActionEvent e) ★

Parameters

e

The action event to process.

Description

Action events are passed to this method for processing. Normally, this method is called by `processEvent()`.

processEvent

protected void processEvent (AWTEvent e) ★

Parameters

e

The event to process.

Description

Low level `AWTEvent`s are passed to this method for processing.

BorderLayout | BOOK INDEX | Canvas

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Canvas

Name

Canvas

[Graphic: Figure from the text]

Description

`Canvas` is a `Component` that provides a drawing area and is often used as a base class for new components.

Class Definition

```
public class java.awt.Canvas
    extends java.awt.Component {

  // Constructors
  public Canvas();

  // Instance Methods
  public void addNotify();
  public void paint (Graphics g);
}
```

Constructors

Canvas

public Canvas()

Description

Constructs a `Canvas` object.

Instance Methods

addNotify

public void addNotify()

Overrides

`Component.addNotify()`

Description

Creates `Canvas`'s peer.

paint

public void paint (Graphics g)

Parameters

g

Graphics context of component.

Description

Empty method to be overridden in order to draw something in graphics context.

See Also

`Component`, `Graphics`

PREVIOUS | HOME | NEXT
Button | BOOK INDEX | CardLayout

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

CardLayout

Name

CardLayout

[Graphic: Figure from the text]

Description

The `CardLayout LayoutManager` provides the means to manage multiple components, displaying one at a time. Components are displayed in the order in which they are added to the layout, or in an arbitrary order by using an assignable name.

Class Definition

```
public class java.awt.CardLayout
    extends java.lang.Object
    implements java.awt.LayoutManager2, java.io.Serializable {

  // Constructors
  public CardLayout();
  public CardLayout (int hgap, int vgap);
  // Instance Methods
  public void addLayoutComponent (Component comp,
      Object constraints); ★
  public void addLayoutComponent (String name, Component component); ☆
  public void first (Container parent);
  public int getHgap(); ★
  public abstract float getLayoutAlignmentX(Container target); ★
  public abstract float getLayoutAlignmentY(Container target); ★
  public int getVgap(); ★
  public abstract void invalidateLayout(Container target); ★
  public void last (Container parent);
  public void layoutContainer (Container target);
  public abstract Dimension maximumLayoutSize(Container target); ★
  public Dimension minimumLayoutSize (Container target);
  public void next (Container parent);
  public Dimension preferredLayoutSize (Container target);
  public void previous (Container parent);
  public void removeLayoutComponent (Component component);
  public void setHgap (int hgap); ★
  public void setVgap (int vgap); ★
  public void show (Container parent, String name);
  public String toString();
}
```

Constructors

CardLayout

public CardLayout()

Description

Constructs a `CardLayout` object.

public CardLayout (int hgap, int vgap)

Parameters

hgap

Horizontal space around left and right of container

vgap

Vertical space around top and bottom of container

Description

Constructs a `CardLayout` object with the values specified as the gaps around the container managed by this instance of `CardLayout`.

Instance Methods

addLayoutComponent

public void addLayoutComponent (Component comp, Object constraints) ★

Parameters

comp

The component being added.

constraints

An object describing the constraints on this component.

Implements

`LayoutManager2.addLayoutComponent()`

Description

Adds the component `comp` to a container subject to the given `constraints`. This is a more generalized version of `addLayoutComponent(String, Component)`. It corresponds to `java.awt.Container's add(Component, Object)`. In practice, it is used the same in Java 1.1 as in Java 1.0.2, except with the parameters swapped:

```
Panel p = new Panel();
p.setLayoutManager(new CardLayout());
p.add(new Button("OK"), "Don Julio");
```

addLayoutComponent

public void addLayoutComponent (String name, Component component) ☆

Parameters

name

Name of the component to add.

component

The actual component being added.

Implements

```
LayoutManager.addLayoutComponent()
```

Description

Places `component` under the layout's management, assigning it the given `name`. This has been replaced in version 1.1 with the more general `addLayoutComponent(Component, Object)`.

first

public void first (Container parent)

Parameters

parent

The container whose displayed component is changing.

Throws

`IllegalArgumentException`

If the `LayoutManager` of `parent` is not `CardLayout`.

Description

Sets the container to display the first component in parent.

getHgap

public int getHgap() ★

Returns

The horizontal gap for this `CardLayout` instance.

getLayoutAlignmentX

public abstract float getLayoutAlignmentX (Container target) ★

Parameters

target

The container to inspect.

Returns

The value .5 for all containers.

Description

This method returns the preferred alignment of the given container `target`. A return value of 0 is left aligned, .5 is centered, and 1 is right aligned.

getLayoutAlignmentY

public abstract float getLayoutAlignmentY (Container target) ★

Parameters

target

The container to inspect.

Returns

The value .5 for all containers.

Description

This method returns the preferred alignment of the given container `target`. A return value of 0 is top aligned, .5 is centered, and 1 is bottom aligned.

getVgap

public int getVgap() ★

Returns

The vertical gap for this `CardLayout` instance.

invalidateLayout

public abstract void invalidateLayout (Container target) ★

Parameters

target

The container to invalidate.

Description

Does nothing.

last

public void last (Container parent)

Parameters

parent

The container whose displayed component is changing.

Throws

`IllegalArgumentException`

If the `LayoutManager` of `parent` is not `CardLayout`.

Description

Sets the container to display the final component in parent.

layoutContainer

public void layoutContainer (Container target)

Parameters

target

The container that needs to be redrawn.

Implements

`LayoutManager.layoutContainer()`

Description

Displays the currently selected component contained within `target`.

maximumLayoutSize

public abstract Dimension maximumLayoutSize (Container target) ★

Parameters

target

The container to inspect.

Returns

A `Dimension` whose horizontal and vertical components are `Integer.MAX_VALUE`.

Description

For `CardLayout`, a maximal `Dimension` is always returned.

minimumLayoutSize

public Dimension minimumLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Minimum `Dimension` of the container `target`.

Implements

`LayoutManager.minimumLayoutSize()`

Description

Calculates minimum size of the `target` container.

next

public void next (Container parent)

Parameters

parent

The container whose displayed component is changing.

Throws

`IllegalArgumentException`

If the `LayoutManager` of `parent` is not `CardLayout`.

Description

Sets the container to display the following component in the parent.

preferredLayoutSize

public Dimension preferredLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Preferred `Dimension of` the container `target`.

Implements

`LayoutManager.preferredLayoutSize()`

Description

Calculates preferred size of the `target` container.

previous

public void previous (Container parent)

Parameters

parent

The container whose displayed component is changing.

Throws

`IllegalArgumentException`

If the `LayoutManager` of `parent` is not `CardLayout`.

Description

Sets the container to display the prior component in `parent`.

removeLayoutComponent

public void removeLayoutComponent (Component component)

Parameters

component

Component to stop tracking.

Implements

`LayoutManager.removeLayoutComponent()`

Description

Removes `component` from the layout manager's internal tables.

setHgap

public void setHgap (int hgap) ★

Parameters

hgap

The horizontal gap value.

Description

Sets the horizontal gap for the left and right of the container.

setVgap

public void setVgap (int vgap) ★

Parameters

vgap

The vertical gap value.

Description

Sets the vertical gap for the top and bottom of the container.

show

public void show (Container parent, String name)

Parameters

parent

The container whose displayed component is changing.

name

Name of component to display.

Throws

`IllegalArgumentException`

If `LayoutManager` of `parent` is not `CardLayout`.

Description

Sets the container to display the component `name` in `parent`.

toString

public String toString()

Returns

A string representation of the `CardLayout` object.

Overrides

`Object.toString()`

See Also

`Component`, `Container`, `Dimension`, `LayoutManager`, `LayoutManager2`, `Object`, `String`

Checkbox

Name

Checkbox

[Graphic: Figure from the text]

Description

The `Checkbox` is a `Component` that provides a true or false toggle switch for user input.

Class Definition

```
public class java.awt.Checkbox
    extends java.awt.Component
    implements java.awt.ItemSelectable {

  // Constructors
  public Checkbox();
  public Checkbox (String label);
  public Checkbox (String label, boolean state); ★
  public Checkbox (String label, boolean state, CheckboxGroup group); ★
  public Checkbox (String label, CheckboxGroup group, boolean state);

  // Instance Methods
  public void addItemListener (ItemListener l); ★
  public void addNotify();
  public CheckboxGroup getCheckboxGroup();
  public String getLabel();
  public Object[] getSelectedObjects(); ★
  public boolean getState();
  public void removeItemListener (ItemListener l); ★
  public void setCheckboxGroup (CheckboxGroup group);
  public synchronized void setLabel (String label);
  public void setState (boolean state);

  // Protected Instance Methods
  protected String paramString();
  protected void processEvent (AWTEvent e); ★
  protected void processItemEvent (ItemEvent e); ★
}
```

Constructors

Checkbox

public Checkbox()

Description

> Constructs a `Checkbox` object with no label that is initially `false`.

public Checkbox (String label)

Parameters

> *label*
>
> > Text to display with the `Checkbox`.

Description

> Constructs a `Checkbox` object with the given `label` that is initially `false`.

public Checkbox (String label, boolean state) ★

Parameters

label

Text to display with the `Checkbox`.

state

Intial value of the `Checkbox`.

Description

Constructs a `Checkbox` with the given `label`, initialized to the given `state`.

public Checkbox (String label, boolean state, CheckboxGroup group) ★

Parameters

label

Text to display with the `Checkbox`.

state

Intial value of the `Checkbox`.

group

The `CheckboxGroup` this `Checkbox` should belong to.

Description

Constructs a `Checkbox` with the given `label`, initialized to the given `state` and belonging to `group`.

public Checkbox (String label, CheckboxGroup group, boolean state)

Parameters

label

Text to display with the `Checkbox`.

group

The `CheckboxGroup` this `Checkbox` should belong to.

state

Intial value of the `Checkbox`.

Description

Constructs a `Checkbox` object with the given settings.

Instance Methods

addItemListener

public void addItemListener (ItemListener l) ★

Parameters

l

The listener to be added.

Implements

`ItemSelectable.addItemListener(ItemListener l)`

Description

Adds a listener for the `ItemEvent` objects this `Checkbox` generates.

addNotify

public void addNotify()

Overrides

`Component.addNotify()`

Description

Creates `Checkbox` peer.

getCheckboxGroup

public CheckboxGroup getCheckboxGroup()

Returns

The current `CheckboxGroup` associated with the `Checkbox`, if any.

getLabel

public String getLabel()

Returns

The text associated with the `Checkbox`.

getSelectedObjects

public Object[] getSelectedObjects() ★

Implements

`ItemSelectable.getSelectedObjects()`

Description

If the `Checkbox` is checked, returns an array with length 1 containing the label of the `Checkbox`; otherwise returns `null`.

getState

public boolean getState()

Returns

The current state of the `Checkbox`.

removeItemListener

public void removeItemListener (ItemListener l) ★

Parameters

l

The listener to be removed.

Implements

`ItemSelectable.removeItemListener (ItemListener l)`

Description

Removes the specified `ItemListener` so it will not receive `ItemEvent` objects from this `Checkbox`.

setCheckboxGroup

public void setCheckboxGroup (CheckboxGroup group)

Parameters

group

New group in which to place the `Checkbox`.

Description

Associates the `Checkbox` with a different `CheckboxGroup`.

setLabel

public synchronized void setLabel (String label)

Parameters

label

New text to associate with `Checkbox`.

Description

Changes the text associated with the `Checkbox`.

setState

public void setState (boolean state)

Parameters

state

New state for the `Checkbox`.

Description

Changes the state of the `Checkbox`.

Protected Instance Methods

paramString

protected String paramString()

Returns

String with current settings of `Checkbox`.

Overrides

`Component.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

processEvent

protected void processEvent(AWTEvent e) ★

Parameters

e

The event to process.

Description

Low level `AWTEvents` are passed to this method for processing.

processItemEvent

protected void processItemEvent(ItemEvent e) ★

Parameters

e

The item event to process.

Description

Item events are passed to this method for processing. Normally, this method is called by `processEvent()`.

See Also

`CheckboxGroup`, `Component`, `ItemEvent`, `ItemSelectable`, `String`

CheckboxGroup

Name

CheckboxGroup

[Graphic: Figure from the text]

Description

The `CheckboxGroup` class provides the means to group multiple `Checkbox` items into a mutual exclusion set, so that only one checkbox in the set has the value `true` at any time. The checkbox with the value `true` is the currently selected checkbox. Mutually exclusive checkboxes usually have a different appearance from regular checkboxes and are also called "radio buttons."

Class Definition

```
public class java.awt.CheckboxGroup
    extends java.lang.Object
    implements java.io.Serializable {

  // Constructors
  public CheckboxGroup();

  // Instance Methods
  public Checkbox getCurrent(); ☆
  public Checkbox getSelectedCheckbox() ★
  public synchronized void setCurrent (Checkbox checkbox); ☆
  public synchronized void setSelectedCheckbox (Checkbox checkbox); ★
  public String toString();
}
```

Constructors

CheckboxGroup

public CheckboxGroup()

Description

> Constructs a `CheckboxGroup` object.

Instance Methods

getCurrent

public Checkbox getCurrent() ☆

Returns

> The currently selected `Checkbox` within the `CheckboxGroup`.

Description

> Replaced by the more aptly named `getSelectedCheckbox()`.

getSelectedCheckbox

public Checkbox getSelectedCheckbox() ★

Returns

> The currently selected `Checkbox` within the `CheckboxGroup`.

setCurrent

public synchronized void setCurrent (Checkbox checkbox) ☆

Parameters

checkbox

The `Checkbox` to select.

Description

Changes the currently selected `Checkbox` within the `CheckboxGroup`.

Description

Replaced by `setSelectedCheckbox(Checkbox)`.

setSelectedCheckbox

public synchronized void setSelectedCheckbox (Checkbox checkbox) ★

Parameters

checkbox

The `Checkbox` to select.

Description

Changes the currently selected `Checkbox` within the `CheckboxGroup`.

toString

public String toString()

Returns

A string representation of the `CheckboxGroup` object.

Overrides

```
    Object.toString()
```

See Also

`Checkbox`, `Object`, `String`

Checkbox | BOOK INDEX | CheckboxMenuItem

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

CheckboxMenuItem

Name

CheckboxMenuItem

[Graphic: Figure from the text]

Description

The `CheckboxMenuItem` class represents a menu item with a boolean state.

Class Definition

```
public class java.awt.CheckboxMenuItem
    extends java.awt.MenuItem
    implements java.awt.ItemSelectable {

  // Constructors
  public CheckboxMenuItem(); ★
  public CheckboxMenuItem (String label);
  public CheckboxMenuItem (String label, boolean state); ★

  // Instance Methods
  public void addItemListener (ItemListener l); ★
  public void addNotify();
  public Object[] getSelectedObjects(); ★
  public boolean getState();
  public String paramString();
  public void removeItemListener (ItemListener l); ★
  public synchronized void setState (boolean condition);

  // Protected Instance Methods
  protected void processEvent (AWTEvent e); ★
  protected void processItemEvent (ItemEvent e); ★
}
```

Constructors

CheckboxMenuItem

public CheckboxMenuItem() ★

Description

Constructs a `CheckboxMenuItem` object with no label.

public CheckboxMenuItem (String label)

Parameters

label

Text that appears on `CheckboxMenuItem`.

Description

Constructs a `CheckboxMenuItem` object whose value is initially `false`.

public CheckboxMenuItem (String label, boolean state) ★

Parameters

label

Text that appears on `CheckboxMenuItem`.

state

The initial state of the menu item.

Description

Constructs a `CheckboxMenuItem` object with the specified `label` and `state`.

Instance Methods

addItemListener

public void addItemListener (ItemListener l) ★

Parameters

l

The listener to be added.

Implements

```
ItemSelectable.addItemListener(ItemListener l)
```

Description

Adds a listener for the `ItemEvent` objects this `CheckboxMenuItem` fires off.

addNotify

public void addNotify()

Overrides

```
MenuItem.addNotify()
```

Description

Creates `CheckboxMenuItem`'s peer.

getSelectedObjects

public Object[] getSelectedObjects() ★

Implements

`ItemSelectable.getSelectedObjects()`

Description

If the `CheckboxMenuItem` is checked, returns an array with length `1` containing the label of the `CheckboxMenuItem`; otherwise returns `null`.

getState

public boolean getState()

Returns

The current state of the `CheckboxMenuItem`.

paramString

public String paramString()

Returns

A string with current settings of `CheckboxMenuItem`.

Overrides

`MenuItem.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

removeItemListener

public void removeItemListener (ItemListener l) ★

Parameters

l

The listener to be removed.

Implements

`ItemSelectable.removeItemListener (ItemListener l)`

Description

Removes the specified `ItemListener` so it will not receive `ItemEvent` objects from this `CheckboxMenuItem`.

setState

public synchronized void setState (boolean condition)

Parameters

condition

New state for the `CheckboxMenuItem`.

Description

Changes the state of the `CheckboxMenuItem`.

Protected Instance Methods

processEvent

protected void processEvent(AWTEvent e) ★

Parameters

e

The event to process.

Overrides

`MenuItem.processEvent(AWTEvent)`

Description

Low level `AWTEvents` are passed to this method for processing.

processItemEvent

protected void processItemEvent(ItemEvent e) ★

Parameters

e

The item event to process.

Description

Item events are passed to this method for processing. Normally, this method is called by `processEvent()`.

See Also

`ItemEvent`, `ItemSelectable`, `MenuItem`, `String`

Choice

Choice

Name

Choice

[Graphic: Figure from the text]

Description

The `Choice` is a `Component` that provides a drop-down list of choices to choose from.

Class Definition

```
public class java.awt.Choice
    extends java.awt.Component
    implements java.awt.ItemSelectable {

  // Constructors
  public Choice();

  // Instance Methods
  public synchronized void add (String item); ★
  public synchronized void addItem (String item); ☆
  public void addItemListener (ItemListener l); ★
  public void addNotify();
  public int countItems(); ☆
  public String getItem (int index);
  public int getItemCount(); ★
  public int getSelectedIndex();
  public synchronized String getSelectedItem();
  public synchronized Object[] getSelectedObjects(); ★
  public synchronized void insert (String item, int index); ★
  public synchronized void remove (int position); ★
  public synchronized void remove (String item); ★
  public synchronized void removeAll(); ★
  public void removeItemListener (ItemListener l); ★
  public synchronized void select (int pos);
  public synchronized void select (String str);

  // Protected Instance Methods
  protected String paramString();
  protected void processEvent (AWTEvent e); ★
  protected void processItemEvent (ItemEvent e); ★
}
```

Constructors

Choice

public Choice()

Description

> Constructs a `Choice` object.

Instance Methods

add

public synchronized void add (String item) ★

Parameters

item

Text for new entry.

Throws

`NullPointerException`

If `item` is null.

Description

Adds a new entry to the available choices.

addItem

public synchronized void addItem (String item) ☆

Parameters

item

Text for new entry.

Throws

`NullPointerException`

If `item` is null.

Description

Replaced by `add(String)`.

addItemListener

public void addItemListener (ItemListener l) ★

Parameters

l

The listener to be added.

Implements

`ItemSelectable.addItemListener(ItemListener l)`

Description

Adds a listener for the `ItemEvent` objects this `Choice` generates.

addNotify

public void addNotify()

Overrides

`Component.addNotify()`

Description

Creates `Choice`'s peer.

countItems

public int countItems() ☆

Returns

Number of items in the `Choice`.

Description

Replaced by `getItemCount()`.

getItem

public String getItem (int index)

Parameters

index

Position of entry.

Returns

A string for an entry at a given position.

Throws

`ArrayIndexOutOfBoundsException`

If `index` is invalid; indices start at zero.

getItemCount

public int getItemCount() ★

Returns

Number of items in the `Choice`.

getSelectedIndex

public int getSelectedIndex()

Returns

Position of currently selected entry.

getSelectedItem

public synchronized String getSelectedItem()

Returns

Currently selected entry as a String.

getSelectedObjects

public synchronized Object[] getSelectedObjects() ★

Implements

`ItemSelectable.getSelectedObjects()`

Description

A single-item array containing the current selection.

insert

public synchronized void insert (String item, int index) ★

Parameters

item

The string to add.

index

The position for the new string.

Throws

`IllegalArgumentException`

If `index` is less than zero.

Description

Inserts `item` in the given position.

remove

public synchronized void remove (int position) ★

Parameters

position

The index of an entry in the `Choice` component.

Description

Removes the entry in the given position.

public synchronized void remove (String string) ★

Parameters

string

Text of an entry within the `Choice` component.

Throws

`IllegalArgumentException`

If `string` is not in the `Choice`.

Description

Makes the first entry that matches `string` the selected item.

removeAll

public synchronized void removeAll() ★

Description

Removes all the entries from the `Choice`.

removeItemListener

public void removeItemListener (ItemListener l) ★

Parameters

l

The listener to be removed.

Implements

`ItemSelectable.removeItemListener (ItemListener l)`

Description

Removes the specified `ItemListener` so it will not receive `ItemEvent` objects from this `Choice`.

select

public synchronized void select (int pos)

Parameters

pos

The index of an entry in the `Choice` component.

Throws

`IllegalArgumentException`

If the position is not valid.

Description

Makes the entry in the given position.

public synchronized void select (String str)

Parameters

str

Text of an entry within the `Choice` component.

Description

Makes the first entry that matches `str` the selected item for the `Choice`.

Protected Instance Methods

paramString

protected String paramString()

Returns

A string with current settings of `Choice`.

Overrides

`Component.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

processEvent

protected void processEvent (AWTEvent e) ★

Parameters

e

The event to process.

Description

Low level `AWTEvents` are passed to this method for processing.

processItemEvent

protected void processItemEvent (ItemEvent e) ★

Parameters

e

The item event to process.

Description

Item events are passed to this method for processing. Normally, this method is called by `processEvent()`.

  public int getGreen();
  public int getRed();
  public int getRGB();
  public int hashCode();
  public String toString();
}
```

Constants

black

public static final Color black

The color black.

blue

public static final Color blue

The color blue.

cyan

public static final Color cyan

The color cyan.

darkGray

public static final Color darkGray

The color dark gray.

gray

public static final Color gray

The color gray.

green

public static final Color green

The color green.

lightGray

public static final Color lightGray

The color light gray.

magenta

public static final Color magenta

The color magenta.

orange

public static final Color orange

The color orange.

pink

public static final Color pink

The color pink.

red

public static final Color red

The color red.

white

public static final Color white

The color white.

yellow

public static final Color yellow

The color yellow.

Constructors

Color

public Color (int rgb)

Parameters

rgb

Composite color value

Description

Constructs a `Color` object with the given `rgb` value.

public Color (int red, int green, int blue)

Parameters

red

Red component of color in the range[0, 255]

green

Green component of color in the range[0, 255]

blue

Blue component of color in the range[0, 255]

Description

Constructs a `Color` object with the given `red`, `green`, and `blue` values.

public Color (float red, float green, float blue)

Parameters

red

Red component of color in the range[0.0, 1.0]

green

Green component of color in the range[0.0, 1.0]

blue

Blue component of color in the range[0.0, 1.0]

Description

Constructs a `Color` object with the given `red`, `green`, and `blue` values.

Class Methods

decode

public static Color decode (String nm) ★

Parameters

nm

A `String` representing a color as a 24-bit integer.

Returns

The color requested.

Throws

`NumberFormatException`

If `nm` cannot be converted to a number.

Description

Gets color specified by the given string.

getColor

public static Color getColor (String name)

Parameters

name

The name of a system property indicating which color to fetch.

Returns

Color instance of `name` requested, or `null` if the `name` is invalid.

Description

Gets color specified by the system property name.

public static Color getColor (String name, Color defaultColor)

Parameters

name

The `name` of a system property indicating which color to fetch.

defaultColor

Color to return if `name` is not found in properties, or invalid.

Returns

Color instance of `name` requested, or `defaultColor` if the `name` is invalid.

Description

Gets color specified by the system property `name`.

public static Color getColor (String name, int defaultColor)

Parameters

name

The `name` of a system property indicating which color to fetch.

defaultColor

Color to return if `name` is not found in properties, or invalid.

Returns

Color instance of `name` requested, or `defaultColor` if the `name` is invalid.

Description

Gets color specified by the system property `name`. The default color is specified as a 32-bit RGB value.

getHSBColor

public static Color getHSBColor (float hue, float saturation, float brightness)

Parameters

hue

Hue component of `Color` to create, in the range[0.0, 1.0].

saturation

Saturation component of `Color` to create, in the range[0.0, 1.0].

brightness

Brightness component of `Color` to create, in the range[0.0, 1.0].

Returns

Color instance for values provided.

Description

Create an instance of `Color` by using hue, saturation, and brightness instead of red, green, and blue values.

HSBtoRGB

public static int HSBtoRGB (float hue, float saturation, float brightness)

Parameters

hue

Hue component of `Color` to convert, in the range[0.0, 1.0].

saturation

Saturation component of `Color` to convert, in the range[0.0, 1.0].

brightness

Brightness component of `Color` to convert, in the range[0.0, 1.0].

Returns

Color value for hue, saturation, and brightness provided.

Description

Converts a specific hue, saturation, and brightness to a `Color` and returns the red, green, and blue values in a composite integer value.

RGBtoHSB

public static float[] RGBtoHSB (int red, int green, int blue, float[] hsbvalues)

Parameters

red

Red component of `Color` to convert, in the range[0, 255].

green

Green component of `Color` to convert, in the range[0, 255].

blue

Blue component of `Color` to convert, in the range[0, 255].

hsbvalues

Three element array in which to put the result. This array is used as the method's return object. If `null`, a new array is allocated.

Returns

Hue, saturation, and brightness values for `Color` provided, in elements 0, 1, and 2 (respectively) of the returned array.

Description

Allows you to convert specific red, green, blue value to the hue, saturation, and brightness equivalent.

Instance Methods

brighter

public Color brighter()

Returns

Brighter version of current color.

Description

Creates new `Color` that is somewhat brighter than current.

darker

public Color darker()

Returns

Darker version of current color.

Description

Creates new `Color` that is somewhat darker than current.

equals

public boolean equals (Object object)

Parameters

object

The object to compare.

Returns

`true` if `object` represents the same color, `false` otherwise.

Overrides

`Object.equals(Object)`

Description

Compares two different `Color` instances for equivalence.

getBlue

public int getBlue()

Returns

Blue component of current color.

getGreen

public int getGreen()

Returns

Green component of current color.

getRed

public int getRed()

Returns

Red component of current color.

getRGB

public int getRGB()

Returns

Current color as a composite value.

Description

Gets integer value of current color.

hashCode

public int hashCode()

Returns

A hashcode to use when storing `Color` in a `Hashtable`.

Overrides

`Object.hashCode()`

Description

Generates a hashcode for the `Color`.

toString

public String toString()

Returns

> A string representation of the `Color` object.

Overrides

> `Object.toString()`

See Also

`Object`, `Properties`, `Serializable`, `String`

Component

Name

Component

[Graphic: Figure from the text]

Description

The `Component` class is the parent of all non-menu GUI components.

Class Definition

```
public abstract class java.awt.Component
    extends java.lang.Object
    implements java.awt.image.ImageObserver

  protected void processMouseMotionEvent (MouseEvent e); ★
}
```

Constants

BOTTOM_ALIGNMENT

public final static float BOTTOM_ALIGNMENT ★

Constant representing bottom alignment in `getAlignmentY()`.

CENTER_ALIGNMENT

public final static float CENTER_ALIGNMENT ★

Constant representing center alignment in `getAlignmentX()` and `getAlignmentY()`.

LEFT_ALIGNMENT

public final static float LEFT_ALIGNMENT ★

Constant representing left alignment in `getAlignmentX()`.

RIGHT_ALIGNMENT

public final static float RIGHT_ALIGNMENT ★

Constant representing right alignment in `getAlignmentX()`.

TOP_ALIGNMENT

public final static float TOP_ALIGNMENT ★

Constant representing top alignment in `getAlignmentY()`.

Variables

locale

protected Locale locale ★

Description

> The locale for the component. Used for internationalization support.

Constructors

Component

protected Component() ★

Description

> This constructor creates a "lightweight" component. This constructor allows `Component` to be directly subclassed using code written entirely in Java.

Instance Methods

action

public boolean action (Event e, Object o) ☆

Parameters

> *e*
>
> > `Event` instance identifying what triggered the call to this method.
>
> *o*

Argument specific to the component subclass that generated the event.

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when user performs some action in `Component`. This method is a relic of the old 1.0.2 event model and is replaced by the `process...Event()` methods.

add

public synchronized void add (PopupMenu popup) ★

Parameters

popup

The menu to add.

Description

After the `PopupMenu` is added to a component, it can be shown in the component's coordinate space.

addComponentListener

public void addComponentListener (ComponentListener l) ★

Description

Adds a listener for the `ComponentEvent` objects this `Component` generates.

addFocusListener

public void addFocusListener (FocusListener l) ★

Description

Adds a listener for the `FocusEvent` objects this `Component` generates.

addKeyListener

public void addKeyListener (KeyListener l) ★

Description

Adds a listener for the `KeyEvent` objects this `Component` generates.

addMouseListener

public void addMouseListener (MouseListener l) ★

Description

Adds a listener for the `MouseEvent` objects this `Component` generates.

addMouseMotionListener

public void addMouseMotionListener (MouseMotionListener l) ★

Description

Adds a listener for the motion `MouseEvent` objects this `Component` generates.

addNotify

public void addNotify()

Description

Creates peer of `Component`'s subclass.

bounds

public Rectangle bounds() ☆

Returns

Gets bounding rectangle of `Component`.

Description

A `Rectangle` that returns the outer limits of the `Component`. Replaced by `getBounds()` in 1.1.

checkImage

public int checkImage (Image image, ImageObserver observer)

Parameters

image

`Image` to check.

observer

The object an image will be rendered onto.

Returns

`ImageObserver` Flags ORed together indicating the image's status.

Description

Checks status of image construction.

public int checkImage (Image image, int width, int height, ImageObserver observer)

Parameters

image

Image to check.

width

Horizontal size image will be scaled to.

height

Vertical size image will be scaled to.

observer

Object image will be rendered onto.

Returns

`ImageObserver` flags ORed together indicating the image's status.

Description

Checks status of image construction.

contains

public boolean contains (int x, int y) ★

Parameters

x

The x coordinate, in this `Component`'s coordinate system.

y

The y coordinate, in this `Component`'s coordinate system.

Returns

`true` if the `Component` contains the point; `false` otherwise.

public boolean contains (Point p) ★

Parameters

p

The point to be tested, in this `Component`'s coordinate system.

Returns

`true` if the `Component` contains the point; `false` otherwise.

createImage

public Image createImage (ImageProducer producer)

Parameters

producer

Class that implements `ImageProducer` interface to create the new image.

Returns

Newly created image instance.

Description

Creates an `Image` based upon an `ImageProducer`.

public Image createImage (int width, int height)

Parameters

width

Horizontal size for in-memory `Image`.

height

Vertical size for in-memory `Image`.

Returns

Newly created image instance.

Description

Creates an empty in-memory `Image` for double buffering; to draw on the image, use its graphics context.

deliverEvent

public void deliverEvent (Event e) ☆

Parameters

e

`Event` instance to deliver.

Description

Delivers event to the component for processing.

disable

public void disable() ☆

Description

Disables component so that it is unresponsive to user interactions. Replaced by `setEnabled(false)`.

dispatchEvent

public final void dispatchEvent (AWTEvent e) ★

Parameters

e

The `AWTEvent` to process.

Description

Tells the component to deal with the `AWTEvent e`.

doLayout

public void doLayout() ★

Description

Lays out component. This method is a replacement for `layout()`.

enable

public void enable() ☆

Description

Enables component so that it is responsive to user interactions. Use `setEnabled(true)` instead.

public void enable (boolean condition) ☆

Parameters

condition

`true` to enable the component; `false` to disable it.

Description

Enables or disables the component based upon `condition`. Use `setEnabled(boolean)` instead.

getAlignmentX

public float getAlignmentX() ★

Returns

A number between 0 and 1 representing the horizontal alignment of this component.

Description

One of the constants `LEFT_ALIGNMENT`, `CENTER_ALIGNMENT`, or `RIGHT_ALIGNMENT` may be returned. `CENTER_ALIGNMENT` is returned by default.

getAlignmentY

public float getAlignmentY() ★

Returns

A number between 0 and 1 representing the vertical alignment of this component.

Description

One of the constants `TOP_ALIGNMENT`, `CENTER_ALIGNMENT`, or `BOTTOM_ALIGNMENT` may be returned. `CENTER_ALIGNMENT` is returned by default.

getBackground

public Color getBackground()

Returns

Background color of the component.

getBounds

public Rectangle getBounds() ★

Returns

Gets bounding rectangle of `Component`.

Description

Returns a `Rectangle` that returns the outer limits of the `Component`.

getColorModel

public synchronized ColorModel getColorModel()

Returns

`ColorModel` used to display the current component.

getComponentAt

public Component getComponentAt (int x, int y) ★

Parameters

x

The x coordinate, in this `Component`'s coordinate system.

y

The y coordinate, in this `Component`'s coordinate system.

Returns

Returns the `Component` containing the given point.

public Component getComponentAt (Point p) ★

Parameters

p

The point to be tested, in this `Component`'s coordinate system.

Returns

Returns the `Component` containing the given point.

getCursor

public Cursor getCursor() ★

Returns

Current cursor of the component.

getFont

public Font getFont()

Returns

Current font of the component.

getFontMetrics

public FontMetrics getFontMetrics (Font f)

Parameters

f

A `Font` object, whose platform specific information is desired.

Returns

Size information for the given `Font`.

getForeground

public Color getForeground()

Returns

Foreground color of component.

getGraphics

public Graphics getGraphics()

Throws

`InternalException`

If acquiring graphics context is unsupported.

Returns

`Component`'s graphics context.

getLocale

public Locale getLocale() ★

Throws

`IllegalComponentStateException`

If the component does not have a locale or it has not been added to a hierarchy that does.

Returns

`Component`'s locale.

getLocation

public Point getLocation() ★

Returns

Position of component.

Description

Gets the current position of this `Component` in its parent's coordinate space.

getLocationOnScreen

public Point getLocationOnScreen() ★

Returns

Position of component.

Description

Gets the current position of this `Component` in the screen's coordinate space.

getMaximumSize

public Dimension getMaximumSize() ★

Returns

The maximum dimensions of the component.

Description

By default, a maximal `Dimension` is returned.

getMinimumSize

public Dimension getMinimumSize() ★

Returns

The minimum dimensions of the component.

getName

public String getName() ★

Returns

This component's name.

getParent

public Container getParent()

Returns

> Parent `Container` of `Component`.

Description

> Gets container that this `Component` is held in.

getPeer

public ComponentPeer getPeer() ☆

Returns

> Peer of `Component`.

getPreferredSize

public Dimension getPreferredSize() ★

Returns

> The preferred dimensions of the component.

getSize

public Dimension getSize() ★

Returns

> Dimensions of component.

Description

> Gets width and height of component.

getToolkit

public Toolkit getToolkit()

Returns

`Toolkit` of `Component`.

getTreeLock

public final Object getTreeLock() ★

Returns

The AWT tree locking object.

Description

Returns the object used for tree locking and layout operations.

gotFocus

public boolean gotFocus (Event e, Object o) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

o

Argument specific to the component subclass that generated the event.

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Called when `Component` gets input focus. This method is not used in the 1.1 event model.

handleEvent

public boolean handleEvent (Event e) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

High-level event handling routine that calls helper routines. Replaced by `processEvent(AWTEvent)`.

hide

public void hide() ☆

Description

Hides component from view. Replaced by `setVisible(false)`.

imageUpdate

public boolean imageUpdate (Image image, int infoflags, int x, int y, int width, int height)

Parameters

image

`Image` being loaded.

infoflags

`ImageObserver` flags ORed together of available information.

x

x coordinate of upper-left corner of `Image`.

y

y coordinate of upper-left corner of `Image`.

width

Horizontal dimension of `Image`.

height

Vertical dimension of `Image`.

Returns

`true` if `Image` fully loaded, `false` otherwise.

Implements

`ImageObserver.imageUpdate()`

Description

An asynchronous update interface for receiving notifications about `Image` information as it is loaded. Meaning of parameters changes with values of flags.

inside

public boolean inside (int x, int y) ☆

Parameters

x

Horizontal position.

y

Vertical position.

Returns

`true` if the point (`x`, `y`) falls within the component's bounds, `false` otherwise.

Description

Checks if coordinates are within bounding box of `Component`. Replaced by `contains(int, int)`.

invalidate

public void invalidate()

Description

Sets the component's valid state to `false`.

isEnabled

public boolean isEnabled()

Returns

`true` if enabled, `false` otherwise.

Description

Checks to see if the `Component` is currently enabled.

isFocusTraversable

public boolean isFocusTraversable() ★

Returns

`true` if this `Component` can be traversed using Tab and Shift-Tab, `false` otherwise.

Description

Checks to see if the `Component` is navigable using the keyboard.

isShowing

public boolean isShowing()

Returns

`true` if showing, `false` otherwise.

Description

Checks to see if the `Component` is currently showing.

isValid

public boolean isValid()

Returns

`true` if valid, `false` otherwise.

Description

Checks to see if the `Component` is currently valid.

isVisible

public boolean isVisible()

Returns

`true` if visible, `false` otherwise.

Description

Checks to see if the `Component` is currently visible.

keyDown

public boolean keyDown (Event e, int key) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

key

Integer representation of key pressed.

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called whenever the user presses a key. Replaced by `processKeyEvent(KeyEvent)`.

keyUp

public boolean keyUp (Event e, int key) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

key

Integer representation of key released.

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called whenever the user releases a key. Replaced by `processKeyEvent(KeyEvent)`.

layout

public void layout() ☆

Description

Lays out component. Replaced by `doLayout()`.

list

public void list()

Description

Prints the contents of the `Component` to `System.out`.

public void list (PrintStream out)

Parameters

out

Output stream to send results to.

Description

Prints the contents of the `Component` to a `PrintStream`.

public void list (PrintStream out, int indentation)

Parameters

out

Output stream to send results to.

indentation

Indentation to use when printing.

Description

Prints the contents of the `Component` indented to a `PrintStream`.

public void list (PrintWriter out)

Parameters

out

Output stream to send results to.

Description

Prints the contents of the `Component` to a `PrintWriter`.

public void list (PrintWriter out, int indentation)

Parameters

out

Output stream to send results to.

indentation

Indentation to use when printing.

Description

Prints the contents of the `Component` indented to a `PrintWriter`.

locate

public Component locate (int x, int y) ☆

Parameters

x

Horizontal position.

y

Vertical position.

Returns

`Component` if the point (`x`, `y`) falls within the component, `null` otherwise.

Description

Replaced by `getComponentAt(int, int)`.

location

public Point location() ☆

Returns

Position of component.

Description

Gets the current position of this `Component` in its parent's coordinate space. Replaced by `getLocation()`.

lostFocus

public boolean lostFocus (Event e, Object o) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

o

Argument specific to the component subclass that generated the event.

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when `Component` loses input focus. Replaced by `processFocusEvent(FocusEvent)`.

minimizeSize

public Dimension minimumSize() ☆

Returns

The minimum dimensions of the component. Replaced by `getMinimumSize()`.

mouseDown

public boolean mouseDown (Event e, int x, int y) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

x

Horizontal position of the mouse within `Component` when `Event` initiated

y

Vertical position of the mouse within `Component` when `Event` initiated

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when the user presses a mouse button over `Component`. Replaced by `processMouseEvent(MouseEvent)`.

mouseDrag

public boolean mouseDrag (Event e, int x, int y) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

x

Horizontal position of the mouse within `Component` when `Event` initiated

y

Vertical position of the mouse within `Component` when `Event` initiated

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when the user is pressing a mouse button and moves the mouse. Replaced by `processMouseMotionEvent(MouseEvent)`.

mouseEnter

public boolean mouseEnter (Event e, int x, int y) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

x

Horizontal position of the mouse within `Component` when `Event` initiated

y

Vertical position of the mouse within `Component` when `Event` initiated

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when the mouse enters `Component`. Replaced by `processMouseEvent(MouseEvent)`.

mouseExit

public boolean mouseExit (Event e, int x, int y) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

x

Horizontal position of the mouse within `Component` when `Event` initiated

y

Vertical position of the mouse within `Component` when `Event` initiated

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when the mouse exits `Component`. Replaced by `processMouseEvent(MouseEvent)`.

mouseMove

public boolean mouseMove (Event e, int x, int y) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

x

Horizontal position of the mouse within `Component` when `Event` initiated

y

Vertical position of the mouse within `Component` when `Event` initiated

Returns

`true` if event handled, `false` to propagate it to parent container.

Description

Method called when the user is not pressing a mouse button and moves the mouse. Replaced by `processMouseMotionEvent(MouseEvent)`.

mouseUp

public boolean mouseUp (Event e, int x, int y) ☆

Parameters

e

`Event` instance identifying what triggered the call to this method.

x

Horizontal position of the mouse within `Component` when `Event` initiated

y

Vertical position of the mouse within `Component` when `Event` initiated

Returns

`true` if event is handled, `false` to propagate it to the parent container.

Description

Method called when user releases mouse button over `Component`. Replaced by `processMouseEvent(MouseEvent)`.

move

public void move (int x, int y) ☆

Parameters

x

New horizontal position for component.

y

New vertical position for component.

Description

> Relocates component. Replaced by `setLocation(int, int)`.

nextFocus

public void nextFocus() ☆

Description

> Moves focus from current component to next one in parent container. Replaced by `transferFocus()`.

paint

public void paint (Graphics g)

Parameters

> *g*
>
> > Graphics context of component.

Description

> Empty method to be overridden to draw something in the graphics context.

paintAll

public void paintAll (Graphics g)

Parameters

> *g*
>
> > Graphics context of component.

Description

> Method to validate component and paint its peer if it is visible.

postEvent

public boolean postEvent (Event e) ☆

Parameters

e

`Event` instance to post to component

Returns

If `Event` is handled, `true` is returned. Otherwise, `false` is returned.

Description

Tells `Component` to deal with `Event`.

preferredSize

public Dimension preferredSize() ☆

Returns

The preferred dimensions of the component. Replaced by `getPreferredSize()`.

prepareImage

public boolean prepareImage (Image image, ImageObserver observer)

Parameters

image

`Image` to start loading.

observer

Component on which image will be rendered.

Returns

`true` if `Image` is fully loaded, `false` otherwise.

Description

Forces `Image` to start loading.

public boolean prepareImage (Image image, int width, int height, ImageObserver observer)

Parameters

image

`Image` to start loading.

width

Horizontal size of the `Image` after scaling.

height

Vertical size of the `Image` after scaling.

observer

Component on which image will be rendered.

Returns

`true` if `Image` is fully loaded, `false` otherwise.

Description

Forces `Image` to start loading.

print

public void print (Graphics g)

Parameters

g

Graphics context.

Description

Empty method to be overridden to print something into the graphics context.

printAll

public void printAll (Graphics g)

Parameters

g

Graphics context.

Description

Method to print this component and its children.

remove

public void remove (MenuComponent popup) ★

Parameters

popup

The menu to remove.

Description

After adding a `PopupMenu`, you can use this method to remove it.

removeComponentListener

public void removeComponentListener (ComponentListener l) ★

Description

> Removes the specified `ComponentListener` from this `Component`.

removeFocusListener

public void removeFocusListener (FocusListener l) ★

Description

> Removes the specified `FocusListener` from this `Component`.

removeKeyListener

public void removeKeyListener (KeyListener l) ★

Description

> Removes the specified `KeyListener` from this `Component`.

removeMouseListener

public void removeMouseListener (MouseListener l) ★

Description

> Removes the specified `MouseListener` from this `Component`.

removeMouseMotionListener

public void removeMouseMotionListener (MouseMotionListener l) ★

Description

> Removes the specified `MouseMotionListener` from this `Component`.

removeNotify

public void removeNotify()

Description

Removes peer of `Component`'s subclass.

repaint

public void repaint()

Description

Requests scheduler to redraw the component as soon as possible.

public void repaint (long tm)

Parameters

tm

Millisecond delay allowed before repaint.

Description

Requests scheduler to redraw the component within a time period.

public void repaint (int x, int y, int width, int height)

Parameters

x

Horizontal origin of bounding box to redraw.

y

Vertical origin of bounding box to redraw.

width

Width of bounding box to redraw.

height

Height of bounding box to redraw.

Description

Requests scheduler to redraw a portion of component as soon as possible.

public void repaint (long tm, int x, int y, int width, int height)

Parameters

tm

Millisecond delay allowed before repaint.

x

Horizontal origin of bounding box to redraw.

y

Vertical origin of bounding box to redraw.

width

Width of bounding box to redraw.

height

Height of bounding box to redraw.

Description

Requests scheduler to redraw a portion of component within a time period.

requestFocus

public void requestFocus()

Description

Requests the input focus for this `Component`.

reshape

public void reshape (int x, int y, int width, int height) ☆

Parameters

x

New horizontal position for component.

y

New vertical position for component.

width

New width for component.

height

New height for component.

Description

Relocates and resizes component. Replaced by `setBounds(int, int, int, int)`.

resize

public void resize (Dimension d) ☆

Parameters

d

New dimensions for the component.

Description

Resizes component. Replaced by `setSize(Dimension)`.

public void resize (int width, int height) ☆

Parameters

width

New width for component.

height

New height for component.

Description

Resizes component. Replaced by `setSize(int, int)`.

setBackground

public void setBackground (Color c)

Parameters

c

New background color.

Description

Changes the component's background color.

setBounds

public void setBounds (int x, int y, int width, int height) ★

Parameters

x

New horizontal position for component.

y

New vertical position for component.

width

New width for component.

height

New height for component.

Description

Relocates and resizes the component.

public void setBounds (Rectangle r) ★

Parameters

r

New coordinates for component.

Description

Relocates and resizes component.

setCursor

public synchronized void setCursor (Cursor cursor) ★

Parameters

cursor

The new cursor for the component.

Description

Changes the component's cursor.

setEnabled

public void setEnabled (boolean b) ★

Parameters

b

`true` to enable the component, `false` to disable it.

Description

Enables or disables the component. Replaces `enable()`, `enable(boolean)`, and `disable()`.

setFont

public synchronized void setFont (Font f)

Parameters

f

Font to change component to.

Description

Changes the font of the component.

setForeground

public void setForeground (Color c)

Parameters

c

New foreground color.

Description

Changes the foreground color of component's area.

setLocale

public void setLocale (Locale l) ★

Parameters

l

The locale object for the component.

Description

Sets the `Component`'s locale.

setLocation

public void setLocation (int x, int y) ★

Parameters

x

New horizontal position for component.

y

New vertical position for component.

Description

Relocates the component.

public void setLocation (Point p) ★

Parameters

p

New position for component.

Description

Relocates the component.

setName

public void setName (String name) ★

Parameters

name

New name for component.

Description

Sets the component's name.

setSize

public void setSize (int width, int height) ★

Parameters

width

New width for component.

height

New height for component.

Description

Resizes the component.

public void setSize (Dimension d) ★

Parameters

d

New dimensions for the component.

Description

Resizes the component.

setVisible

public void setVisible (boolean b) ★

Parameters

b

`true` to show component, `false` to hide it.

Description

Shows or hides the component based on the `b` parameter.

show

public void show() ☆

Description

Replaced by `setVisible(true)`.

public void show (boolean condition) ☆

Parameters

condition

`true` to show the component, `false` to hide it.

Description

Replaced by `setVisible(boolean)`.

size

public Dimension size() ☆

Returns

Dimensions of the component.

Description

Gets width and height of the component. Replaced by `getSize()`.

toString

public String toString()

Returns

A string representation of the `Component` object.

Overrides

`Object.toString()`

transferFocus

public void transferFocus() ★

Description

Transfers focus to the next component in the container hierarchy.

update

public void update (Graphics g)

Parameters

g

Graphics context of component.

Description

Called to update the component's display area.

validate

public void validate()

Description

Sets the component's valid state to `true`.

Protected Instance Methods

disableEvents

protected final void disableEvents (long eventsToDisable) ★

Parameters

eventsToDisable

A value representing certain kinds of events. This can be constructed by ORing the event mask constants defined in `java.awt.AWTEvent`.

Description

By default, a component receives events corresponding to the event listeners that have registered. If a component should not receive events of a certain type, even if there is a listener registered for that type of event, this method can be used to disable that event type.

enableEvents

protected final void enableEvents (long eventsToEnable) ★

Parameters

eventsToEnable

A value representing certain kinds of events. This can be constructed by ORing the event mask constants defined in `java.awt.AWTEvent`.

Description

By default, a component receives events corresponding to the event listeners that have registered. If a component should receive other types of events as well, this method can be used to request them.

paramString

protected String paramString()

Returns

A `String` with the current settings of the `Component`.

Description

Helper method for `toString()` to generate a string of current settings.

processComponentEvent

protected void processComponentEvent(ComponentEvent e) ★

Parameters

e

The event to process.

Description

Component events are passed to this method for processing. Normally, this method is called by `processEvent()`.

processEvent

protected void processEvent(AWTEvent e) ★

Parameters

e

The event to process.

Description

Low level `AWTEvent`s are passed to this method for processing.

processFocusEvent

protected void processFocusEvent(FocusEvent e) ★

Parameters

e

The event to process.

Description

Focus events are passed to this method for processing. Normally, this method is called by `processEvent()`.

processKeyEvent

protected void processKeyEvent(KeyEvent e) ★

Parameters

e

The event to process.

Description

Key events are passed to this method for processing. Normally, this method is called by `processEvent()`.

processMouseEvent

protected void processMouseEvent(MouseEvent e) ★

Parameters

e

The event to process.

Description

Mouse events are passed to this method for processing. Normally, this method is called by `processEvent()`.

processMouseMotionEvent

protected void processMouseMotionEvent(MouseEvent e) ★

Parameters

e

The event to process.

Description

> Mouse motion events are passed to this method for processing. Normally, this method is called by `processEvent()`.

Container

Name

Container

[Graphic: Figure from the text]

Description

The `Container` class serves as a general purpose holder of other `Component` objects.

Class Definition

```
public abstract class java.awt.Container
    extends java.awt.Component {
  // Constructors
  protected Container(); ★

  // Instance Methods
  public Component add (Component component);
  public Component add (Component component, int position);
  public void add (Component comp, Object constraints); ★
  public void add (Component comp, Object constraints,
      int position); ★
  public Component add (String name, Component component); ☆
  public void addContainerListener (ContainerListener l); ★
  public void addNotify();
  public int countComponents();
  public void deliverEvent (Event e); ★
  public void doLayout(); ★
  public float getAlignmentX(); ★
  public float getAlignmentY(); ★
  public Component getComponent (int n);
  public Component getComponentAt (int x, int y);  ★
  public Component getComponentAt (Point p);  ★
  public int getComponentCount(); ★
  public Component[] getComponents();
  public Insets getInsets(); ★
  public LayoutManager getLayout();
  public Dimension getMaximumSize(); ★
  public Dimension getMinimumSize();  ★
  public Dimension getPreferredSize();  ★
  public Insets insets();
  public void invalidate(); ★
  public boolean isAncestorOf (Component c); ★
  public void layout(); ☆
  public void list (PrintStream out, int indentation);
  public void list (PrintWriter out, int indentation); ★
  public Component locate (int x, int y); ☆
  public Dimension minimumSize(); ☆
  public void paint (Graphics g); ★
  public void paintComponents (Graphics g);
  public Dimension preferredSize(); ☆
  public void print (Graphics g); ★
  public void printComponents (Graphics g);
  public void remove (int index); ★
  public void remove (Component component);
```

```
  public void removeAll();
  public void removeContainerListener (ContainerListener l); ★
  public void removeNotify();
  public void setLayout (LayoutManager manager);
  public void validate();
  // Protected Instance Methods
  protected void addImpl (Component comp, Object constraints,
      int index); ★
  protected String paramString();
  protected void processContainerEvent (ContainerEvent e); ★
  protected void processEvent (AWTEvent e); ★
  protected void validateTree(); ★
}
```

Constructors

Container

protected Container() ★

Description

> This constructor creates a "lightweight" container. This constructor allows `Container` to be subclassed using code written entirely in Java.

Instance Methods

add

public Component add (Component component)

Parameters

> *component*
>
> > `Component` to add to container.

Returns

`Component` just added.

Throws

`IllegalArgumentException` if you add `component` to itself.

Description

Adds `component` as the last component in the container.

public Component add (Component component, int position)

Parameters

component

`Component` to add to container.

position

Position of component; -1 adds the component as the last in the container.

Returns

`Component just added.`

Throws

`ArrayIndexOutOfBoundsException`

If `position` invalid.

`IllegalArgumentException`

If you add `Component` to itself.

Description

Adds `component` to container at a certain position.

public void add (Component component, Object constraints) ★

Parameters

component

`Component` to add to container.

constraints

An object describing constraints on the component being added.

Description

Adds `component` to container subject to `contraints`.

public void add (Component component, Object constraints, int index) ★

Parameters

component

`Component` to add to container.

constraints

An object describing constraints on the component being added.

index

The position of the component in the container's list.

Description

Adds `component` to container subject to `contraints` at position `index`.

public Component add (String name, Component component) ☆

Parameters

name

Name of component being added. This parameter is often significant to the layout manager of the container (e.g "North", "Center").

component

`Component` to add to container.

Returns

`Component` just added.

Throws

IllegalArgumentException

If you add `component` to itself.

Description

Adds the component to the container with the given `name`. Replaced by the more general `add(Component, Object)`.

addContainerListener

public void addContainerListener (ContainerListener l) ★

Parameters

l

An object that implements the `ContainerListener` interface.

Description

Add a listener for the container events.

addNotify

public void addNotify()

Overrides

`Component.addNotify()`

Description

Creates `Container`'s peer and peers of contained components.

countComponents

public int countComponents()

Returns

Number of components within `Container`.

deliverEvent

public void deliverEvent (Event e) ☆

Parameters

e

`Event` instance to deliver.

Overrides

`Component.deliverEvent(Event)`

Description

Tries to locate the component contained in the container that should receive the event.

doLayout

public void doLayout() ★

Description

Lays out the container. This method is a replacement for `layout()`.

getAlignmentX

public float getAlignmentX() ★

Returns

A number between 0 and 1 representing the horizontal alignment of this component.

Overrides

`Component.getAlignmentX()`

Description

If the container's layout manager implements `LayoutManager2`, this method returns the `getLayoutAlignmentX()` value of the layout manager. Otherwise the `getAlignmentX()` value of `Component` is returned.

getAlignmentY

public float getAlignmentY() ★

Returns

A number between 0 and 1 representing the vertical alignment of this component.

Overrides

`Component.getAlignmentY()`

Description

If the container's layout manager implements `LayoutManager2`, this method returns the `getLayoutAlignmentY()` value of the layout manager. Otherwise the `getAlignmentY()` value of `Component` is returned.

getComponent

public synchronized Component getComponent (int position)

Parameters

position

Position of component to get.

Throws

`ArrayIndexOutOfBoundsException`

If `position` is invalid.

Returns

`Component` at designated `position` within `Container`.

getComponentAt

public Component getComponentAt (int x, int y) ★

Parameters

x

The x coordinate, in this `Container`'s coordinate system.

y

The y coordinate, in this `Container`'s coordinate system.

Returns

Returns the `Component` containing the give point.

public Component getComponentAt (Point p) ★

Parameters

p

The point to be tested, in this `Container`'s coordinate system.

Returns

Returns the `Component` containing the give point.

getComponentCount

public int getComponentCount() ★

Returns

Returns the number of components in the container.

getComponents

public Component[] getComponents()

Returns

Array of components within the container.

getInsets

public Insets getInsets()

Returns

The insets of the container.

getLayout

public LayoutManager getLayout()

Returns

`LayoutManager` of `Container`.

getMaximumSize

public Dimension getMaximumSize() ★

Overrides

`Component.getMaximumSize()`

Returns

The maximum dimensions of the component.

getMinimumSize

public Dimension getMinimumSize() ★

Overrides

`Component.getMinimumSize()`

Returns

The minimum dimensions of the component.

getPreferredSize

public Dimension getPreferredSize() ★

Returns

The preferred dimensions of the component.

insets

public Insets insets() ☆

Returns

Current `Insets` of `Container`. Replaced by `getInsets()`.

invalidate

public void invalidate()

Overrides

`Component.invalidate()`

Description

Sets the container's valid state to `false`.

isAncestorOf

public boolean isAncestorOf (Component c) ★

Parameters

c

The component in question.

Returns

If `c` is contained in the container's hierarchy, returns `true`; otherwise `false`.

layout

public void layout() ☆

Overrides

`Component.layout()`

Description

Replaced by `doLayout()`.

list

public void list (PrintStream out, int indentation)

Parameters

out

Output `Stream` to send results to.

indentation

Indentation to use when printing.

Overrides

`Component.list(PrintStream, int)`

Description

Recursively lists all components in `Container`.

public void list (PrintWriter out, int indentation)

Parameters

out

Output `Writer` to send results to.

indentation

Indentation to use when printing.

Overrides

`Component.list(PrintWriter, int)`

Description

Recursively lists all components in `Container`.

locate

public Component locate (int x, int y) ☆

Parameters

x

Horizontal position to check.

y

Vertical position to check.

Returns

`Component` within `Container` at given coordinates, or `Container`.

Overrides

`Component.locate(int, int)`

Description

Replaced by `getComponentAt(int, int)`.

minimizeSize

public Dimension minimumSize() ☆

Returns

Minimum dimensions of contained objects.

Overrides

`Component.minimumSize()`

Description

Replaced by `getMinimumSize()`.

paint

public void paint (Graphics g)

Parameters

g

Graphics context of container.

Overrides

`Component.paint()`

Description

This method tells any lightweight components that are children of this container to paint themselves.

paintComponents

public void paintComponents (Graphics g)

Parameters

g

Graphics context of `Container`.

Description

Paints the different components in `Container`.

preferredSize

public Dimension preferredSize() ☆

Returns

Preferred dimensions of contained objects.

Overrides

`Component.preferredSize()`

Description

Replaced by `getPreferredSize()`.

print

public void print (Graphics g)

Parameters

g

Graphics context of container.

Overrides

`Component.print()`

Description

This method tells any lightweight components that are children of this container to print themselves.

printComponents

public void printComponents (Graphics g)

Parameters

g

Graphics context of `Container`.

Description

Prints the different components in `Container`.

remove

public void remove (int index) ★

Parameters

index

Index of the component to remove.

Description

Removes the component in position `index` from `Container`.

public void remove (Component component)

Parameters

component

`Component` to remove.

Description

Removes `component` from `Container`.

removeAll

public void removeAll()

Description

Removes all components from `Container`.

removeContainerListener

public void removeContainerListener (ContainerListener l) ★

Parameters

l

One of this `Container`'s `ContainerListener`s.

Description

Remove a container event listener.

removeNotify

public void removeNotify()

Overrides

`Component.removeNotify()`

Description

Removes `Container`'s peer and peers of contained components.

setLayout

public void setLayout (LayoutManager manager)

Parameters

manager

New `LayoutManager` for `Container`.

Description

Changes `LayoutManager` of `Container`.

validate

public void validate()

Overrides

`Component.validate()`

Description

Sets `Container`'s valid state to `true` and recursively validates its children.

Protected Instance Methods

addImpl

protected void addImpl (Component comp, Object constraints, int index) ★

Parameters

comp

The component to add.

constraints

Constraints on the component.

index

Position at which to add this component. Pass -1 to add the component at the end.

Description

This method adds a component subject to the given constraints at a specific position in the container's list of components. It is a helper method for the various overrides of `add()`.

paramString

protected String paramString()

Returns

String with current settings of `Container`.

Overrides

`Component.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

processContainerEvent

protected void processContainerEvent (ContainerEvent e) ★

Parameters

e

The event to process.

Description

Container events are passed to this method for processing. Normally, this method is called by `processEvent()`.

processEvent

protected void processEvent (AWTEvent e) ★

Parameters

e

The event to process.

Overrides

`Component.processEvent()`

Description

Low level `AWTEvent`s are passed to this method for processing.

validateTree

protected void validateTree() ★

Description

Descends recursively into the `Container`'s components and recalculates layout for any subtrees that are marked invalid.

Cursor ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Cursor ★

Name

Cursor ★

[Graphic: Figure from the text]

Description

The `Cursor` class represents the mouse pointer. It encapsulates information that used to be in `java.awt.Frame` in the 1.0.2 release.

Class Definition

```
public class java.awt.Cursor
    extends java.lang.Object
    implements java.io.Serializable {
  // Constants
  public final static int CROSSHAIR_CURSOR;
  public final static int DEFAULT_CURSOR;
  public final static int E_RESIZE_CURSOR;
  public final static int HAND_CURSOR;
  public final static int MOVE_CURSOR;
  public final static int N_RESIZE_CURSOR;
  public final static int NE_RESIZE_CURSOR;
  public final static int NW_RESIZE_CURSOR;
  public final static int S_RESIZE_CURSOR;
  public final static int SE_RESIZE_CURSOR;
  public final static int SW_RESIZE_CURSOR;
  public final static int TEXT_CURSOR;
  public final static int W_RESIZE_CURSOR;
  public final static int WAIT_CURSOR;
  // Class Variables
  protected static Cursor[] predefined;
  // Class Methods
  public static Cursor getDefaultCursor();
  public static Cursor getPredefinedCursor (int type);
  // Constructors
  public Cursor (int type);
  // Instance Methods
  public int getType();
}
```

Constants

CROSSHAIR_CURSOR

public final static int CROSSHAIR_CURSOR

Constant representing a cursor that looks like a crosshair.

DEFAULT_CURSOR

public final static int DEFAULT_CURSOR

Constant representing the platform's default cursor.

E_RESIZE_CURSOR

public final static int E_RESIZE_CURSOR

Constant representing the cursor for resizing an object on the left.

HAND_CURSOR

public final static int HAND_CURSOR

Constant representing a cursor that looks like a hand.

MOVE_CURSOR

public final static int MOVE_CURSOR

Constant representing a cursor used to move an object.

N_RESIZE_CURSOR

public final static int N_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the top.

NE_RESIZE_CURSOR

public final static int NE_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the top left corner.

NW_RESIZE_CURSOR

public final static int NW_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the top right corner.

S_RESIZE_CURSOR

public final static int S_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the bottom.

SE_RESIZE_CURSOR

public final static int SE_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the bottom left corner.

SW_RESIZE_CURSOR

public final static int SW_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the bottom right corner.

TEXT_CURSOR

public final static int TEXT_CURSOR

Constant representing a cursor used within text.

W_RESIZE_CURSOR

public final static int W_RESIZE_CURSOR

Constant representing a cursor for resizing an object on the right side.

WAIT_CURSOR

public final static int WAIT_CURSOR

Constant representing a cursor that indicates the program is busy.

Class Variables

predefined

protected static Cursor[] predefined

An array of cursor instances corresponding to the predefined cursor types.

Class Methods

getDefaultCursor

public static Cursor getDefaultCursor()

Returns

The default system cursor.

getPredefinedCursor

public static Cursor getPredefinedCursor (int type)

Parameters

type

One of the type constants defined in this class.

Returns

A `Cursor` object with the specified type.

Constructors

Cursor

public Cursor (int type)

Parameters

type

One of the type constants defined in this class.

Description

Constructs a `Cursor` object with the specified type.

Instance Methods

getType

public int getType()

Returns

The type of cursor.

See Also

`Frame`

Graphics

Name

Graphics

[Graphic: Figure from the text]

Description

The `Graphics` class is an abstract class that represents an object on which you can draw. The concrete classes that are actually used to represent graphics objects are platform dependent, but because they extend the `Graphics` class, must implement the methods here.

Class Definition

```
public abstract class java.awt.Graphics
    extends java.lang.Object {

  // Constructors
  protected Graphics();

  // Instance Methods
  public abstract void clearRect (int x, int y, int width, int height);
  public abstract void clipRect (int x, int y, int width, int height);
  public abstract void copyArea (int x, int y, int width, int height,
      int deltax, int deltay);
  public abstract Graphics create();
  public Graphics create (int x, int y, int width, int height);
  public abstract void dispose();
  public void draw3DRect (int x, int y, int width, int height,
      boolean raised);
  public abstract void drawArc (int x, int y, int width, int height,
      int startAngle, int arcAngle);
  public void drawBytes (byte text[], int offset, int length,
      int x, int y);
  public void drawChars (char text[], int offset, int length,
      int x, int y);
  public abstract boolean drawImage (Image image, int x, int y,
      ImageObserver observer);
  public abstract boolean drawImage (Image image, int x, int y,
      int width, int height, ImageObserver observer);
  public abstract boolean drawImage (Image image, int x, int y,
      Color backgroundColor, ImageObserver observer);
  public abstract boolean drawImage (Image image, int x, int y,
      int width, int height, Color backgroundColor, ImageObserver observer);
  public abstract boolean drawImage(Image img, int dx1, int dy1,
      int dx2, int dy2, int sx1, int sy1, int sx2, int sy2, ImageObserver
      observer); ★
  public abstract boolean drawImage(Image img, int dx1, int dy1,
      int dx2, int dy2, int sx1, int sy1, int sx2, int sy2, Color bgcolor,
      ImageObserver observer); ★
  public abstract void drawLine (int x1, int y1, int x2, int y2);
  public abstract void drawOval (int x, int y, int width, int height);
  public abstract void drawPolygon (int xPoints[], int yPoints[],
      int numPoints);
  public void drawPolygon (Polygon p);
  public abstract void drawPolyline(int[ ] xPoints, int[ ] yPoints,
      int nPoints); ★
  public void drawRect (int x, int y, int width, int height);
  public abstract void drawRoundRect (int x, int y, int width,
      int height, int arcWidth, int arcHeight);
  public abstract void drawString (String text, int x, int y);
  public void fill3DRect (int x, int y, int width, int height,
      boolean raised);
  public abstract void fillArc (int x, int y, int width, int height,
      int startAngle, int arcAngle);
  public abstract void fillOval (int x, int y, int width, int height);
  public abstract void fillPolygon (int xPoints[], int yPoints[],
      int numPoints);
  public void fillPolygon (Polygon p);

  public abstract void translate (int x, int y);
}
```

Constructors

Graphics

protected Graphics()

Description

Called by constructors of platform specific subclasses.

Instance Methods

clearRect

public abstract void clearRect (int x, int y, int width, int height)

Parameters

x

x coordinate of origin of area to clear.

y

y coordinate of origin of area to clear.

width

size in horizontal direction to clear.

height

size in vertical direction to clear.

Description

Resets a rectangular area to the background color.

clipRect

public abstract void clipRect (int x, int y, int width, int height)

Parameters

x

x coordinate of origin of clipped area.

y

y coordinate of origin of clipped area.

width

size in horizontal direction to clip.

height

size in vertical direction to clip.

Description

Reduces the drawing area to the intersection of the current drawing area and the rectangular area defined by `x`, `y`, `width`, and `height`.

copyArea

public abstract void copyArea (int x, int y, int width, int height, int deltax, int deltay)

Parameters

x

x coordinate of origin of area to copy.

y

y coordinate of origin of area to copy.

width

size in horizontal direction to copy.

height

size in vertical direction to copy.

deltax

offset in horizontal direction to copy area to.

deltay

offset in vertical direction to copy area to.

Description

Copies a rectangular area to a new area, whose top left corner is (`x+deltax`, `y+deltay`).

create

public abstract Graphics create()

Returns

New graphics context.

Description

Creates a second reference to the same graphics context.

public Graphics create (int x, int y, int width, int height)

Parameters

x

x coordinate of origin of new graphics context.

y

y coordinate of origin of new graphics context.

width

size in horizontal direction.

height

size in vertical direction.

Returns

New graphics context

Description

Creates a second reference to a subset of the same graphics context.

dispose

public abstract void dispose()

Description

Frees system resources used by graphics context.

draw3DRect

public void draw3DRect (int x, int y, int width, int height, boolean raised)

Parameters

x

x coordinate of the rectangle origin.

y

y coordinate of the rectangle origin

width

Width of the rectangle to draw.

height

Height of the rectangle to draw.

raised

Determines if rectangle drawn is raised or not; `true` for a raised rectangle.

Description

Draws an unfilled 3-D rectangle from (`x`, `y`) of size `width` x `height`.

drawArc

public abstract void drawArc (int x, int y, int width, int height, int startAngle, int arcAngle)

Parameters

x

x coordinate of the bounding rectangle's origin.

y

y coordinate of the bounding rectangle's origin

width

Width of the bounding rectangle for the arc.

height

Height of the bounding rectangle for the arc.

startAngle

Angle at which arc begins, in degrees

arcAngle

length of arc, in degrees

Description

Draws an unfilled arc from `startAngle` to `arcAngle` within bounding rectangle from (`x`, `y`) of size `width` x `height`. Zero degrees is at three o'clock; positive angles are counter clockwise.

drawBytes

public void drawBytes (byte text[], int offset, int length, int x, int y)

Parameters

text

Text to draw, as a byte array.

offset

Starting position within `text` to draw.

length

Number of bytes to draw.

x

x coordinate of baseline origin.

y

y coordinate of baseline origin.

Throws

ArrayIndexOutOfBoundsException

If `offset` or `length` is invalid.

Description

Draws text on screen, starting with `text[offset]` and ending with `text[offset+length-1]`.

drawChars

public void drawChars (char text[], int offset, int length, int x, int y)

Parameters

text

Text to draw, as a char array.

offset

Starting position within `text` to draw.

length

Number of bytes to draw.

x

x coordinate of baseline origin.

y

y coordinate of baseline origin.

Throws

ArrayIndexOutOfBoundsException

If `offset` or `length` is invalid.

Description

Draws text on screen, starting with `text[offset]` and ending with `text[offset+length-1]`.

drawImage

public abstract boolean drawImage (Image image, int x, int y, ImageObserver observer)

Parameters

image

Image to draw.

x

x coordinate of image origin.

y

y coordinate of image origin.

observer

Object that watches for image information; almost always `this`.

Returns

`true` if the image has fully loaded when the method returns, `false` otherwise.

Description

Draws image to screen at (`x`, `y`), at its original size. Drawing may be asynchronous. If `image` is not fully loaded when the method returns, `observer` is notified when additional information made available.

public abstract boolean drawImage (Image image, int x, int y, int width, int height, ImageObserver observer)

Parameters

image

Image to draw.

x

x coordinate of image origin.

y

y coordinate of image origin.

width

New image size in horizontal direction.

height

New image size in vertical direction.

observer

Object that watches for image information; almost always `this`.

Returns

`true` if the image has fully loaded when the method returns, `false` otherwise.

Description

Draws image to screen at (`x`, `y`), scaled to `width` x `height`. Drawing may be asynchronous. If `image` is not fully loaded when the method returns, `observer` is notified when additional information made available.

public abstract boolean drawImage (Image image, int x, int y, Color backgroundColor, ImageObserver observer)

Parameters

image

Image to draw.

x

x coordinate of image origin.

y

y coordinate of image origin.

backgroundColor

Color to show through image where transparent.

observer

Object that watches for image information; almost always `this`.

Returns

`true` if the image has fully loaded when the method returns, `false` otherwise.

Description

Draws image to screen at (`x`, `y`), at its original size. Drawing may be asynchronous. If `image` is not fully loaded when the method returns, `observer` is notified when additional information made available. The background color is visible through any transparent pixels.

public abstract boolean drawImage (Image image, int x, int y, int width, int height, Color backgroundColor, ImageObserver observer)

Parameters

image

Image to draw.

x

x coordinate of image origin.

y

y coordinate of image origin.

width

New image size in horizontal direction.

height

New image size in vertical direction.

backgroundColor

Color to show through image where transparent.

observer

Object that watches for image information; almost always `this`.

Returns

`true` if the image has fully loaded when the method returns, `false` otherwise.

Description

Draws image to screen at (`x`, `y`), scaled to `width` x `height`. Drawing may be asynchronous. If `image` is not fully loaded when the method returns, `observer` is notified when additional information made available. The background color is visible through any transparent pixels.

public abstract boolean drawImage (Image image, int dx1, int dy1, int dx2, int dy2, int sx1, int sy1, int sx2, int sy2, ImageObserver observer) ★

Parameters

image

Image to draw.

dx1

x coordinate of one corner of destination (device) rectangle.

dy1

y coordinate of one corner of destination (device) rectangle.

dx2

x coordinate of the opposite corner of destination (device) rectangle.

dy2

y coordinate of the opposite corner of destination (device) rectangle.

sx1

x coordinate of one corner of source (image) rectangle.

sy1

y coordinate of one corner of source (image) rectangle.

sx2

x coordinate of the opposite corner of source (image) rectangle.

sy2

y coordinate of the opposite corner of source (image) rectangle.

observer

Object that watches for image information; almost always `this`.

Returns

`true` if the image has fully loaded when the method returns, `false` otherwise.

Description

Draws the part of image described by `dx1`, `dy1`, `dx2`, and `dy2` to the screen into the rectangle described by `sx1`, `sy1`, `sx2`, and `sy2`. Drawing may be asynchronous. If `image` is not fully loaded when the method returns, `observer` is notified when additional information is made available.

public abstract boolean drawImage (Image image, int dx1, int dy1, int dx2, int dy2, int sx1, int sy1, int sx2, int sy2, Color backgroundColor, ImageObserver observer) ★

Parameters

image

Image to draw.

dx1

x coordinate of one corner of destination (device) rectangle.

dy1

y coordinate of one corner of destination (device) rectangle.

dx2

x coordinate of the opposite corner of destination (device) rectangle.

dy2

y coordinate of the opposite corner of destination (device) rectangle.

sx1

x coordinate of one corner of source (image) rectangle.

sy1

y coordinate of one corner of source (image) rectangle.

sx2

x coordinate of the opposite corner of source (image) rectangle.

sy2

y coordinate of the opposite corner of source (image) rectangle.

backgroundColor

Color to show through image where transparent.

observer

Object that watches for image information; almost always `this`.

Returns

`true` if the image has fully loaded when the method returns, `false` otherwise.

Description

Draws the part of image described by `dx1`, `dy1`, `dx2`, and `dy2` to the screen into the rectangle described by `sx1`, `sy1`, `sx2`, and `sy2`. Drawing may be asynchronous. If `image` is not fully loaded when the method returns, `observer` is notified when additional information made available. The background color is visible through any transparent pixels.

drawLine

public abstract void drawLine (int x1, int y1, int x2, int y2)

Parameters

x1

x coordinate of one point on line.

y1

y coordinate of one point on line.

x2

x coordinate of the opposite point on line.

y2

y coordinate of the opposite point on line.

Description

Draws a line connecting `(x1, y1)` and `(x2, y2)`.

drawOval

public abstract void drawOval (int x, int y, int width, int height)

Parameters

x

x coordinate of bounding rectangle origin.

y

y coordinate of bounding rectangle origin

width

Width of bounding rectangle to draw in.

height

Height of bounding rectangle to draw in.

Description

Draws an unfilled oval within bounding rectangle from (`x`, `y`) of size `width` x `height`.

drawPolygon

public abstract void drawPolygon (int xPoints[], int yPoints[], int numPoints)

Parameters

xPoints[]

The array of x coordinates for each point.

yPoints[]

The array of y coordinates for each point.

numPoints

The number of elements in both `xPoints` and `yPoints` arrays to use.

Description

Draws an unfilled polygon based on first `numPoints` elements in `xPoints` and `yPoints`.

public void drawPolygon (Polygon p)

Parameters

p

Points of object to draw.

Description

Draws an unfilled polygon based on points within the `Polygon p`.

drawPolyline

public abstract void drawPolyline (int xPoints[], int yPoints[], int nPoints) ★

Parameters

xPoints[]

The array of x coordinates for each point.

yPoints[]

The array of y coordinates for each point.

nPoints

The number of elements in both `xPoints` and `yPoints` arrays to use.

Description

Draws a series of line segments based on first `numPoints` elements in `xPoints` and `yPoints`.

drawRect

public void drawRect (int x, int y, int width, int height)

Parameters

x

x coordinate of rectangle origin.

y

y coordinate of rectangle origin

width

Width of rectangle to draw.

height

Height of rectangle to draw.

Description

Draws an unfilled rectangle from (`x`, `y`) of size `width` x `height`.

drawRoundRect

public abstract void drawRoundRect (int x, int y, int width, int height, int arcWidth, int arcHeight)

Parameters

x

x coordinate of bounding rectangle origin.

y

y coordinate of bounding rectangle origin

width

Width of rectangle to draw.

height

Height of rectangle to draw.

arcWidth

Width of arc of rectangle corner.

arcHeight

Height of arc of rectangle corner.

Description

Draws an unfilled rectangle from (`x`, `y`) of size `width` x `height` with rounded corners.

drawString

public abstract void drawString (String text, int x, int y)

Parameters

text

Text to draw.

x

x coordinate of baseline origin.

y

y coordinate of baseline origin.

Description

Draws text on screen.

fill3DRect

public void fill3DRect (int x, int y, int width, int height, boolean raised)

Parameters

x

x coordinate of rectangle origin.

y

y coordinate of rectangle origin

width

Width of rectangle to draw.

height

Height of rectangle to draw.

raised

`true` to draw a rectangle that appears raised; `false` to draw a rectangle that appears depressed.

Description

Draws a filled 3-D rectangle from (`x`, `y`) of size `width` x `height`.

fillArc

public abstract void fillArc (int x, int y, int width, int height, int startAngle, int arcAngle)

Parameters

x

x coordinate of bounding rectangle origin.

y

y coordinate of bounding rectangle origin

width

Width of bounding rectangle to draw in.

height

Height of bounding rectangle to draw in.

startAngle

Starting angle of arc.

arcAngle

The extent of the arc, measured from startAngle

Description

Draws a filled arc from `startAngle` to `arcAngle` within bounding rectangle from (`x`, `y`) of size `width` x `height`. Zero degrees is at three o'clock; positive angles are counter clockwise.

fillOval

public abstract void fillOval (int x, int y, int width, int height)

Parameters

x

x coordinate of bounding rectangle origin.

y

y coordinate of bounding rectangle origin

width

Width of bounding rectangle to draw in.

height

Height of bounding rectangle to draw in.

Description

Draws filled oval within bounding rectangle from (`x`, `y`) of size `width` x `height`.

fillPolygon

public abstract void fillPolygon (int xPoints[], int yPoints[], int numPoints)

Parameters

xPoints[]

The array of x coordinates for each point.

yPoints[]

The array of y coordinates for each point.

numPoints

The number of elements in both `xPoints` and `yPoints` arrays to use.

Throws

ArrayIndexOutOfBoundsException

If `numPoints` > `xPoints.length` or `numPoints` > `yPoints.length`.

Description

Draws filled polygon based on first `numPoints` elements in `xPoints` and `yPoints`.

public void fillPolygon (Polygon p)

Parameters

p

Points of object to draw.

Description

Draws filled polygon based on points within the `Polygon p`.

fillRect

public abstract void fillRect (int x, int y, int width, int height)

Parameters

x

x coordinate of rectangle origin.

y

y coordinate of rectangle origin

width

Width of rectangle to draw.

height

Height of rectangle to draw.

Description

Draws filled rectangle from (`x`, `y`) of size `width` x `height`.

fillRoundRect

public abstract void fillRoundRect (int x, int y, int width, int height, int arcWidth, int arcHeight)

Parameters

x

x coordinate of bounding rectangle origin.

y

y coordinate of bounding rectangle origin

width

Width of rectangle to draw.

height

Height of rectangle to draw.

arcWidth

Width of arc of rectangle corner.

arcHeight

Height of arc of rectangle corner.

Description

Draws a filled rectangle from (`x`, `y`) of size `width` x `height` with rounded corners.

finalize

public void finalize()

Overrides

`Object.finalize()`

Description

Tells the garbage collector to dispose of graphics context.

getClip

public abstract Shape getClip () ★

Returns

> Shape describing the clipping are of the graphics context.

getClipBounds

public abstract Rectangle getClipBounds() ★

Returns

> Rectangle describing the clipping area of the graphics context.

getClipRect

public abstract Rectangle getClipRect() ☆

Returns

> Replaced by `getClipBounds()`.

getColor

public abstract Color getColor()

Returns

> The current drawing `Color` of the graphics context.

getFont

public abstract Font getFont()

Returns

> The current `Font` of the graphics context.

getFontMetrics

public FontMetrics getFontMetrics()

Returns

The `FontMetrics` of the current font of the graphics context.

public abstract FontMetrics getFontMetrics (Font font)

Parameters

font

Font to get metrics for.

Returns

The `FontMetrics` of the given font for the graphics context.

setClip

public abstract void setClip (int x, int y, int width, int height) ★

Parameters

x

x coordinate of rectangle

y

y coordinate of rectangle

width

width of rectangle

height

height of rectangle

Description

Changes current clipping region to the specified rectangle.

public abstract void setClip (Shape clip) ★

Parameters

clip

The new clipping shape.

Description

Changes current clipping region to the specified shape.

setColor

public abstract void setColor (Color color)

Parameters

color

New color.

Description

Changes current drawing color of graphics context.

setFont

public abstract void setFont (Font font)

Parameters

font

New font.

Description

Changes current font of graphics context.

setPaintMode

public abstract void setPaintMode()

Description

Changes painting mode to normal mode.

setXORMode

public abstract void setXORMode (Color xorColor)

Parameters

xorColor

XOR mode drawing color.

Description

Changes painting mode to XOR mode; in this mode, drawing the same object in the same color at the same location twice has no net effect.

toString

public String toString()

Returns

A string representation of the `Graphics` object.

Overrides

`Object.toString()`

translate

public void translate (int x, int y)

Parameters

x

x coordinate of new drawing origin.

y

y coordinate of new drawing origin.

Description

Moves the origin of drawing operations to (x, y).

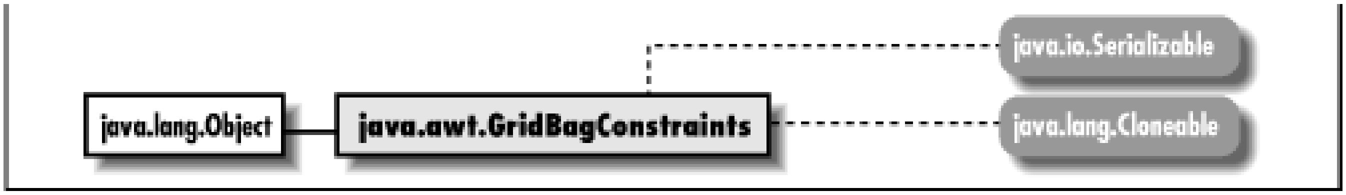
JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

GridBagConstraints

Name

GridBagConstraints



Description

The `GridBagConstraints` class provides the means to control the layout of components within a `Container` whose `LayoutManager` is `GridBagLayout`.

Class Definition

```
public class java.awt.GridBagConstraints
    extends java.lang.Object
    implements java.lang.Cloneable, java.io.Serializable {

  // Constants
  public final static int BOTH;
  public final static int CENTER;
  public final static int EAST;
  public final static int HORIZONTAL;
  public final static int NONE;
  public final static int NORTH;
  public final static int NORTHEAST;
  public final static int NORTHWEST;
  public final static int RELATIVE;
  public final static int REMAINDER;
  public final static int SOUTH;
  public final static int SOUTHEAST;
  public final static int SOUTHWEST;
  public final static int VERTICAL;
  public final static int WEST;

  // Variables
  public int anchor;
  public int fill;
  public int gridheight;
  public int gridwidth;
  public int gridx;
  public int gridy;
  public Insets insets;
  public int ipadx;
  public int ipady;
  public double weightx
  public double weighty

  // Constructors
  public GridBagConstraints();

  // Instance Methods
  public Object clone();
}
```

Constants

BOTH

public final static int BOTH

Constant for possible `fill` value.

CENTER

public final static int CENTER

Constant for possible `anchor` value.

EAST

public final static int EAST

Constant for possible `anchor` value.

HORIZONTAL

public final static int HORIZONTAL

Constant for possible `fill` value.

NONE

public final static int NONE

Constant for possible `fill` value.

NORTH

public final static int NORTH

Constant for possible `anchor` value.

NORTHEAST

public final static int NORTHEAST

Constant for possible `anchor` value.

NORTHWEST

public final static int NORTHWEST

Constant for possible `anchor` value.

RELATIVE

public final static int RELATIVE

Constant for possible `gridx`, `gridy`, `gridwidth`, or `gridheight` value.

REMAINDER

public final static int REMAINDER

Constant for possible `gridwidth` or `gridheight` value.

SOUTH

public final static int SOUTH

Constant for possible `anchor` value.

SOUTHEAST

public final static int SOUTHEAST

Constant for possible `anchor` value.

SOUTHWEST

public final static int SOUTHWEST

Constant for possible `anchor` value.

VERTICAL

public final static int VERTICAL

Constant for possible `fill` value.

WEST

public final static int WEST

Constant for possible `anchor` value.

Variables

anchor

public int anchor

Specifies the alignment of the component in the event that it is smaller than the space allotted for it by the layout manager; e.g., `CENTER` centers the object within the region.

fill

public int fill

The component's resize policy if additional space available.

gridheight

public int gridheight

Number of columns a component occupies.

gridwidth

public int gridwidth

Number of rows a component occupies.

gridx

public int gridx

Horizontal grid position at which to add component.

gridy

public int gridy

Vertical grid position at which to add component.

insets

public Insets insets

Specifies the outer padding around the component.

ipadx

public int ipadx

Serves as the internal padding within the component in both the right and left directions.

ipady

public int ipady

Serves as the internal padding within the component in both the top and bottom directions.

weightx

public double weightx

Represents the percentage of extra horizontal space that will be given to this component if there is additional space available within the container.

weighty

public double weighty

Represents the percentage of extra vertical space that will be given to this component if there is additional space available within the container.

Constructors

GridBagConstraints

public GridBagConstraints()

Description

> Constructs a `GridBagConstraints` object.

Instance Methods

clone

public Object clone()

Returns

> A new instance of `GridBagConstraints` with same values for constraints.

Overrides

> `Object.clone()`

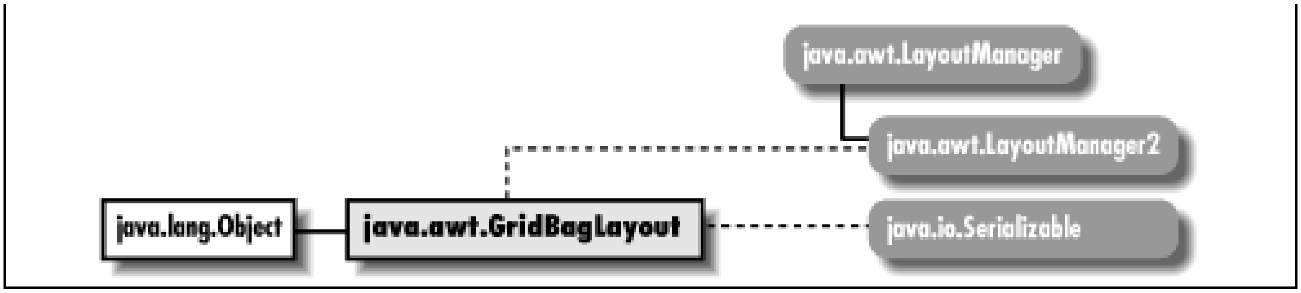
See Also

`Cloneable`, `GridBagLayout`, `Insets`, `Object`, `Serializable`

GridBagLayout

Name

GridBagLayout



Description

The `GridBagLayout LayoutManager` provides the means to layout components in a flexible grid-based display model.

Class Definition

```
public class java.awt.GridBagLayout
    extends java.lang.Object
    implements java.awt.LayoutManager2, java.io.Serializable {

  // Protected Constants
  protected static final MAXGRIDSIZE;
  protected static final MINSIZE;
  protected static final PREFERREDSIZE;

  // Variables
  public double columnWeights[];
  public int columnWidths[];
  public int rowHeights[];
  public double rowWeights[];

  // Protected Variables
  protected Hashtable comptable;
  protected GridBagConstraints defaultConstraints;
  protected GridBagLayoutInfo layoutInfo;

  // Constructors
  public GridBagLayout();

  // Instance Methods
  public void addLayoutComponent (Component comp, Object constraints); ★
  public void addLayoutComponent (String name, Component component);
  public GridBagConstraints getConstraints (Component component);
  public abstract float getLayoutAlignmentX(Container target); ★
  public abstract float getLayoutAlignmentY(Container target); ★
  public int[][] getLayoutDimensions();
  public Point getLayoutOrigin();
  public double[][] getLayoutWeights();
  public abstract void invalidateLayout(Container target); ★
  public void layoutContainer (Container target);
  public Point location (int x, int y);
  public abstract Dimension maximumLayoutSize(Container target); ★
  public Dimension minimumLayoutSize (Container target);
  public Dimension preferredLayoutSize (Container target);
  public void removeLayoutComponent (Component component);
  public void setConstraints (Component component,
      GridBagConstraints constraints);
  public String toString();

  // Protected Instance Methods
  protected void AdjustForGravity (GridBagConstraints constraints,
      Rectangle r);
  protected void ArrangeGrid (Container target);
  protected GridBagLayoutInfo GetLayoutInfo (Container target,
      int sizeFlag);
  protected Dimension GetMinSize (Container target,
      GridBagLayoutInfo info);
  protected GridBagConstraints lookupConstraints (Component comp);
}
```

Protected Constants

MAXGRIDSIZE

protected static final MAXGRIDSIZE

Maximum number of rows and columns within container managed by `GridBagLayout`.

MINSIZE

protected static final MINSIZE

Used for internal sizing purposes.

PREFERREDSIZE

protected static final PREFERREDSIZE

Used for internal sizing purposes.

Variables

columnWeights

public double[] columnWeights

The `weightx` values of the components in the row with the most elements.

columnWidths

public int[] columnWidths

The `width` values of the components in the row with the most elements.

rowHeights

public int[] rowHeights

The `height` values of the components in the column with the most elements.

rowWeights

public double[] rowWeights

The `weighty` values of the components in the column with the most elements.

Protected Variables

comptable

protected Hashtable comptable

Internal table to manage components.

defaultConstraints

protected GridBagConstraints defaultConstraints

Constraints to use for `Component`s that have none.

layoutInfo

protected GridBagLayoutInfo layoutInfo

Internal information about the `GridBagLayout`.

Constructors

GridBagLayout

public GridBagLayout()

Description

> Constructs a `GridBagLayout` object.

Instance Methods

addLayoutComponent

public void addLayoutComponent (Component comp, Object constraints) ★

Parameters

comp

The component being added.

constraints

An object describing the constraints on this component.

Implements

`LayoutManager2.addLayoutComponent()`

Description

Adds the component `comp` to container subject to the given `constraints`. This is a more generalized version of `addLayoutComponent(String, Component)`. It corresponds to `java.awt.Container's add(Component, Object)`.

public void addLayoutComponent (String name, Component component)

Parameters

name

Name of component to add.

component

Actual component being added.

Implements

`LayoutManager.addLayoutComponent()`

Description

Does nothing.

getConstraints

public GridBagConstraints getConstraints (Component component)

Parameters

component

Component whose constraints are desired

Returns

`GridBagConstraints` for component requested.

getLayoutAlignmentX

public abstract float getLayoutAlignmentX (Container target) ★

Parameters

target

The container to inspect.

Returns

The value .5 for all containers.

Description

This method returns the preferred alignment of the given container `target`. A return value of 0 is left aligned, .5 is centered, and 1 is right aligned.

getLayoutAlignmentY

public abstract float getLayoutAlignmentY (Container target) ★

Parameters

target

The container to inspect.

Returns

The value .5 for all containers.

Description

This method returns the preferred alignment of the given container `target`. A return value of 0 is top aligned, .5 is centered, and 1 is bottom aligned.

getLayoutDimensions

public int[][] getLayoutDimensions()

Returns

Returns two single dimension arrays as a multi-dimensional array. Index 0 is an array of widths (`columnWidths` instance variable), while index 1 is an array of heights (`rowHeights` instance variable).

getLayoutOrigin

public Point getLayoutOrigin()

Returns

Returns the origin of the components within the `Container` whose `LayoutManager` is `GridBagLayout`.

getLayoutWeights

public double[][] getLayoutWeights()

Returns

Returns two single dimension arrays as a multi-dimensional array. Index 0 is an array of columns weights (`columnWeights` instance variable), while index 1 is an array of row weights (`rowWeights` instance variable).

invalidateLayout

public abstract void invalidateLayout (Container target) ★

Parameters

target

The container to invalidate.

Description

Does nothing.

layoutContainer

public void layoutContainer (Container target)

Parameters

target

The container that needs to be redrawn.

Implements

`LayoutManager.layoutContainer()`

Description

Draws components contained within `target`.

location

public Point location (int x, int y)

Parameters

x

The x coordinate of the grid position to find.

y

The y coordinate of the grid position to find.

Returns

Returns the grid element under the location provided at position (`x`, `y`) in pixels. Note that the returned Point uses the `GridBagLayout`'s grid for its coordinate space.

Description

Locates the grid position in the `Container` under the given location.

maximumLayoutSize

public abstract Dimension maximumLayoutSize (Container target) ★

Parameters

target

The container to inspect.

Returns

A `Dimension` whose horizontal and vertical components are `Integer.MAX_VALUE`.

Description

For `GridBagLayout`, a maximal `Dimension` is always returned.

minimumLayoutSize

public Dimension minimumLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Minimum `Dimension` of container target.

Implements

`LayoutManager.minimumLayoutSize()`

Description

Calculates minimum size of `target` container.

preferredLayoutSize

public Dimension preferredLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Preferred `Dimension` of container target

Implements

`LayoutManager.preferredLayoutSize()`

Description

Calculates preferred size of `target` container.

removeLayoutComponent

public void removeLayoutComponent (Component component)

Parameters

component

Component to stop tracking.

Implements

`LayoutManager.removeLayoutComponent()`

Description

Does nothing.

setConstraints

public void setConstraints (Component component, GridBagConstraints constraints)

Parameters

component

Component to set constraints for

constraints

Constraints for component

Description

Changes the `GridBagConstraints` on `component` to those provided.

toString

public String toString()

Returns

A string representation of the `GridBagLayout` object.

Overrides

`Object.toString()`

Protected Instance Methods

AdjustForGravity

protected void AdjustForGravity (GridBagConstraints constraints, Rectangle r)

Parameters

constraints

Constraints to use for adjustment of Rectangle.

r

Rectangular area that needs to be adjusted.

Description

Helper routine for laying out a cell of the grid. The routine adjusts the values for `r` based upon the `constraints`.

ArrangeGrid

protected void ArrangeGrid (Container target)

Parameters

target

`Container` to layout.

Description

Helper routine that does the actual arrangement of components in `target`.

GetLayoutInfo

protected GridBagLayoutInfo GetLayoutInfo (Container target, int sizeFlag)

Parameters

target

Container to get information about.

sizeFlag

One of the constants MINSIZE or PREFERREDSIZE.

Returns

Returns an internal class used to help size the container.

GetMinSize

protected Dimension GetMinSize (Container target, GridBagLayoutInfo info)

Parameters

target

Container to calculate size.

info

Specifics about the container's constraints.

Returns

Minimum Dimension of container target based on info.

Description

Helper routine for calculating size of container.

lookupConstraints

protected GridBagConstraints lookupConstraints (Component comp)

Parameters

comp

`Component` in question.

Returns

A reference to the `GridBagConstraints` object for this component.

Description

Helper routine for calculating size of container.

See Also

`Component`, `Container`, `Dimension`, `GridBagConstraints`, `Hashtable`, `LayoutManager`, `LayoutManager2`, `Object`, `Point`, `Rectangle`, `String`

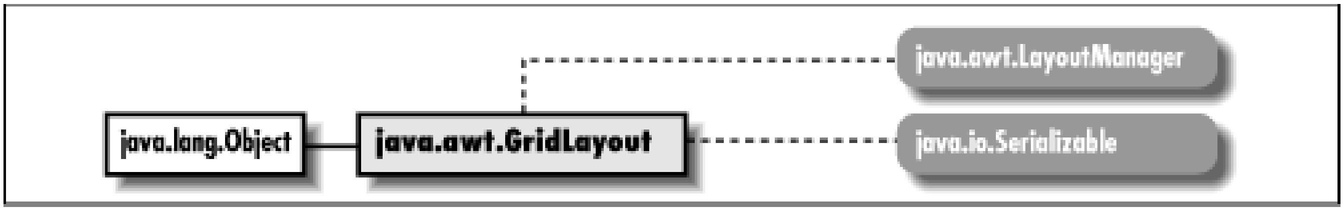
GridLayout

Name

GridLayout



Description

The `GridLayout LayoutManager` provides the means to layout components in a grid of rows and columns.

Class Definition

```
public class java.awt.GridLayout
        extends java.lang.Object
        implements java.awt.LayoutManager, java.io.Serializable
 {

// Constructors
  public GridLayout(); ★
  public GridLayout (int rows, int cols);
  public GridLayout (int rows, int cols, int hgap, int vgap);
// Instance Methods
  public void addLayoutComponent (String name, Component component);
  public int getColumns(); ★
  public int getHgap(); ★
  public int getRows(); ★

  public int getVgap(); ★
  public void layoutContainer (Container target);
  public Dimension minimumLayoutSize (Container target);
  public Dimension preferredLayoutSize (Container target);
  public void removeLayoutComponent (Component component);
  public int setColumns(int cols); ★
  public int setHgap(int hgap); ★
  public int setRows(int rows); ★

  public int setVgap(int vgap); ★
  public String toString();
}
```

Constructors

GridLayout

public GridLayout() ★

Description

> Constructs a `GridLayout` object with a default single row and one column per component.

public GridLayout (int rows, int cols)

Parameters

> *rows*
>
> > Requested number of rows in container.
>
> *cols*

Requested number of columns in container.

Description

Constructs a `GridLayout` object with the requested number of rows and columns. Note that the actual number of rows and columns depends on the number of objects in the layout, not the constructor's parameters.

public GridLayout (int rows, int cols, int hgap, int vgap)

Parameters

rows

Requested number of rows in container.

cols

Requested number of columns in container.

hgap

Horizontal space between each component in a row.

vgap

Vertical space between each row.

Description

Constructs a `GridLayout` object with the requested number of `rows` and `columns` and the values specified as the gaps between each component. Note that the actual number of rows and columns depends on the number of objects in the layout, not the constructor's parameters.

Instance Methods

addLayoutComponent

public void addLayoutComponent (String name, Component component)

Parameters

name

Name of component to add.

component

Actual component being added.

Implements

`LayoutManager.addLayoutComponent()`

Description

Does nothing.

getColumns

public int getColumns() ★

Returns

The number of columns.

getHgap

public int getHgap() ★

Returns

The horizontal gap for this `GridLayout` instance.

getRows

public int getRows() ★

Returns

The number of rows.

getVgap

public int getVgap() ★

Returns

The vertical gap for this `GridLayout` instance.

layoutContainer

public void layoutContainer (Container target)

Parameters

target

The container that needs to be redrawn.

Implements

`LayoutManager.layoutContainer()`

Description

Draws the components contained within the `target`.

minimumLayoutSize

public Dimension minimumLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Minimum `Dimension` of the container `target`.

Implements

`LayoutManager.minimumLayoutSize()`

Description

Calculates the minimum size of the `target` container.

preferredLayoutSize

public Dimension preferredLayoutSize (Container target)

Parameters

target

The container whose size needs to be calculated.

Returns

Preferred `Dimension` of the container `target`.

Implements

`LayoutManager.preferredLayoutSize()`

Description

Calculates the preferred size of the `target` container.

removeLayoutComponent

public void removeLayoutComponent (Component component)

Parameters

component

Component to stop tracking.

Implements

`LayoutManager.removeLayoutComponent()`

Description

Does nothing.

setColumns

public void setColumns(int cols) ★

Parameters

cols

The new number of columns.

Description

Sets the number of columns.

setHgap

public void setHgap(int hgap) ★

Parameters

hgap

The horizontal gap value.

Description

Sets the horizontal gap between components.

setRows

public void setRows(int rows) ★

Parameters

rows

The new number of rows.

Description

Sets the number of rows.

setVgap

public void setVgap(int vgap) ★

Parameters

vgap

The vertical gap value.

Description

Sets the vertical gap between components.

toString

public String toString()

Returns

A string representation of the `GridLayout` object.

Overrides

`Object.toString()`

See Also

`Component`, `Container`, `Dimension`, `LayoutManager`, `Object`, `String`

GridBagLayout | BOOK INDEX | IllegalComponentStateException

★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

IllegalComponentStateException ★

Name

IllegalComponentStateException ★

[Graphic: Figure from the text]

Description

An `Exception` indicating that a `Component` was not in an appropriate state to perform a requested action.

Class Definition

```
public class java.awt.IllegalComponentStateException
    extends java.lang.IllegalStateException {

  // Constructors
  public IllegalComponentStateException();
  public IllegalComponentStateException (String s);
}
```

Constructors

IllegalComponentStateException

public IllegalComponentStateException()

Description

Constructs the exception object with no detail message.

public IllegalComponentStateException (String s)

Parameters

s

Detail message

Description

Constructs the exception object with the given detail message.

See Also

`Exception`, `String`

SystemColor ★

Name

SystemColor ★

[Graphic: Figure from the text]

Description

`SystemColor` provides information on the colors that the windowing system uses to display windows and other graphic components. Most windowing systems allow the user to choose different color schemes; `SystemColor` enables programs to find out what colors are in use in order to paint themselves in a consistent manner.

Class Definition

```
public final class java.awt.SystemColor
    extends java.awt.Color
    implements java.io.Serializable {
  // Constants
  public final static int ACTIVE_CAPTION;
  public final static int ACTIVE_CAPTION_BORDER;
  public final static int ACTIVE_CAPTION_TEXT;

activeCaption

public static final SystemColor activeCaption

Background color for captions in window borders.

activeCaptionBorder

public static final SystemColor activeCaptionBorder

Border color for captions in window borders.

activeCaptionText

public static final SystemColor activeCaptionText

Text color for captions in window borders.

control

public static final SystemColor control

Background color for controls.

controlDkShadow

public static final SystemColor controlDkShadow

Dark shadow color for controls.

controlHighlight

public static final SystemColor controlHighlight

Highlight color for controls.

controlLtHighlight

public static final SystemColor controlLtHighlight

Light highlight color for controls.

controlShadow

public static final SystemColor controlShadow

Shadow color for controls.

controlText

public static final SystemColor controlText

Text color for controls.

desktop

public static final SystemColor desktop

Desktop background color.

inactiveCaption

public static final SystemColor inactiveCaption

Background color for inactive captions in window borders.

inactiveCaptionBorder

public static final SystemColor inactiveCaptionBorder

Border color for inactive captions in window borders.

inactiveCaptionText

public static final SystemColor inactiveCaptionText

Text color for inactive captions in window borders.

info

public static final SystemColor info

Background color for informational text.

infoText

public static final SystemColor infoText

Text color for informational text.

menu

public static final SystemColor menu

Background color for menus.

menuText

public static final SystemColor menuText

Text color for menus.

scrollbar

public static final SystemColor scrollbar

Background color for scrollbars.

text

public static final SystemColor text

Background color for text components.

textHighlight

public static final SystemColor textHighlight

Background color for highlighted text.

textHighlightText

public static final SystemColor textHighlightText

Text color for highlighted text.

textInactiveText

public static final SystemColor textInactiveText

Text color for inactive text.

textText

public static final SystemColor textText

Text color for text components.

window

public static final SystemColor window

Background color for windows.

windowBorder

public static final SystemColor windowBorder

Border color for windows.

windowText

public static final SystemColor windowText

Text color for windows.

Instance Methods

getRGB

public int getRGB()

Returns

> Current color as a composite value

Overrides

> `Color.getRGB()`

Description

> Gets integer value of current system color.

toString

public String toString()

Returns

> A string representation of the `SystemColor` object.

Overrides

> `Color.toString()`

`Color`, `Serializable`, `String`

ClipboardOwner ★

Name

ClipboardOwner ★

[Graphic: Figure from the text]

Description

`ClipboardOwner` is implemented by classes that want to be notified when someone else sets the contents of a clipboard.

Interface Definition

```
public abstract interface java.awt.datatransfer.ClipboardOwner {
  // Interface Methods
  public abstract void lostOwnership (Clipboard clipboard, Transferable contents);
}
```

Interface Methods

lostOwnership

public abstract void lostOwnership (Clipboard clipboard, Transferable contents)

Parameters

clipboard

The clipboard whose contents have changed.

contents

The contents that this owner originally put on the clipboard.

Description

Tells the `ClipboardOwner` that the `contents` it placed on the given `clipboard` are no longer there.

See Also

`Clipboard, StringSelection, Transferable`

DataFlavor ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

DataFlavor ★

Name

DataFlavor ★

[Graphic: Figure from the text]

Description

The `DataFlavor` class encapsulates information about data formats.

Class Definition

```
public class java.awt.datatransfer.DataFlavor
   extends java.lang.Object {
  // Class Variables
  public static DataFlavor plainTextFlavor;
  public static DataFlavor stringFlavor;
  // Constructors
  public DataFlavor (Class representationClass,
    String humanPresentableName);
  public DataFlavor (String MIMEType, String humanPresentableName);
  // Instance Methods
  public boolean equals (DataFlavor dataFlavor);
  public String getHumanPresentableName();
  public String getMIMEType();
  public Class getRepresentationClass();
  public boolean isMIMETypeEqual (String MIMEType);
  public final boolean isMIMETypeEqual (DataFlavor dataFlavor);
  public void setHumanPresentableName (String humanPresentableName);
  // Protected Instance Methods
  protected String normalizeMIMEType (String MIMEType);
  protected String normalizeMIMETypeParameter (String parameterName,
    String parameterValue);
}
```

Class Variables

plainTextFlavor

public static DataFlavor plainTextFlavor

A preset `DataFlavor` object representing plain text.

stringFlavor

public static DataFlavor stringFlavor

A preset `DataFlavor` object representing a Java `String`.

Constructors

DataFlavor

public DataFlavor (Class representationClass, String humanPresentableName)

Parameters

representationClass

The Java class that represents data in this flavor.

humanPresentableName

A name for this flavor that humans will recognize.

Description

Constructs a `DataFlavor` object with the given characteristics. The MIME type for this `DataFlavor` is `application/x-java-serialized-object <Java ClassName>`.[1]

[1] The type name changed to `x-java-serialized-object` in the 1.1.1 release.

public DataFlavor (String MIMEType, String humanPresentableName)

Parameters

MIMEType

The MIME type string this `DataFlavor` represents.

humanPresentableName

A name for this flavor that humans will recognize.

Description

Constructs a `DataFlavor` object with the given characteristics. The representation class used for this `DataFlavor` is `java.io.InputStream`.

Instance Methods

equals

public boolean equals (DataFlavor dataFlavor)

Parameters

dataFlavor

The flavor to compare.

Returns

`true` if `dataFlavor` is equivalent to this `DataFlavor`, `false` otherwise.

Description

Compares two different `DataFlavor` instances for equivalence.

getHumanPresentableName

public String getHumanPresentableName()

Returns

The name of this flavor.

getMIMEType

public String getMIMEType()

Returns

The MIME type string for this flavor.

getRepresentationClass

public Class getRepresentationClass()

Returns

The Java class that will be used to represent data in this flavor.

isMIMETypeEqual

public boolean isMIMETypeEqual (String MIMEType)

Parameters

MIMEType

The type to compare.

Returns

`true` if the given MIME type is the same as this `DataFlavor`'s MIME type; `false` otherwise.

Description

Compares two different `DataFlavor` MIME types for equivalence.

public final boolean isMIMETypeEqual (DataFlavor dataFlavor)

Parameters

dataFlavor

The flavor to compare.

Returns

`true` if `DataFlavor`'s MIME type is the same as this `DataFlavor`'s MIME type; `false` otherwise.

Description

Compares two different `DataFlavor` MIME types for equivalence.

setHumanPresentableName

public void setHumanPresentableName (String humanPresentableName)

Parameters

humanPresentableName

A name for this flavor that humans will recognize.

Description

Changes the name of the `DataFlavor`.

Protected Instance Methods

normalizeMIMEType

protected String normalizeMIMEType (String MIMEType)

Parameters

MIMEType

The MIME type string to normalize.

Returns

Normalized MIME type string.

Description

This method is called for each MIME type string. Subclasses can override this method to add default parameter/value pairs to MIME strings.

normalizeMIMETypeParameter

protected String normalizeMIMETypeParameter (String parameterName, String parameterValue)

Parameters

parameterName

The MIME type parameter to normalize.

parameterValue

The corresponding value.

Returns

Normalized MIME type parameter string.

Description

> This method is called for each MIME type parameter string. Subclasses can override this method to handle special parameters, such as those that are case-insensitive.

See Also

`Class`, `String`

ClipboardOwner ★ | BOOK INDEX | StringSelection ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

StringSelection ★

Name

StringSelection ★

[Graphic: Figure from the text]

Description

`StringSelection` is a "convenience" class that can be used for copy and paste operations on Unicode text strings. For example, you could place a string on the system's clipboard with the following code:

```
Clipboard c =
  Toolkit.getDefaultToolkit().getSystemClipboard();
StringSelection s = new StringSelection(
  "Be safe when you cut and paste.");
c.setContents(s, s);
```

Class Definition

```
public class java.awt.datatransfer.StringSelection
   extends java.lang.Object
   implements java.awt.datatransfer.ClipboardOwner,
         java.awt.datatransfer.Transferable {
```

```
  // Constructor
  public StringSelection(String data);
  // Instance Methods
  public synchronized Object getTransferData (DataFlavor flavor)
    throws UnsupportedFlavorException, IOException;
  public synchronized DataFlavor[] getTransferDataFlavors();
  public boolean isDataFlavorSupported (DataFlavor flavor);
  public void lostOwnership (Clipboard clipboard, Transferable contents);
}
```

Constructors

StringSelection

public StringSelection (String data)

Parameters

data

The string to be placed in a clipboard.

Description

Constructs a `StringSelection` object from the given string.

Instance Methods

getTransferData

public synchronized Object getTransferData (DataFlavor flavor) throws UnsupportedFlavorException, IOException

Parameters

flavor

The requested flavor for the returned data, which can be either `DataFlavor.stringFlavor` or `DataFlavor.plainTextFlavor`.

Returns

The string that the `StringSelection` was constructed with. This is returned either as a `String` object or a `Reader` object, depending on the flavor requested.

Throws

UnsupportedFlavorException

If the requested flavor is not supported.

IOException

If a `Reader` representing the string could not be created.

Implements

`Transferable.getTransferData(DataFlavor)`

Description

Returns the string this `StringSelection` represents. This is returned either as a `String` object or a `Reader` object, depending on the flavor requested.

getTransferDataFlavors

public synchronized DataFlavor[] getTransferDataFlavors()

Returns

An array of the data flavors the `StringSelection` supports.

Implements

`Transferable.getTransferDataFlavors()`

Description

`DataFlavor.stringFlavor` and `DataFlavor.plainTextFlavor` are returned.

isDataFlavorSupported

public boolean isDataFlavorSupported (DataFlavor flavor)

Parameters

flavor

The flavor in question.

Returns

`true` if `flavor` is supported; `false` otherwise.

Implements

`Transferable.isDataFlavorSupported(DataFlavor)`

lostOwnership

public void lostOwnership (Clipboard clipboard, Transferable contents)

Parameters

clipboard

The clipboard whose contents are changing.

contents

The contents that were on the clipboard.

Implements

`ClipboardOwner.lostOwnership(Clipboard, Transferable)`

Description

Does nothing.

See Also

`Clipboard`, `ClipboardOwner`, `DataFlavor`, `String`, `Transferable`

Transferable ★

Name

Transferable ★

[Graphic: Figure from the text]

Description

The `Transferable` interface is implemented by objects that can be placed on `Clipboard`s.

Interface Definition

```
public abstract interface Transferable {
  // Instance Methods
  public abstract Object getTransferData (DataFlavor flavor)
    throws UnsupportedFlavorException, IOException;
  public abstract DataFlavor[] getTransferDataFlavors();
  public abstract boolean isDataFlavorSupported (DataFlavor flavor);
}
```

Interface Methods

getTransferData

public abstract Object getTransferData (DataFlavor flavor) throws UnsupportedFlavorException, IOException

Parameters

flavor

The requested flavor for the returned data.

Returns

The data represented by this `Transferable` object, in the requested flavor.

Throws

UnsupportedFlavorException

If the requested flavor is not supported.

IOException

If a `Reader` representing the data could not be created.

Description

Returns the data this `Transferable` object represents. The class of object returned depends on the flavor requested.

getTransferDataFlavors

public abstract DataFlavor[] getTransferDataFlavors()

Returns

An array of the supported data flavors.

Description

The data flavors should be returned in order, sorted from most to least descriptive.

isDataFlavorSupported

public abstract boolean isDataFlavorSupported (DataFlavor flavor)

Parameters

flavor

The flavor in question.

Returns

`true` if `flavor` is supported; `false` otherwise.

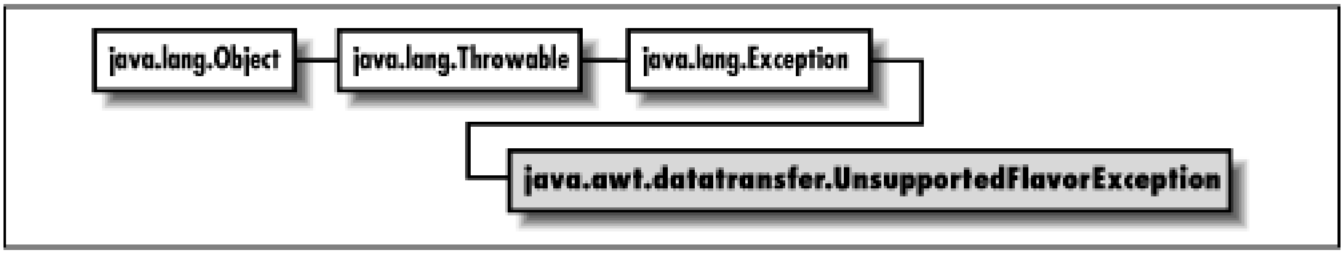
See Also

`Clipboard`, `DataFlavor`, `Reader`, `StringSelection`, `Transferable`

UnsupportedFlavorException ★

Name

UnsupportedFlavorException ★



Description

This exception is thrown from `Transferable.getTransferData(DataFlavor)` to indicate that the `DataFlavor` requested is not available.

Class Definition

```
public class java.awt.datatransfer.UnsupportedFlavorException
   extends java.lang.Exception {
  // Constructor
  public UnsupportedFlavorException (DataFlavor flavor);
}
```

Constructors

UnsupportedFlavorException

public UnsupportedFlavorException (DataFlavor flavor)

Parameters

flavor

The flavor that caused the exception.

See Also

`DataFlavor`, `Exception`, `Transferable`

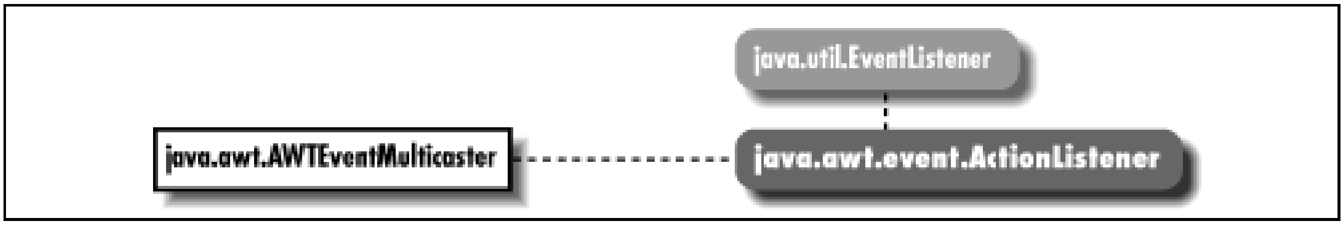
Transferable | BOOK INDEX | ActionEvent

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ActionListener ★

Name

ActionListener ★



Description

Objects that implement the `ActionListener` interface can receive `ActionEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.ActionListener
   extends java.util.EventListener {
  // Interface Methods
  public abstract void actionPerformed (ActionEvent e);
}
```

Interface Methods

actionPerformed

public abstract void actionPerformed (ActionEvent e)

Parameters

e

The action event that occurred.

Description

Notifies the `ActionListener` that an event occurred.

See Also

`ActionEvent`, `AWTEventMultisaster`, `EventListener`

PREVIOUS | HOME | NEXT
ActionEvent ★ | BOOK INDEX | AdjustmentEvent ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

AdjustmentEvent ★

Name

AdjustmentEvent ★

[Graphic: Figure from the text]

Description

`AdjustmentEvent`s are generated by objects that implement the `Adjustable` interface. `Scrollbar` is one example of such an object.

Class Definition

```
public class java.awt.event.AdjustmentEvent
   extends java.awt.AWTEvent {
  // Constants
  public final static int ADJUSTMENT_FIRST;
  public final static int ADJUSTMENT_LAST;
  public final static int ADJUSTMENT_VALUE_CHANGED;
  public final static int BLOCK_DECREMENT;
  public final static int BLOCK_INCREMENT;
  public final static int TRACK;
  public final static int UNIT_DECREMENT;
  public final static int UNIT_INCREMENT;
  // Constructors
  public AdjustmentEvent (Adjustable source, int id, int type, int value);
  // Instance Methods
  public Adjustable getAdjustable();
  public int getAdjustmentType();
  public int getValue();
  public String paramString();
}
```

Constants

ADJUSTMENT_FIRST

public final static int ADJUSTMENT_FIRST

Specifies the beginning range of adjustment event ID values.

ADJUSTMENT_LAST

public final static int ADJUSTMENT_LAST

Specifies the ending range of adjustment event ID values.

ADJUSTMENT_VALUE_CHANGED

public final static int ADJUSTMENT_VALUE_CHANGED

Event type ID for value changed.

BLOCK_DECREMENT

public final static int BLOCK_DECREMENT

Adjustment type for block decrement.

BLOCK_INCREMENT

public final static int BLOCK_INCREMENT

Adjustment type for block increment.

TRACK

public final static int TRACK

Adjustment type for tracking.

UNIT_DECREMENT

public final static int UNIT_DECREMENT

Adjustment type for unit decrement.

UNIT_INCREMENT

public final static int UNIT_INCREMENT

Adjustment type for unit increment.

Constructors

AdjustmentEvent

public AdjustmentEvent (Adjustable source, int id, int type, int value)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

type

The type of adjustment event.

value

The value of the `Adjustable` object.

Description

Constructs an `AdjustmentEvent` with the given characteristics.

Instance Methods

getAdjustable

public Adjustable getAdjustable()

Returns

The source of this event.

getAdjustmentType

public int getAdjustmentType()

Returns

One of the adjustment type constants.

Description

The type will be `BLOCK_DECREMENT`, `BLOCK_INCREMENT`, `TRACK`, `UNIT_DECREMENT`, or `UNIT_INCREMENT`.

getValue

public int getValue()

Returns

The new value of the `Adjustable` object.

paramString

public String paramString()

Returns

String with current settings of the `AdjustmentEvent`.

Overrides

`AWTEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

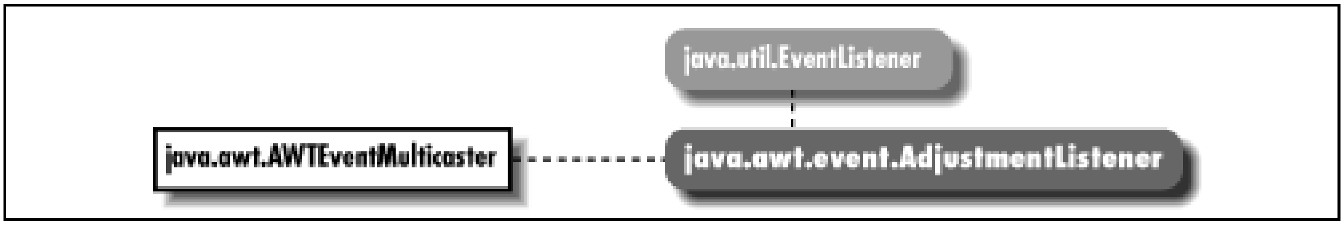
See Also

`Adjustable`, `AdjustmentListener`, `AWTEvent`, `Scrollbar`

AdjustmentListener ★

Name

AdjustmentListener ★



java.util.EventListener
java.awt.AWTEventMulticaster
java.awt.event.AdjustmentListener

Description

Objects that implement the `AdjustmentListener` interface can receive `AdjustmentEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.AdjustmentListener
   extends java.util.Eventlistener {
  // Interface Methods
  public abstract void adjustmentValueChanged (AdjustmentEvent e);
}
```

Interface Methods

adjustmentPerformed

public abstract void adjustmentValueChanged (AdjustmentEvent e)

Parameters

e

The adjustment event that occurred.

Description

Notifies the `AdjustmentListener` that an event occurred.

See Also

`AdjustmentEvent`, `AWTEventMultiCaster`, `EventListener`

AdjustmentEvent ★ | BOOK INDEX | ComponentAdapter ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ComponentAdapter ★

Name

ComponentAdapter ★

[Graphic: Figure from the text]

Description

`ComponentAdapter` is a class that implements the methods of `ComponentListener` with empty functions. It may be easier for you to extend `ComponentAdapter`, overriding only those methods you are interested in, than to implement `ComponentListener` and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.ComponentAdapter
   extends java.lang.Object
   implements java.awt.event.ComponentListener {
  // Instance Methods
  public void componentHidden (ComponentEvent e);
  public void componentMoved (ComponentEvent e);
  public void componentResized (ComponentEvent e);
  public void componentShown (ComponentEvent e);
}
```

Instance Methods

componentHidden

public void componentHidden (ComponentEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component is hidden.

componentMoved

public void componentMoved (ComponentEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component is moved.

componentResized

public void componentResized (ComponentEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component is resized.

componentShown

public void componentShown (ComponentEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component is shown.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ComponentEvent ★

Name

ComponentEvent ★

[Graphic: Figure from the text]

Description

Component events are generated when a component is shown, hidden, moved, or resized. AWT automatically deals with component moves and resizing; these events are provided only for notification. Subclasses of `ComponentEvent` deal with other specific component-level events.

Class Definition

```
public class java.awt.event.ComponentEvent
```

```
   extends java.awt.AWTEvent {
  // Constants
  public final static int COMPONENT_FIRST;
  public final static int COMPONENT_HIDDEN;
  public final static int COMPONENT_LAST;
  public final static int COMPONENT_MOVED;
  public final static int COMPONENT_RESIZED;
  public final static int COMPONENT_SHOWN;
  // Constructors
  public ComponentEvent (Component source, int id);
  // Instance Methods
  public Component getComponent();
  public String paramString();
}
```

Constants

COMPONENT_FIRST

public final static int COMPONENT_FIRST

Specifies the beginning range of component event ID values.

COMPONENT_HIDDEN

public final static int COMPONENT_HIDDEN

Event type ID indicating that the component was hidden.

COMPONENT_LAST

public final static int COMPONENT_LAST

Specifies the ending range of component event ID values.

COMPONENT_MOVED

public final static int COMPONENT_MOVED

Event type ID indicating that the component was moved.

COMPONENT_RESIZED

public final static int COMPONENT_RESIZED

Event type ID indicating that the component was resized.

COMPONENT_SHOWN

public final static int COMPONENT_SHOWN

Event type ID indicating that the component was shown.

Constructors

ComponentEvent

public ComponentEvent (Component source, int id)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

Description

Constructs a `ComponentEvent` with the given characteristics.

Instance Methods

getComponent

public Component getComponent()

Returns

The source of this event.

paramString

public String paramString()

Returns

String with current settings of the `ComponentEvent`.

Overrides

`AWTEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

See Also

`AWTEvent`, `Component`, `ComponentAdapter`, `ComponentListener`, `ContainerEvent`, `FocusEvent`, `InputEvent`, `PaintEvent`, `WindowEvent`

ComponentListener ★

Name

ComponentListener ★

[Graphic: Figure from the text]

Description

Objects that implement the `ComponentListener` interface can receive `ComponentEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.ComponentListener
   extends java.util.EventListener {
  // Instance Methods
  public abstract void componentHidden (ComponentEvent e);
  public abstract void componentMoved (ComponentEvent e);
  public abstract void componentResized (ComponentEvent e);
  public abstract void componentShown (ComponentEvent e);
}
```

Interface Methods

componentHidden

public abstract void componentHidden (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Notifies the `ComponentListener` that a component was hidden.

componentMoved

public abstract void componentMoved (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Notifies the `ComponentListener` that a component was moved.

componentResized

public abstract void componentResized (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Notifies the `ComponentListener` that a component was resized.

componentShown

public abstract void componentShown (ComponentEvent e)

Parameters

e

The component event that occurred.

Description

Notifies the `ComponentListener` that a component was shown.

ComponentEvent ★ | BOOK INDEX | ContainerAdapter ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ContainerAdapter ★

Name

ContainerAdapter ★

[Graphic: Figure from the text]

Description

The ContainerAdapter class implements the methods of ContainerListener with empty functions. It may be easier for you to extend ContainerAdapter, overriding only those methods you are interested in, than to implement ContainerListener and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.ContainerAdapter
   extends java.lang.Object
   implements java.awt.event.ContainerListener {
  // Instance Methods
  public void componentAdded (ContainerEvent e);
  public void componentRemoved (ContainerEvent e);
}
```

Instance Methods

componentAdded

public void componentAdded (ComponentEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component is added to a container.

componentRemoved

public void componentRemoved (ComponentEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component is removed from a container.

See Also

`ContainerEvent`, `ContainerListener`

ContainerEvent ★

Name

ContainerEvent ★

[Graphic: Figure from the text]

Description

Container events are fired off when a component is added to or removed from a container. The AWT automatically deals with adding components to containers; these events are provided only for notification.

Class Definition

```
public class java.awt.event.ContainerEvent
   extends java.awt.event.ComponentEvent {
  // Constants
  public final static int COMPONENT_ADDED;
  public final static int COMPONENT_REMOVED;
  public final static int CONTAINER_FIRST;
  public final static int CONTAINER_LAST;
  // Constructors
  public ContainerEvent (Component source, int id, Component child);
  // Instance Methods
  public Component getChild();
  public Container getContainer();
  public String paramString();
}
```

Constants

COMPONENT_ADDED

public final static int COMPONENT_ADDED

Event type ID indicating that a component was added to a container.

CONTAINER_FIRST

public final static int CONTAINER_FIRST

Specifies the beginning range of container event ID values.

CONTAINER_LAST

public final static int CONTAINER_LAST

Specifies the ending range of container event ID values.

COMPONENT_REMOVED

public final static int COMPONENT_REMOVED

Event type ID indicating that a component was removed from a container.

Constructors

ContainerEvent

public ContainerEvent (Component source, int id, Component child)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

child

The component that was added or removed.

Description

Constructs a `ContainerEvent` with the given characteristics.

Instance Methods

getChild

public Component getChild()

Returns

The component that is being added or removed.

getContainer

public Container getContainer()

Returns

The container for this event.

paramString

public String paramString()

Returns

String with current settings of the `ContainerEvent`.

Overrides

`ComponentEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

See Also

`Component`, `ComponentEvent`, `Container`, `ContainerAdapter`, `ContainerListener`

ContainerListener ★

Name

ContainerListener ★

[Graphic: Figure from the text]

Description

Objects that implement the `ContainerListener` interface can receive `ContainerEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.ContainerListener
   extends java.util.EventListener {
  // Instance Methods
  public abstract void componentAdded (ContainerEvent e);
  public abstract void componentRemoved (ContainerEvent e);
}
```

Interface Methods

componentAdded

public abstract void componentAdded (ContainerEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `ContainerListener` that a component has been added to the container.

componentRemoved

public abstract void componentRemoved (ContainerEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `ContainerListener` that a component has been removed from the container.

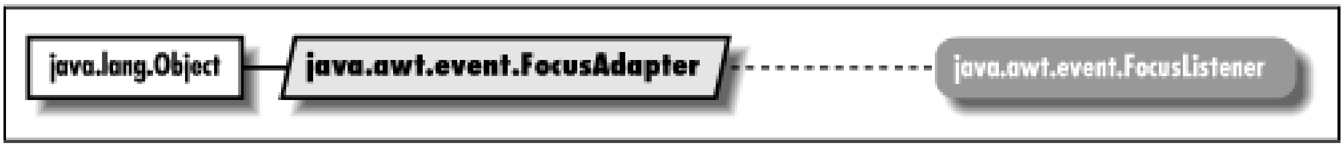
See Also

`ContainerAdapter`, `ContainerEvent`, `EventListener`

FocusAdapter ★

Name

FocusAdapter ★



Description

The `FocusAdapter` class implements the methods of `FocusListener` with empty functions. It may be easier for you to extend `FocusAdapter`, overriding only those methods you are interested in, than to implement `FocusListener` and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.FocusAdapter
   extends java.lang.Object
   implements java.awt.event.FocusListener {
  // Instance Methods
  public void focusGained (FocusEvent e);
  public void focusLost (FocusEvent e);
}
```

Instance Methods

focusGained

public void focusGained (FocusEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component gains focus.

focusLost

public void focusLost (FocusEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a component loses focus.

See Also

`FocusEvent`, `FocusListener`

FocusEvent ★

Name

FocusEvent ★

[Graphic: Figure from the text]

Description

Focus events are generated when a component gets or loses input focus. Focus events come in two flavors, permanent and temporary. Permanent focus events occur with explicit focus changes. For example, when the user tabs through components, this causes permanent focus events. An example of a temporary focus event is when a component loses focus as its containing window is deactivated.

Class Definition

```
public class java.awt.event.FocusEvent
   extends java.awt.event.ComponentEvent {
  // Constants
  public final static int FOCUS_FIRST;
  public final static int FOCUS_GAINED;
  public final static int FOCUS_LAST;
  public final static int FOCUS_LOST;
  // Constructors
  public FocusEvent (Component source, int id);
  public FocusEvent (Component source, int id, boolean temporary);
  // Instance Methods
  public boolean isTemporary();
  public String paramString();
}
```

Constants

FOCUS_FIRST

public final static int FOCUS_FIRST

Specifies the beginning range of focus event ID values.

FOCUS_GAINED

public final static int FOCUS_GAINED

Event type ID indicating that the component gained the input focus.

FOCUS_LAST

public final static int FOCUS_LAST

Specifies the ending range of focus event ID values.

FOCUS_LOST

public final static int FOCUS_LOST

Event type ID indicating that the component lost the input focus.

Constructors

FocusEvent

public FocusEvent (Component source, int id)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

Description

Constructs a non-temporary `FocusEvent` with the given characteristics.

public FocusEvent (Component source, int id, boolean temporary)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

temporary

A flag indicating whether this is a temporary focus event.

Description

Constructs a `FocusEvent` with the given characteristics.

Instance Methods

isTemporary

public boolean isTemporary()

Returns

> `true` if this is a temporary focus event; `false` otherwise.

paramString

public String paramString()

Returns

> String with current settings of the `FocusEvent`.

Overrides

> `ComponentEvent.paramString()`

Description

> Helper method for `toString()` to generate string of current settings.

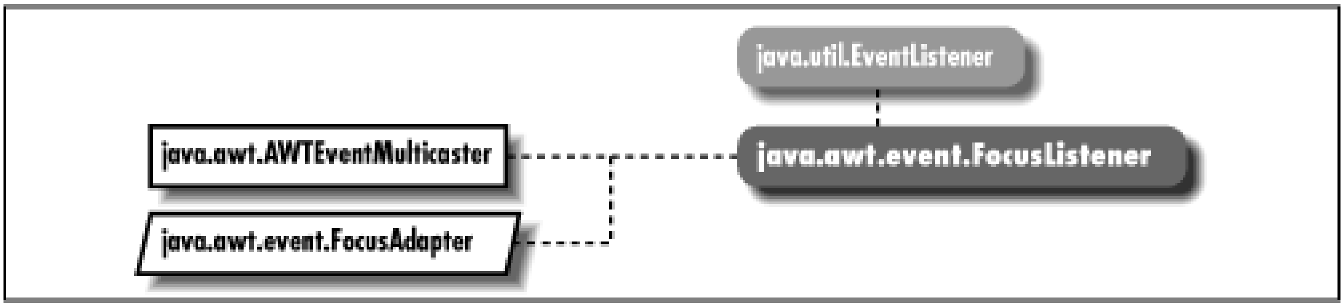
See Also

`Component`, `ComponentEvent`, `FocusAdapter`, `FocusListener`

FocusListener ★

Name

FocusListener ★



java.util.EventListener
java.awt.AWTEventMulticaster
java.awt.event.FocusListener
java.awt.event.FocusAdapter

Description

Objects that implement the `FocusListener` interface can receive `FocusEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.FocusListener
   extends java.util.EventListener {
  // Instance Methods
  public abstract void focusGained (FocusEvent e);
  public abstract void focusLost (FocusEvent e);
}
```

Interface Methods

focusGained

public abstract void focusGained (FocusEvent e)

Parameters

e

The component event that occurred.

Description

Notifies the `FocusListener` that a component gained the input focus.

focusLost

public abstract void focusLost (FocusEvent e)

Parameters

e

The component event that occurred.

Description

Notifies the `FocusListener` that a component lost the input focus.

See Also

`AWTEventMulticaster`, `EventListener`, `FocusAdapter`, `FocusEvent`

FocusEvent ★ BOOK INDEX InputEvent ★

InputEvent ★

Name

InputEvent ★

[Graphic: Figure from the text]

Description

`InputEvent` is the root class for representing user input events. Input events are passed to listeners before the event source processes them. If one of the listeners consumes an event by using `consume()`, the event will not be processed by the event source peer.

Class Definition

```
public abstract class java.awt.event.InputEvent
   extends java.awt.event.ComponentEvent {
  // Constants
  public final static int ALT_MASK;
  public final static int BUTTON1_MASK;
  public final static int BUTTON2_MASK;
  public final static int BUTTON3_MASK;
  public final static int CTRL_MASK;
  public final static int META_MASK;
  public final static int SHIFT_MASK;
  // Instance Methods
  public void consume();
  public int getModifiers();
  public long getWhen();
  public boolean isAltDown();
  public boolean isConsumed();
  public boolean isControlDown();
  public boolean isMetaDown();
  public boolean isShiftDown();
}
```

Constants

ALT_MASK

public final static int ALT_MASK

The ALT key mask. ORed with other masks to form modifiers setting of event.

BUTTON1_MASK

public final static int BUTTON1_MASK

The mouse button 1 key mask. ORed with other masks to form modifiers setting of event.

BUTTON2_MASK

public final static int BUTTON2_MASK

The mouse button 2 key mask. ORed with other masks to form modifiers setting of event. This constant is identical to `ALT_MASK`.

BUTTON3_MASK

public final static int BUTTON3_MASK

The mouse button 3 key mask. ORed with other masks to form modifiers setting of event. This constant is identical to `ALT_MASK`.

CTRL_MASK

public final static int CTRL_MASK

The Control key mask. ORed with other masks to form modifiers setting of event.

META_MASK

public final static int META_MASK

The Meta key mask. ORed with other masks to form modifiers setting of event.

SHIFT_MASK

public final static int SHIFT_MASK

The Shift key mask. ORed with other masks to form modifiers setting of event.

Instance Methods

consume

public void consume()

Description

> A consumed event will not be delivered to its source for default processing.

getModifiers

public int getModifiers()

Returns

The modifier flags, a combination of the `_MASK` constants.

Description

Use this method to find out what modifier keys were pressed when an input event occurred.

getWhen

public long getWhen()

Returns

The time at which this event occurred.

Description

The time of the event is returned as the number of milliseconds since the epoch (00:00:00 UTC, January 1, 1970). Conveniently, `java.util.Date` has a constructor that accepts such values.

isAltDown

public boolean isAltDown()

Returns

`true` if the Alt key was pressed; `false` otherwise.

isConsumed

public boolean isConsumed()

Returns

`true` if the event has been consumed; `false` otherwise.

isControlDown

public boolean isControlDown()

Returns

> `true` if the Control key was pressed; `false` otherwise.

isMetaDown

public boolean isMetaDown()

Returns

> `true` if the Meta key was pressed; `false` otherwise.

isShiftDown

public boolean isShiftDown()

Returns

> `true` if the Shift key was pressed; `false` otherwise.

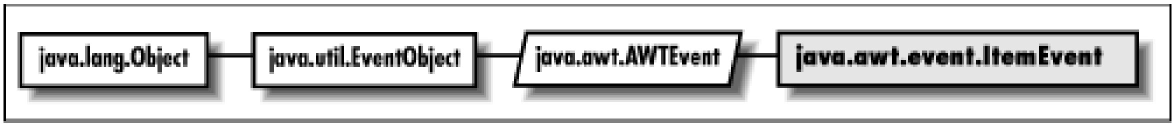
FocusListener ★ BOOK INDEX ItemEvent ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ItemEvent ★

Name

ItemEvent ★



Description

`ItemEvents` are generated by objects that implement the `ItemSelectable` interface. `Choice` is one example of such an object.

Class Definition

```
public class java.awt.event.ItemEvent
   extends java.awt.AWTEvent {
  // Constants
  public final static int DESELECTED;
  public final static int ITEM_FIRST;
  public final static int ITEM_LAST;
  public final static int ITEM_STATE_CHANGED;
  public final static int SELECTED;
  // Constructors
  public ItemEvent (ItemSelectable source, int id, Object item, int stateChange);

// Instance Methods
  public Object getItem();
  public ItemSelectable getItemSelectable();
  public int getStateChange();
  public String paramString();
}
```

Constants

DESELECTED

public final static int DESELECTED

Indicates that an item was deselected.

ITEM_FIRST

public final static int ITEM_FIRST

Specifies the beginning range of item event ID values.

ITEM_LAST

public final static int ITEM_LAST

Specifies the ending range of item event ID values.

ITEM_STATE_CHANGED

public final static int ITEM_STATE_CHANGED

An event type indicating that an item was selected or deselected.

SELECTED

public final static int SELECTED

Indicates that an item was selected.

Constructors

ItemEvent

public ItemEvent (ItemSelectable source, int id, Object item, int stateChange)

Parameters

source

The object that generated the event.

id

The type ID of the event.

item

The item whose state is changing.

stateChange

Either `SELECTED` or `DESELECTED`.

Description

Constructs an `ItemEvent` with the given characteristics.

Instance Methods

getItem

public Object getItem()

Returns

The item pertaining to this event.

Description

Returns the item whose changed state triggered this event.

getItemSelectable

public ItemSelectable getItemSelectable()

Returns

The source of this event.

Description

Returns an object that implements the `ItemSelectable` interface.

getStateChange

public int getStateChange()

Returns

The change in state that triggered this event. The new state is returned.

Description

This method will return SELECTED or DESELECTED.

paramString

public String paramString()

Returns

String with current settings of ItemEvent.

Overrides

AWTEvent.paramString()

Description

Helper method for toString() to generate string of current settings.

See Also

AWTEvent, ItemSelectable, ItemListener

ItemListener ★

Name

ItemListener ★

[Graphic: Figure from the text]

Description

Objects that implement the `ItemListener` interface can receive `ItemEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.ItemListener
   extends java.util.EventListener {
  // Interface Methods
  public abstract void itemStateChanged (ItemEvent e);
}
```

Interface Methods

itemStateChanged

public abstract void itemStateChanged (ItemEvent e)

Parameters

e

The item event that occurred.

Description

Notifies the `ItemListener` that an event occurred.

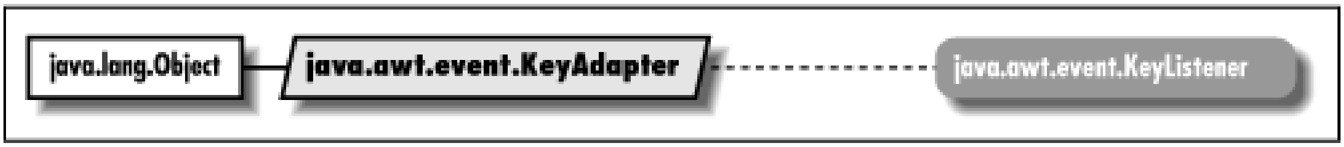
See Also

`AWTEventMultiCaster`, `EventListener`, `ItemEvent`

KeyAdapter ★

Name

KeyAdapter ★



Description

The `KeyAdapter` class implements the methods of `KeyListener` with empty functions. It may be easier for you to extend `KeyAdapter`, overriding only those methods you are interested in, than to implement `KeyListener` and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.KeyAdapter
   extends java.lang.Object
   implements java.awt.event.KeyListener {
  // Instance Methods
  public void keyPressed (KeyEvent e);
  public void keyReleased (KeyEvent e);
  public void keyTyped (KeyEvent e);
}
```

Instance Methods

keyPressed

public void keyPressed (KeyEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a key is pressed.

keyReleased

public void keyReleased (KeyEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a pressed key is released.

keyTyped

public void keyTyped (KeyEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a key has been pressed and released.

See Also

`KeyEvent`, `KeyListener`

KeyEvent ★

Name

KeyEvent ★

[Graphic: Figure from the text]

Description

Key events are generated when the user types on the keyboard.

Class Definition

```
public class java.awt.event.KeyEvent
   extends java.awt.event.InputEvent {
  // Constants
  public final static int CHAR_UNDEFINED;

  public void setModifiers (int modifiers);
}
```

Constants

CHAR_UNDEFINED

public final static int CHAR_UNDEFINED

This constant is used for key presses have that no associated character.

KEY_FIRST

public final static int KEY_FIRST

Specifies the beginning range of key event ID values.

KEY_LAST

public final static int KEY_LAST

Specifies the ending range of key event ID values.

KEY_PRESSED

public final static int KEY_PRESSED

An event ID type for a key press.

KEY_RELEASED

public final static int KEY_RELEASED

An event ID type for a key release.

KEY_TYPED

public final static int KEY_TYPED

An event ID type for a typed key (a press and a release).

VK_0

public final static int VK_0

The 0 key.

VK_1

public final static int VK_1

The 1 key.

VK_2

public final static int VK_2

The 2 key.

VK_3

public final static int VK_3

The 3 key.

VK_4

public final static int VK_4

The 4 key.

VK_5

public final static int VK_5

The 5 key.

VK_6

public final static int VK_6

The 6 key.

VK_7

public final static int VK_7

The 7 key.

VK_8

public final static int VK_8

The 8 key.

VK_9

public final static int VK_9

The 9 key.

VK_A

public final static int VK_A

The `a' key.

VK_ACCEPT

public final static int VK_ACCEPT

This constant is used for Asian keyboards.

VK_ADD

public final static int VK_ADD

The plus (+) key on the numeric keypad.

VK_ALT

public final static int VK_ALT

The Alt key.

VK_B

public final static int VK_B

The `b' key.

VK_BACK_QUOTE

public final static int VK_BACK_QUOTE

The backquote (`) key.

VK_BACK_SLASH

public final static int VK_BACK_SLASH

The backslash key.

VK_BACK_SPACE

public final static int VK_BACK_SPACE

The Backspace key.

VK_C

public final static int VK_C

The `c' key.

VK_CANCEL

public final static int VK_CANCEL

The Cancel key.

VK_CAPS_LOCK

public final static int VK_CAPS_LOCK

The Caps Lock key.

VK_CLEAR

public final static int VK_CLEAR

The Clear key.

VK_CLOSE_BRACKET

public final static int VK_CLOSE_BRACKET

The close bracket `]' key.

VK_COMMA

public final static int VK_COMMA

The comma (,) key.

VK_CONTROL

public final static int VK_CONTROL

The Control key.

VK_CONVERT

public final static int VK_CONVERT

This constant is used for Asian keyboards.

VK_D

public final static int VK_D

The `d' key.

VK_DECIMAL

public final static int VK_DECIMAL

The decimal (.) key on the numeric keypad.

VK_DELETE

public final static int VK_DELETE

The Delete key.

VK_DIVIDE

public final static int VK_DIVIDE

The divide (/) key on the numeric keypad.

VK_DOWN

public final static int VK_DOWN

The Down arrow key.

VK_E

public final static int VK_E

The `e' key.

VK_END

public final static int VK_END

The End key.

VK_ENTER

public final static int VK_ENTER

The Enter key.

VK_EQUALS

public final static int VK_ EQUALS

The equals (=) key.

VK_ESCAPE

public final static int VK_ESCAPE

The Escape key.

VK_F

public final static int VK_F

The `f' key.

VK_F1

public final static int VK_F1

The F1 key.

VK_F2

public final static int VK_F2

The F2 key.

VK_F3

public final static int VK_F3

The F3 key.

VK_F4

public final static int VK_F4

The F4 key.

VK_F5

public final static int VK_F5

The F5 key.

VK_F6

public final static int VK_F6

The F6 key.

VK_F7

public final static int VK_F7

The F7 key.

VK_F8

public final static int VK_F8

The F8 key.

VK_F9

public final static int VK_F9

The F9 key.

VK_F10

public final static int VK_F10

The F10 key.

VK_F11

public final static int VK_F11

The F11 key.

VK_F12

public final static int VK_F12

The F12 key.

VK_FINAL

public final static int VK_FINAL

This constant is used for Asian keyboards.

VK_G

public final static int VK_G

The `g' key.

VK_H

public final static int VK_H

The `h' key.

VK_HELP

public final static int VK_HELP

The Help key.

VK_HOME

public final static int VK_HOME

The Home key.

VK_I

public final static int VK_I

The `i' key.

VK_INSERT

public final static int VK_INSERT

The Insert key.

VK_J

public final static int VK_J

The `j' key.

VK_K

public final static int VK_K

The `k' key.

VK_KANA

public final static int VK_KANA

This constant is used for Asian keyboards.

VK_KANJI

public final static int VK_KANJI

This constant is used for Asian keyboards.

VK_L

public final static int VK_L

The `l' key.

VK_LEFT

public final static int VK_LEFT

The Left arrow key.

VK_M

public final static int VK_M

The `m' key.

VK_MODECHANGE

public final static int VK_MODECHANGE

This constant is used for Asian keyboards.

VK_META

public final static int VK_META

The Meta key.

VK_MULTIPLY

public final static int VK_MULTIPLY

The * key on the numeric keypad.

VK_N

public final static int VK_N

The `n' key.

VK_NONCONVERT

public final static int VK_NONCONVERT

This constant is used for Asian keyboards.

VK_NUM_LOCK

public final static int VK_NUM_LOCK

The Num Lock key.

VK_NUMPAD0

public final static int VK_NUMPAD0

The 0 key on the numeric keypad.

VK_NUMPAD1

public final static int VK_NUMPAD1

The 1 key on the numeric keypad.

VK_NUMPAD2

public final static int VK_NUMPAD2

The 2 key on the numeric keypad.

VK_NUMPAD3

public final static int VK_NUMPAD3

The 3 key on the numeric keypad.

VK_NUMPAD4

public final static int VK_NUMPAD4

The 4 key on the numeric keypad.

VK_NUMPAD5

public final static int VK_NUMPAD5

The 5 key on the numeric keypad.

VK_NUMPAD6

public final static int VK_NUMPAD6

The 6 key on the numeric keypad.

VK_NUMPAD7

public final static int VK_NUMPAD7

The 7 key on the numeric keypad.

VK_NUMPAD8

public final static int VK_NUMPAD8

The 8 key on the numeric keypad.

VK_NUMPAD9

public final static int VK_NUMPAD9

The 9 key on the numeric keypad.

VK_O

public final static int VK_O

The `o' key.

VK_OPEN_BRACKET

public final static int VK_OPEN_BRACKET

The open bracket `[` key.

VK_P

public final static int VK_P

The `p' key.

VK_PAGE_DOWN

public final static int VK_PAGE_DOWN

The Page Down key.

VK_PAGE_UP

public final static int VK_PAGE_UP

The Page Up key.

VK_PAUSE

public final static int VK_PAUSE

The Pause key.

VK_PERIOD

public final static int VK_PERIOD

The period (.) key.

VK_PRINTSCREEN

public final static int VK_PRINTSCREEN

The Print Screen key.

VK_Q

public final static int VK_Q

The `q' key.

VK_QUOTE

public final static int VK_QUOTE

The quotation mark (") key.

VK_R

public final static int VK_R

The `r' key.

VK_RIGHT

public final static int VK_RIGHT

The Right arrow key.

VK_S

public final static int VK_S

The `s' key.

VK_SCROLL_LOCK

public final static int VK_SCROLL_LOCK

The Scroll Lock key.

VK_SEMICOLON

public final static int VK_SEMICOLON

The semicolon (;) key.

VK_SEPARATER

public final static int VK_SEPARATER

The numeric separator key on the numeric keypad (i.e., the locale-dependent key used to separate groups of digits). A misspelling of VK_SEPARATOR.

VK_SHIFT

public final static int VK_SHIFT

The Shift key.

VK_SLASH

public final static int VK_SLASH

The slash (/) key.

VK_SPACE

public final static int VK_SPACE

The space key.

VK_SUBTRACT

public final static int VK_SUBTRACT

The subtract (-) key on the numeric keypad.

VK_T

public final static int VK_T

The `t' key.

VK_TAB

public final static int VK_TAB

The Tab key.

VK_U

public final static int VK_U

The `u' key.

VK_UNDEFINED

public final static int VK_UNDEFINED

An undefined key.

VK_UP

public final static int VK_UP

The Up arrow key.

VK_V

public final static int VK_V

The `v' key.

VK_W

public final static int VK_W

The `w' key.

VK_X

public final static int VK_X

The `x' key.

VK_Y

public final static int VK_Y

The `y' key.

VK_Z

public final static int VK_Z

The `z' key.

Constructors

KeyEvent

public KeyEvent (Component source, int id, long when, int modifiers, int keyCode, char keyChar)

Parameters

> *source*
>
> > The object that generated the event.

id

The event type ID of the event.

when

When the event occurred, in milliseconds from the epoch.

modifiers

What modifier keys were pressed with this key.

keyCode

The code of the key.

keyChar

The character for this key.

Description

Constructs a `KeyEvent` with the given characteristics.

Class Methods

getKeyModifiersText

public static String getKeyModifiersText(int modifiers)

Parameters

modifiers

One or more modifier keys.

Returns

A string describing the modifiers.

getKeyText

public static String getKeyText(int keyCode)

Parameters

keyCode

One of the key codes.

Returns

A string describing the given key.

Instance Methods

getKeyChar

public char getKeyChar()

Returns

The character corresponding to this event. KEY_TYPED events have characters.

getKeyCode

public int getKeyCode()

Returns

The integer key code corresponding to this event. This will be one of the constants defined above. KEY_PRESSED and KEY_RELEASED events have codes. Key codes are virtual keys, not actual. Pressing the `a' key is identical to `A', but has different modifiers. Same for `/' and `?' on a standard keyboard.

isActionKey

public boolean isActionKey()

Returns

`true` if this event is for one of the action keys; `false` otherwise.

Description

In general, an action key is a key that causes an action but has no printing equivalent. The action keys are the function keys, the arrow keys, Caps Lock, End, Home, Insert, Num Lock, Pause, Page Down, Page Up, Print Screen, and Scroll Lock. They do not generate a KEY_TYPED event, only KEY_PRESSED and KEY_RELEASED.

paramString

public String paramString()

Returns

A string with current settings of the `KeyEvent`.

Overrides

`ComponentEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

setKeyChar

public void setKeyChar(char keyChar)

Parameters

keyChar

The new key character.

Description

Sets the character code of this `KeyEvent`.

setKeyCode

public void setKeyCode (int keyCode)

Parameters

keyCode

The new key code.

Description

Sets the key code of this `KeyEvent`.

setModifiers

public void setModifiers (int modifiers)

Parameters

modifiers

The new modifiers.

Description

This is a combination of the mask constants defined in `java.awt.event.InputEvent`.

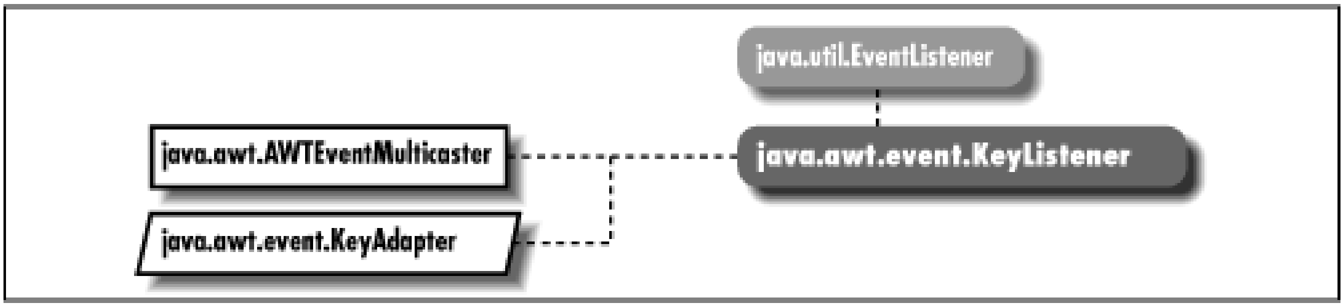
KeyListener ★

Name

KeyListener ★



java.util.EventListener
java.awt.AWTEventMulticaster
java.awt.event.KeyListener
java.awt.event.KeyAdapter

Description

Objects that implement the `KeyListener` interface can receive `KeyEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.KeyListener
   extends java.util.EventListener {
  // Instance Methods
  public abstract void keyPressed (KeyEvent e);
  public abstract void keyReleased (KeyEvent e);
  public abstract void keyTyped (KeyEvent e);
}
```

Interface Methods

keyPressed

public abstract void keyPressed (KeyEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `KeyListener` that a key was pressed.

keyReleased

public abstract void keyReleased (KeyEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `KeyListener` that a key was released.

keyTyped

public abstract void keyTyped (KeyEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `KeyListener` that a key was typed (pressed and released).

See Also

`AWTEventMulticaster`, `EventListener`, `KeyEvent`, `KeyListener`

MouseAdapter ★

Name

MouseAdapter ★

[Graphic: Figure from the text]

Description

The `MouseAdapter` class implements the methods of `MouseListener` with empty functions. It may be easier for you to extend `MouseAdapter`, overriding only those methods you are interested in, than to implement `MouseListener` and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.MouseAdapter
   extends java.lang.Object
   implements java.awt.event.MouseListener {
  // Instance Methods
  public void mouseClicked (MouseEvent e);
  public void mouseEntered (MouseEvent e);
  public void mouseExited (MouseEvent e);
  public void mousePressed (MouseEvent e);
  public void mouseReleased (MouseEvent e);
}
```

Instance Methods

mouseClicked

public void mouseClicked (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the mouse button is clicked (pressed and released).

mouseEntered

public void mouseEntered (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the user moves the mouse cursor into a component.

mouseExited

public void mouseExited (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the moves the mouse cursor out of a component.

mousePressed

public void mousePressed (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the mouse button is pressed.

mouseReleased

public void mouseReleased (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the mouse button is released.

  public synchronized Point getPoint();
  public int getX();
  public int getY();
  public boolean isPopupTrigger();
  public String paramString();
  public synchronized void translatePoint (int x, int y);
}
```

Constants

MOUSE_CLICKED

public final static int MOUSE_CLICKED

An event type ID indicating a mouse click.

MOUSE_DRAGGED

public final static int MOUSE_DRAGGED

An event type ID indicating a mouse move with the button held down.

MOUSE_ENTERED

public final static int MOUSE_ENTERED

An event type ID indicating that a mouse entered a component.

MOUSE_EXITED

public final static int MOUSE_EXITED

An event type ID indicating that a mouse left a component.

MOUSE_FIRST

public final static int MOUSE_FIRST

Specifies the beginning range of mouse event ID values.

MOUSE_LAST

public final static int MOUSE_LAST

Specifies the ending range of mouse event ID values.

MOUSE_MOVED

public final static int MOUSE_MOVED

An event type ID indicating a mouse move.

MOUSE_PRESSED

public final static int MOUSE_PRESSED

An event type ID indicating a mouse button press.

MOUSE_RELEASED

public final static int MOUSE_RELEASED

An event type ID indicating a mouse button release.

Constructors

MouseEvent

public MouseEvent (Component source, int id, long when, int modifiers, int x, int y, int clickCount, boolean popupTrigger)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

when

When the event occurred, in milliseconds from the epoch.

modifiers

What modifier keys were pressed with this key.

x

The horizontal location of the event.

y

The vertical location of the event.

clickCount

The number of times the mouse button has been clicked.

popupTrigger

A flag indicating if this event is a popup trigger event.

Description

Constructs a `MouseEvent` with the given characteristics.

Instance Methods

getClickCount

public int getClickCount()

Returns

The number of consecutive mouse button clicks for this event.

getPoint

public synchronized Point getPoint()

Returns

The location where the event happened.

getX

public int getX()

Returns

The horizontal location where the event happened.

getY

public int getY()

Returns

The vertical location where the event happened.

isPopupTrigger

public boolean isPopupTrigger()

Returns

Returns `true` if this event is the popup menu event for the run-time system.

paramString

public String paramString()

Returns

String with current settings of the `MouseEvent`.

Overrides

`ComponentEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

translatePoint

public synchronized void translatePoint (int x, int y)

Parameters

x

The horizontal amount of translation.

y

The vertical amount of translation.

Description

Translates the location of the event by the given amounts.

MouseAdapter ★ | BOOK INDEX | MouseListener ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

MouseListener ★

Name

MouseListener ★

[Graphic: Figure from the text]

Description

Objects that implement the `MouseListener` interface can receive non-motion oriented `MouseEvent` objects. Listeners must first register themselves with objects that produce events. When events occur, they are then automatically propagated to all registered listeners.

Interface Definition

```
public abstract interface java.awt.event.MouseListener
   extends java.util.EventListener {
  // Instance Methods
  public abstract void mouseClicked (MouseEvent e);
  public abstract void mouseEntered (MouseEvent e);
  public abstract void mouseExited (MouseEvent e);
  public abstract void mousePressed (MouseEvent e);
  public abstract void mouseReleased (MouseEvent e);
}
```

Interface Methods

mouseClicked

public abstract void mouseClicked (MouseEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `MouseListener` that the mouse button was clicked (pressed and released).

mouseEntered

public abstract void mouseEntered (MouseEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `MouseListener` that the mouse cursor has been moved into a component's coordinate space.

mouseExited

public abstract void mouseExited (MouseEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `MouseListener` that the mouse cursor has been moved out of a component's coordinate space.

mousePressed

public abstract void mousePressed (MouseEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `MouseListener` that the mouse button was pressed.

mouseReleased

public abstract void mouseReleased (MouseEvent e)

Parameters

e

The key event that occurred.

Description

Notifies the `MouseListener` that the mouse button was released.

Description

The `MouseMotionAdapter` class implements the methods of `MouseMotionListener` with empty functions. It may be easier for you to extend `MouseMotionAdapter`, overriding only those methods you are interested in, than to implement `MouseMotionListener` and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.MouseMotionAdapter
   extends java.lang.Object
   implements java.awt.event.MouseMotionListener {
  // Instance Methods
  public void mouseDragged (MouseEvent e);
  public void mouseMoved (MouseEvent e);
}
```

Instance Methods

mouseDragged

public void mouseDragged (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the mouse is dragged.

mouseMoved

public void mouseEntered (MouseEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when the mouse moves.

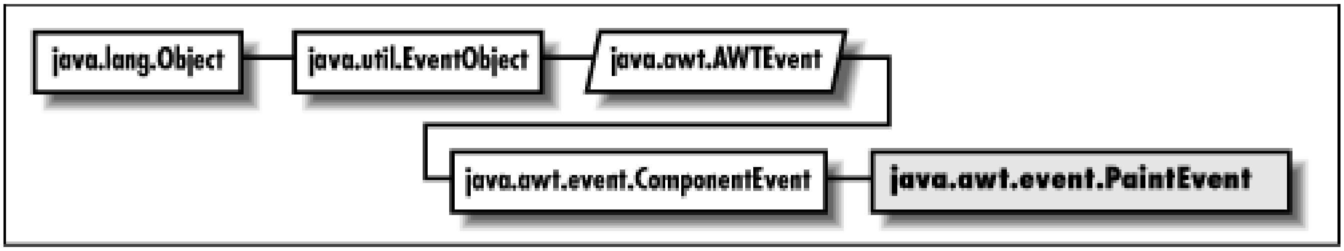
MouseMotionAdapter ★ | BOOK INDEX | PaintEvent ★

PaintEvent ★

Name

PaintEvent ★



Description

The `PaintEvent` class represents the paint and update operations that the AWT performs on components. There is no `PaintListener` interface, so the only way to catch these events is to override `paint(Graphics)` and `update(Graphics)` in `Component`. This class exists so that paint events will get serialized properly.

Class Definition

```
public class java.awt.event.PaintEvent
   extends java.awt.event.ComponentEvent {
  // Constants
  public final static int PAINT;
  public final static int PAINT_FIRST;
  public final static int PAINT_LAST;
  public final static int UPDATE;
  // Constructor
  public PaintEvent (Component source, int id, Rectangle updateRect);
  // Instance Methods
  public Rectangle getUpdateRect();
  public String paramString();
  public void setUpdateRect (Rectangle updateRect);
}
```

Class Definition

```
public class java.awt.event.PaintEvent
        extends java.awt.event.ComponentEvent {
  // Constants
  public final static int PAINT;
  public final static int PAINT_FIRST;
  public final static int PAINT_LAST;
  public final static int UPDATE;
  //Constructor
  public PaintEvent (Component source, int id, Rectangle updateRect);
  // Instance Methods
  public Rectangle getUpdateRect();
  public String paramString();
  public void setUpdateRect (Rectangle updateRect);
}
```

Constants

PAINT

public final static int PAINT

The paint event type.

PAINT_FIRST

public final static int PAINT_FIRST

Specifies the beginning range of paint event ID values.

PAINT_LAST

public final static int PAINT_LAST

Specifies the ending range of paint event ID values.

UPDATE

public final static int UPDATE

The update event type.

Constructor

PaintEvent

public PaintEvent (Component source, ind id, Rectangle updateRect)

Parameters

> *source*
>
> > The source of the event.
>
> *id*
>
> > The event type ID.
>
> *g*
>
> > The rectangular area to paint.

Description

> Constructs a `PaintEvent` with the given characteristics.

Instance Methods

getUpdateRect

public Rectangle getUpdateRect()

Returns

> The rectangular area that needs painting.

paramString

public String paramString()

Returns

> String with current settings of the `PaintEvent`.

Overrides

> `ComponentEvent.paramString()`

Description

> Helper method for `toString()` to generate string of current settings.

setUpdateRect

public void setUpdateRect (Rectangle updateRect)

Parameters

> *updateRect*
>
> > The rectangular area to paint.

Description

> Changes the rectangular area that this `PaintEvent` will paint.

MouseMotionListener ★ BOOK INDEX TextEvent ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

TextEvent ★

Name

TextEvent ★

[Graphic: Figure from the text]

Description

Text events are generated by text components when their contents change, either programmatically or by a user typing.

Class Definition

```
public class java.awt.event.TextEvent
   extends java.awt.AWTEvent {
  // Constants
  public final static int TEXT_FIRST;
  public final static int TEXT_LAST;
  public final static int TEXT_VALUE_CHANGED;
  // Constructors
  public TextEvent (Object source, int id);
  // Instance Methods
  public String paramString();
}
```

Constants

TEXT_FIRST

public final static int TEXT_FIRST

Specifies the beginning range of text event ID values.

TEXT_LAST

public final static int TEXT_LAST

Specifies the ending range of text event ID values.

TEXT_VALUE_CHANGED

public final static int TEXT_VALUE_CHANGED

The only text event type; it indicates that the contents of something have changed.

Constructors

TextEvent

public TextEvent (Object source, int id)

Parameters

source

The object that generated the event.

id

The type ID of the event.

Description

Constructs a `TextEvent` with the given characteristics.

Instance Methods

paramString

public String paramString()

Returns

String with current settings of the `TextEvent`.

Overrides

`AWTEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

See Also

`AWTEvent`, `TextListener`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

WindowAdapter ★

Name

WindowAdapter ★

[Graphic: Figure from the text]

Description

The `WindowAdapter` class implements the methods of `WindowListener` with empty functions. It may be easier for you to extend `WindowAdapter`, overriding only those methods you are interested in, than to implement `WindowListener` and provide the empty functions yourself.

Class Definition

```
public abstract class java.awt.event.WindowAdapter
   extends java.lang.Object
   implements java.awt.event.WindowListener {
  // Instance Methods
  public void windowActivated (WindowEvent e);
  public void windowClosed (WindowEvent e);
  public void windowClosing (WindowEvent e);
  public void windowDeactivated (WindowEvent e);
  public void windowDeiconified (WindowEvent e);
  public void windowIconified (WindowEvent e);
  public void windowOpened (WindowEvent e);
}
```

Instance Methods

windowActivated

public void windowActivated (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a window is activated.

windowClosed

public void windowClosed (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a window is closed.

windowClosing

public void windowClosing (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a window is in the process of closing.

windowDeactivated

public void windowDeactivated (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a window is deactivated.

windowDeiconified

public void windowDeiconified (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when an iconified window is restored.

windowIconified

public void windowIconified (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a window is iconified (minimized).

windowOpened

public void windowOpened (WindowEvent e)

Parameters

e

The event that has occurred.

Description

Does nothing. Override this function to be notified when a window is opened.

  public final static int WINDOW_OPENED;
  // Constructors
  public WindowEvent (Window source, int id);
  // Instance Methods
  public Window getWindow();
  public String paramString();
}
```

Constants

WINDOW_ACTIVATED

public final static int WINDOW_ACTIVATED

Event type ID indicating the window has been activated, brought to the foreground.

WINDOW_CLOSED

public final static int WINDOW_CLOSED

Event type ID indicating the window has closed.

WINDOW_CLOSING

public final static int WINDOW_CLOSING

Event type ID indicating the window is closing.

WINDOW_DEACTIVATED

public final static int WINDOW_DEACTIVATED

Event type ID indicating the window has been deactivated, placed in the background.

WINDOW_DEICONIFIED

public final static int WINDOW_DEICONIFIED

Event type ID indicating the window has been restored from an iconified state.

WINDOW_FIRST

public final static int WINDOW_FIRST

Specifies the beginning range of window event ID values.

WINDOW_ICONIFIED

public final static int WINDOW_ICONIFIED

Event type ID indicating the window has been iconified (minimized).

WINDOW_LAST

public final static int WINDOW_LAST

Specifies the ending range of window event ID values.

WINDOW_OPENED

public final static int WINDOW_OPENED

Event type ID indicating the window has opened.

Constructors

WindowEvent

public WindowEvent (Window source, int id)

Parameters

source

The object that generated the event.

id

The event type ID of the event.

Description

Constructs a `WindowEvent` with the given characteristics.

Instance Methods

getWindow

public Window getWindow()

Returns

The window that generated this event.

paramString

public String paramString()

Returns

String with current settings of the `WindowEvent`.

Overrides

`ComponentEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

  public abstract void windowClosed (WindowEvent e);
  public abstract void windowClosing (WindowEvent e);
  public abstract void windowDeactivated (WindowEvent e);
  public abstract void windowDeiconified (WindowEvent e);
  public abstract void windowIconified (WindowEvent e);
  public abstract void windowOpened (WindowEvent e);
}
```

Interface Methods

windowActivated

public abstract void windowActivated (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window has been activated.

windowClosed

public abstract void windowClosed (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window has closed.

windowClosing

public abstract void windowClosing (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window is closing.

windowDeactivated

public abstract void windowDeactivated (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window has been deactivated.

windowDeiconified

public abstract void windowDeiconified (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window has been restored from an iconified state.

windowIconified

public abstract void windowIconified (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window has iconified (minimized).

windowOpened

public abstract void windowOpened (WindowEvent e)

Parameters

e

The event that occurred.

Description

Notifies the `WindowListener` that a window has opened.

ColorModel

Name

ColorModel

[Graphic: Figure from the text]

Description

The abstract `ColorModel` class defines the way a Java program represents colors. It provides methods for extracting different color components from a pixel.

Class Definition

```
public class java.awt.image.ColorModel
    extends java.lang.Object {
  // Variables
  protected int pixel_bits;
  // Constructors
  public ColorModel (int bits);
  // Class Methods
  public static ColorModel getRGBdefault();
  // Instance Methods
  public void finalize(); ★
  public abstract int getAlpha (int pixel);
  public abstract int getBlue (int pixel);
  public abstract int getGreen (int pixel);
  public int getPixelSize();
  public abstract int getRed (int pixel);
  public int getRGB (int pixel);
}
```

ProtectedVariables

pixel_bits

protected int pixel_bits

The `pixel_bits` variable saves the ColorModel's `bits` setting (the total number of bits per pixel).

Constructors

ColorModel

public ColorModel (int bits)

Parameters

bits

The number of bits required per pixel using this model.

Description

Constructs a `ColorModel` object.

Class Methods

getRGBdefault

public static ColorModel getRGBdefault()

Returns

> The default `ColorModel` format, which uses 8 bits for each of a pixel's color components: alpha (transparency), red, green, and blue.

Instance Methods

finalize

public void finalize() ★

Overrides

> `Object.finalize()`

Description

> Cleans up when this object is garbage collected.

getAlpha

public abstract int getAlpha (int pixel)

Parameters

> *pixel*
>
> > A pixel encoded with this `ColorModel`.

Returns

> The current alpha setting of the pixel.

getBlue

public abstract int getBlue (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current blue setting of the pixel.

getGreen

public abstract int getGreen (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current green setting of the pixel.

getPixelSize

public int getPixelSize()

Returns

The current pixel size for the color model.

getRed

public abstract int getRed (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current red setting of the pixel.

getRGB

public int getRGB (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current combined red, green, and blue settings of the pixel.

Description

Gets the color of `pixel` in the default RGB color model.

See Also

`DirectColorModel`, `IndexColorModel`, `Object`

CropImageFilter

Name

CropImageFilter

[Graphic: Figure from the text]

Description

The `CropImageFilter` class creates a smaller image by cropping (i.e., extracting a rectangular region from) a larger image.

Class Definition

```
public class java.awt.image.CropImageFilter
    extends java.awt.image.ImageFilter {
  // Constructors
  public CropImageFilter (int x, int y, int width, int height);
  // Instance Methods
  public void setDimensions (int width, int height);
  public void setPixels (int x, int y, int width, int height, ColorModel model,
    byte[] pixels, int offset, int scansize);
  public void setPixels (int x, int y, int width, int height, ColorModel model,
    int[] pixels, int offset, int scansize);
  public void setProperties (Hashtable properties);
}
```

Constructors

CropImageFilter

public CropImageFilter (int x, int y, int width, int height)

Parameters

x

x-coordinate of top-left corner of piece to crop.

y

y-coordinate of top-left corner of piece to crop.

width

Width of image to crop.

height

Height of image to crop.

Description

Constructs a `CropImageFilter` that crops the specified region from the original image.

Instance Methods

setDimensions

public void setDimensions (int width, int height)

Parameters

width

Ignored parameter.

height

Ignored parameter.

Overrides

`ImageFilter.setDimensions(int, int)`

Description

Called with the original image's dimensions; these dimensions are ignored. The method in turn calls the `ImageConsumer` with the dimensions of the cropped image.

setPixels

public void setPixels (int x, int y, int width, int height, ColorModel model, byte[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ImageFilter.setPixels(int, int, int, int, ColorModel, byte[], int, int)`

Description

Receives a rectangle of image data from the `ImageProducer`; crops these pixels and delivers them to any `ImageConsumer`s.

public void setPixels (int x, int y, int width, int height, ColorModel model, int[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

ImageFilter.setPixels(int, int, int, int, ColorModel, int[], int, int)

Description

Receives a rectangle of image data from the ImageProducer; crops these pixels and delivers them to any ImageConsumers.

setProperties

public void setProperties (Hashtable properties)

Parameters

properties

The properties for the image.

Overrides

ImageFilter.setProperties(Hashtable)

Description

Adds the "croprect" image property to the properties list.

DirectColorModel

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

DirectColorModel

Name

DirectColorModel

[Graphic: Figure from the text]

Description

The `DirectColorModel` class provides a `ColorModel` that specifies a translation between pixels and alpha, red, green, and blue component values, where the color values are embedded directly within the pixel.

Class Definition

```
public class java.awt.image.DirectColorModel
    extends java.awt.image.ColorModel {
  // Constructors
  public DirectColorModel (int bits, int redMask, int greenMask,
    int blueMask);
  public DirectColorModel (int bits, int redMask, int greenMask,
    int blueMask,
    int alphaMask);
  // Instance Methods
  public final int getAlpha (int pixel);
  public final int getAlphaMask();
  public final int getBlue (int pixel);
  public final int getBlueMask();
  public final int getGreen (int pixel);
  public final int getGreenMask()
  public final int getRed (int pixel);
  public final int getRedMask();
  public final int getRGB (int pixel);
}
```

Constructors

DirectColorModel

public DirectColorModel (int bits, int redMask, int greenMask, int blueMask)

Parameters

bits

The number of bits required per pixel of an image using this model.

redMask

The location of the red component of a pixel.

greenMask

The location of the green component of a pixel.

blueMask

The location of the blue component of a pixel.

Throws

`IllegalArgumentException`

If the mask bits are not contiguous or overlap.

Description

Constructs a `DirectColorModel` object with the given size and color masks; the alpha (transparency) component is not used.

public DirectColorModel (int bits, int redMask, int greenMask, int blueMask, int alphaMask)

Parameters

bits

The number of bits required per pixel of an image using this model.

redMask

The location of the red component of a pixel.

greenMask

The location of the green component of a pixel.

blueMask

The location of the blue component of a pixel.

alphaMask

The location of the alpha component of a pixel.

Throws

`IllegalArgumentException`

If the mask bits are not contiguous or overlap.

Description

Constructs a `DirectColorModel` object with the given size and color masks.

Instance Methods

getAlpha

public final int getAlpha (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current alpha setting of the pixel.

Overrides

`ColorModel.getAlpha(int)`

getAlphaMask

public final int getAlphaMask()

Returns

The current alpha mask setting of the color model.

getBlue

public final int getBlue (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current blue setting of the pixel.

Overrides

`ColorModel.getBlue(int)`

getBlueMask

public final int getBlueMask()

Returns

The current blue mask setting of the color model.

getGreen

public final int getGreen (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current green setting of the pixel.

Overrides

`ColorModel.getGreen(int)`

getGreenMask

public final int getGreenMask()

Returns

The current green mask setting of the color model.

getRed

public final int getRed (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current red setting of the pixel.

Overrides

`ColorModel.getRed(int)`

getRedMask

public final int getRedMask()

Returns

The current red mask setting of the color model.

getRGB

public final int getRGB (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current combined red, green, and blue settings of the pixel.

Overrides

`ColorModel.getRGB(int)`

Description

Gets the color of `pixel` in the default RGB color model.

See Also

`ColorModel`

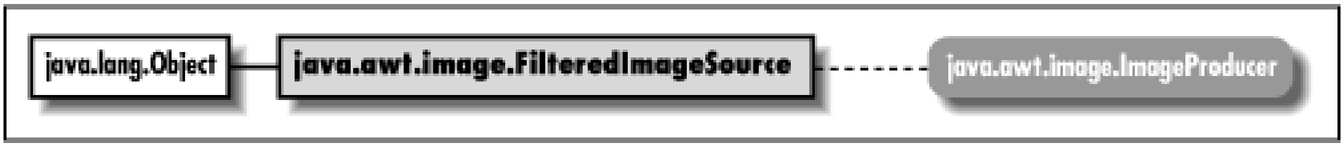
CropImageFilter | BOOK INDEX | FilteredImageSource

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FilteredImageSource

Name

FilteredImageSource



java.lang.Object
java.awt.image.FilteredImageSource
java.awt.image.ImageProducer

Description

The `FilteredImageSource` class acts as glue to put an original `ImageProducer` and `ImageFilter` together to create a new image. As the `ImageProducer` for the new image, `FilteredImageSource` is responsible for registering image consumers for the new image.

Class Definition

```
public class java.awt.image.FilteredImageSource
    extends java.lang.Object
    implements java.awt.image.ImageProducer {
  // Constructors
  public FilteredImageSource (ImageProducer original,
      ImageFilter filter);
  // Instance Methods
  public synchronized void addConsumer (ImageConsumer ic);
  public synchronized boolean isConsumer (ImageConsumer ic);
  public synchronized void removeConsumer (ImageConsumer ic);
  public void requestTopDownLeftRightResend (ImageConsumer ic);
  public void startProduction (ImageConsumer ic);
}
```

Constructors

FilteredImageSource

public FilteredImageSource (ImageProducer original, ImageFilter filter)

Parameters

original

An `ImageProducer` that generates the image to be filtered.

filter

The `ImageFilter` to use to process image data delivered by `original`.

Description

Constructs a `FilteredImageSource` object to filter an image generated by an `ImageProducer`.

Class Methods

addConsumer

public synchronized void addConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` interested in receiving the new image.

Implements

`ImageProducer.addConsumer(ImageConsumer)`

Description

Registers an `ImageConsumer` as interested in `Image` information.

isConsumer

public synchronized boolean isConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to check.

Returns

`true` if `ImageConsumer` is registered with this `ImageProducer`, `false` otherwise.

Implements

`ImageProducer.isConsumer(ImageConsumer)`

removeConsumer

public synchronized void removeConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to remove.

Implements

`ImageProducer.removeConsumer(ImageConsumer)`

Description

Removes an `ImageConsumer` from the registered consumers for this `ImageProducer`.

requestTopDownLeftRightResend

public void requestTopDownLeftRightResend (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to communicate with.

Implements

`ImageProducer.requestTopDownLeftRightResend()`

Description

Requests the retransmission of the `Image` data in top-down, left-to-right order.

startProduction

public void startProduction (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to communicate with.

Implements

`ImageProducer.startProduction(ImageConsumer)`

Description

Registers `ImageConsumer` as interested in `Image` information and tells `ImageProducer` to start creating the filtered `Image` data immediately.

See Also

`ImageFilter`, `ImageConsumer`, `ImageProducer`, `Object`

ImageConsumer

Name

ImageConsumer

[Graphic: Figure from the text]

Description

`ImageConsumer` is an interface that provides the means to consume pixel data and render it for display.

Interface Definition

```
public abstract interface java.awt.image.ImageConsumer {
  // Constants
  public final static int COMPLETESCANLINES;
  public final static int IMAGEABORTED;
  public final static int IMAGEERROR;
  public final static int RANDOMPIXELORDER;
  public final static int SINGLEFRAME;
  public final static int SINGLEFRAMEDONE;
  public final static int SINGLEPASS;
  public final static int STATICIMAGEDONE;
  public final static int TOPDOWNLEFTRIGHT;
  // Interface Methods
  public abstract void imageComplete (int status);
  public abstract void setColorModel (ColorModel model);
  public abstract void setDimensions (int width, int height);
  public abstract void setHints (int hints);
  public abstract void setPixels (int x, int y, int width, int height,
      ColorModel model, byte[] pixels, int offset, int scansize);
  public abstract void setPixels (int x, int y, int width, int height,
      ColorModel model, int[] pixels, int offset, int scansize);
  public abstract void setProperties (Hashtable properties);
}
```

Constants

COMPLETESCANLINES

public final static int COMPLETESCANLINES

Hint flag for the `setHints(int)` method; indicates that the image will be delivered one or more scanlines at a time.

IMAGEABORTED

public final static int IMAGEABORTED

Status flag for the `imageComplete(int)` method indicating that the loading process for the image aborted.

IMAGEERROR

public final static int IMAGEERROR

Status flag for the `imageComplete(int)` method indicating that an error happened during image loading.

RANDOMPIXELORDER

public final static int RANDOMPIXELORDER

Hint flag for the `setHints(int)` method; indicates that the pixels will be delivered in no particular order.

SINGLEFRAME

public final static int SINGLEFRAME

Hint flag for the `setHints(int)` method; indicates that the image consists of a single frame.

SINGLEFRAMEDONE

public final static int SINGLEFRAMEDONE

Status flag for the `imageComplete(int)` method indicating a single frame of the image has loaded.

SINGLEPASS

public final static int SINGLEPASS

Hint flag for the `setHints(int)` method; indicates that each pixel will be delivered once (i.e., the producer will not make multiple passes over the image).

STATICIMAGEDONE

public final static int STATICIMAGEDONE

Status flag for the `imageComplete(int)` method indicating that the image has fully and successfully loaded, and that there are no additional frames.

TOPDOWNLEFTRIGHT

public final static int TOPDOWNLEFTRIGHT

Hint flag for the `setHints(int)` method; indicates that pixels will be delivered in a top to bottom, left to right order.

Interface Methods

imageComplete

public abstract void imageComplete (int status)

Parameters

status

Image loading status flags.

Description

Called when the image, or a frame of an image sequence, is complete to report the completion status.

setColorModel

public abstract void setColorModel (ColorModel model)

Parameters

model

The color model for the image.

Description

Tells the `ImageConsumer` the color model used for most of the pixels in the image.

setDimensions

public abstract void setDimensions (int width, int height)

Parameters

width

Width for image.

height

Height for image.

Description

Tells the consumer the image's dimensions.

setHints

public abstract void setHints (int hints)

Parameters

hints

Image consumption hints.

Description

Gives the consumer information about how pixels will be delivered.

setPixels

public abstract void setPixels (int x, int y, int width, int height, ColorModel model, byte[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Description

Delivers a rectangular block of pixels to the image consumer.

public abstract void setPixels (int x, int y, int width, int height, ColorModel model, int[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Description

Delivers a rectangular block of pixels to the image consumer.

setProperties

public abstract void setProperties (Hashtable properties)

Parameters

properties

The properties for the image.

Description

Delivers a Hashtable that contains the image's properties.

See Also

`ColorModel`, `Hashtable`, `ImageFilter`, `PixelGrabber`, `Object`

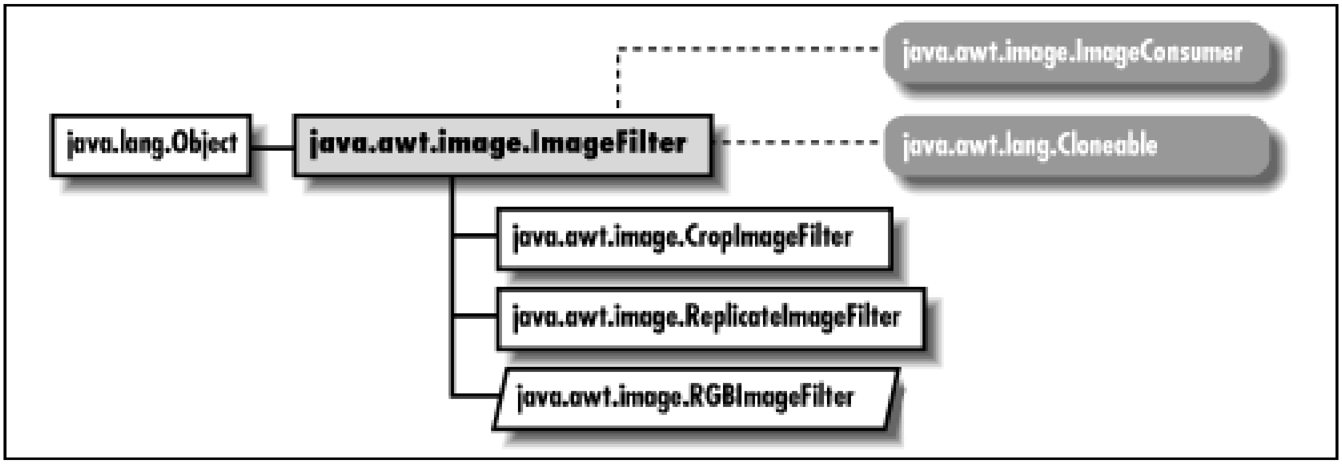
FilteredImageSource BOOK INDEX ImageFilter

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ImageFilter

Name

ImageFilter



java.awt.image.ImageConsumer
java.lang.Object
java.awt.image.ImageFilter
java.awt.lang.Cloneable
java.awt.image.CropImageFilter
java.awt.image.ReplicateImageFilter
java.awt.image.RGBImageFilter

Description

The `ImageFilter` class sits between the `ImageProducer` and `ImageConsumer` as an image is being created to provide a filtered version of that image. Image filters are always used in conjunction with a `FilteredImageSource`. As an implementer of the `ImageConsumer` interface, an image filter receives pixel data from the original image's source and delivers it to another image consumer. The `ImageFilter` class implements a null filter (i.e., the new image is the same as the original); to produce a filter that modifies an image, create a subclass of `ImageFilter`.

Class Definition

```
public class java.awt.image.ImageFilter
    extends java.lang.Object
    implements java.awt.image.ImageConsumer, java.lang.Cloneable {
  // Variables
  protected ImageConsumer consumer;
  // Constructors
  public ImageFilter();
  // Instance Methods
  public Object clone();
  public ImageFilter getFilterInstance (ImageConsumer ic);
  public void imageComplete (int status);
  public void resendTopDownLeftRight (ImageProducer ip);
  public void setColorModel (ColorModel model);
  public void setDimensions (int width, int height);
  public void setHints (int hints);
  public void setPixels (int x, int y, int width, int height,
      ColorModel model, byte[] pixels, int offset, int scansize);
  public void setPixels (int x, int y, int width, int height,
      ColorModel model, int[] pixels, int offset, int scansize);
  public void setProperties (Hashtable properties);
}
```

Protected Variables

consumer

protected ImageConsumer consumer

The consumer variable is a reference to the actual `ImageConsumer` for the `Image`.

Constructors

ImageFilter

public ImageFilter()

Description

> Constructs an empty `ImageFilter` instance.

Instance Methods

clone

public Object clone()

Overrides

`Object.clone()`

Returns

A copy of the `ImageFilter` instance.

getFilterInstance

public ImageFilter getFilterInstance (ImageConsumer ic)

Parameters

ic

The consumer in question.

Returns

A copy of the `ImageFilter` instance.

Description

Returns the filter that will do the filtering for `ic`.

imageComplete

void imageComplete (int status)

Parameters

status

Image loading completion status flags.

Implements

`ImageConsumer.imageComplete(int)`

Description

Called by the `ImageProducer` to indicate an image's completion status. `ImageFilter` passes these flags to the consumer unchanged.

resendTopDownLeftRight

public void resendTopDownLeftRight (ImageProducer ip)

Parameters

ip

The `ImageProducer` generating the original image.

Description

Called by the `ImageConsumer` to ask the filter to resend the image data in the top-down, left-to-right order. In `ImageFilter`, this method calls the same method in the `ImageProducer`, thus relaying the request.

setColorModel

void setColorModel (ColorModel model)

Parameters

model

The color model for the image.

Implements

`ImageConsumer.setColorModel(ColorModel)`

Description

Sets the image's color model.

setDimensions

void setDimensions (int width, int height)

Parameters

width

Width for image.

height

Height for image.

Implements

```
ImageConsumer.setDimensions(int, int)
```

Description

Sets the image's dimensions.

setHints

void setHints (int hints)

Parameters

hints

Image consumption hints.

Implements

```
ImageConsumer.setHints(int)
```

Description

Called by the `ImageProducer` to deliver hints about how the image data will be delivered. `ImageFilter` passes these hints on to the `ImageConsumer`.

setPixels

void setPixels (int x, int y, int width, int height, ColorModel model, byte[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Implements

`ImageConsumer.setPixels(int, int, int, int, ColorModel, byte[], int, int)`

Description

Delivers a rectangular block of pixels to the `ImageFilter`. `ImageFilter` passes these pixels on to the consumer unchanged.

void setPixels (int x, int y, int width, int height, ColorModel model, int[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Implements

`ImageConsumer.setPixels(int, int, int, int, ColorModel, int[], int, int)`

Description

Delivers a rectangular block of pixels to the `ImageFilter`. `ImageFilter` passes these pixels on to the consumer unchanged.

setProperties

void setProperties (Hashtable properties)

Parameters

properties

The properties for the image.

Implements

`ImageConsumer.setProperties(Hashtable)`

Description

Initializes the image's properties. `ImageFilter` adds the property "filter" to the `Hashtable`, and passes the result on to the image consumer; the value of the property is the string returned by the filter's `toString()` method. If the property "filter" is already in the `Hashtable`, `ImageFilter` adds the string returned by its `toString()` method to the value already associated with that property.

See Also

`Cloneable`, `ColorModel`, `CropImageFilter`, `Hashtable`, `ImageConsumer`, `ImageProducer`, `Object`, `ReplicateImageFilter`, `RGBImageFilter`

ImageObserver

Name

ImageObserver

[Graphic: Figure from the text]

Description

`ImageObserver` is an interface that provides constants and the callback mechanism to receive asynchronous information about the status of an image as it loads.

Interface Definition

```
public abstract interface java.awt.image.ImageObserver {
  // Constants
  public static final int ABORT;
  public static final int ALLBITS;
  public static final int ERROR;
  public static final int FRAMEBITS;
  public static final int HEIGHT;
  public static final int PROPERTIES;
  public static final int SOMEBITS;
  public static final int WIDTH;
  // Interface Methods
  public abstract boolean imageUpdate (Image image, int infoflags,
     int x, int y, int width, int height);
}
```

Constants

ABORT

public static final int ABORT

The ABORT flag indicates that the image aborted during loading. An attempt to reload the image may succeed, unless ERROR is also set.

ALLBITS

public static final int ALLBITS

The ALLBITS flag indicates that the image has completely loaded successfully. The x, y, width, and height arguments to imageUpdate() should be ignored.

ERROR

public static final int ERROR

The ERROR flag indicates that an error happened during the image loading process. An attempt to reload the image will fail.

FRAMEBITS

public static final int FRAMEBITS

The FRAMEBITS flag indicates that a complete frame of a multi-frame image has loaded. The x, y, width, and height arguments to imageUpdate() should be ignored.

HEIGHT

public static final int HEIGHT

The HEIGHT flag indicates that the height information is available for an image; the image's height is in the height argument to imageUpdate().

PROPERTIES

public static final int PROPERTIES

The `PROPERTIES` flag indicates that the properties information is available for an image.

SOMEBITS

public static final int SOMEBITS

The `SOMEBITS` flag indicates that the image has started loading and some pixels are available. The bounding rectangle for the pixels that have been delivered so far is indicated by the `x`, `y`, `width`, and `height` arguments to `imageUpdate()`.

WIDTH

public static final int WIDTH

The `WIDTH` flag indicates that the width information is available for an image; the image's width is in the `width` argument to `imageUpdate()`.

Interface Methods

imageUpdate

public abstract boolean imageUpdate (Image image, int infoflags, int x, int y, int width, int height)

Parameters

image

Image that is being loaded.

infoflags

The `ImageObserver` flags for the information that is currently available.

x

Meaning depends on `infoflags` that are set.

y

Meaning depends on `infoflags` that are set.

width

Meaning depends on `infoflags` that are set.

height

Meaning depends on `infoflags` that are set.

Returns

`true` if image has completed loading (successfully or unsuccessfully), `false` if additional information needs to be loaded.

Description

Provides the callback mechanism for the asynchronous loading of images.

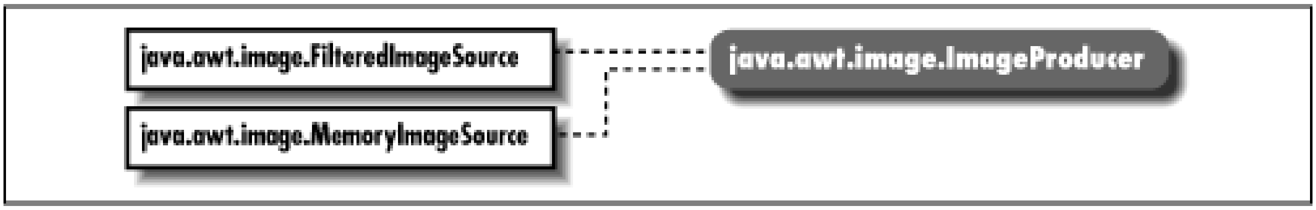
ImageFilter BOOK INDEX ImageProducer

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ImageProducer

Name

ImageProducer



java.awt.image.FilteredImageSource
java.awt.image.MemoryImageSource
java.awt.image.ImageProducer

Description

`ImageProducer` is an interface that provides the methods necessary for the production of images and the communication with classes that implement the `ImageConsumer` interface.

Interface Definition

```
public abstract interface java.awt.image.ImageProducer {
  // Interface Methods
  public abstract void addConsumer (ImageConsumer ic);
  public abstract boolean isConsumer (ImageConsumer ic);
  public abstract void removeConsumer (ImageConsumer ic);
  public abstract void requestTopDownLeftRightResend (ImageConsumer ic);
  public abstract void startProduction (ImageConsumer ic);
}
```

Interface Methods

addConsumer

public abstract void addConsumer (ImageConsumer ic)

Parameters

ic

An `ImageConsumer` that wants to receive image data.

Description

Registers an `ImageConsumer` as interested in image information.

isConsumer

public abstract boolean isConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to check.

Returns

`true` if `ImageConsumer` has registered with the `ImageProducer`, `false` otherwise.

removeConsumer

public abstract void removeConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to remove.

Description

Removes an `ImageConsumer` from registered consumers for this `ImageProducer`.

requestTopDownLeftRightResend

public abstract void requestTopDownLeftRightResend (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to communicate with.

Description

Requests the retransmission of the image data in top-down, left-to-right order.

startProduction

public abstract void startProduction (ImageConsumer ic)

Parameters

ic

ImageConsumer to communicate with.

Description

Registers `ImageConsumer` as interested in image information and tells `ImageProducer` to start sending the image data immediately.

IndexColorModel

Name

IndexColorModel

[Graphic: Figure from the text]

Description

The `IndexColorModel` class is a `ColorModel` that uses a color map lookup table (with a maximum size of 256) to convert pixel values into their alpha, red, green, and blue component parts.

Class Definition

```
public class java.awt.image.IndexColorModel
    extends java.awt.image.ColorModel {
  // Constructors
  public IndexColorModel (int bits, int size,
      byte[] colorMap, int start, boolean hasalpha);
  public IndexColorModel (int bits, int size,
      byte[] colorMap, int start, boolean hasalpha, int transparent);
  public IndexColorModel (int bits, int size,
      byte[] red, byte[] green, byte[] blue);
  public IndexColorModel (int bits, int size,
      byte[] red, byte[] green, byte[] blue, byte[] alpha);
  public IndexColorModel (int bits, int size,
      byte[] red, byte[] green, byte[] blue, int transparent);
  // Instance Methods
  public final int getAlpha (int pixel);
  public final void getAlphas (byte[] alphas);
  public final int getBlue (int pixel);
  public final void getBlues (byte[] blues);
  public final int getGreen (int pixel);
  public final void getGreens (byte[] greens);
  public final int getMapSize();
  public final int getRed (int pixel);
  public final void getReds (byte[] reds);
  public final int getRGB (int pixel);
  public final int getTransparentPixel();
}
```

Constructors

IndexColorModel

public IndexColorModel (int bits, int size, byte[] colorMap, int start, boolean hasalpha)

Parameters

bits

The number of bits in a pixel.

size

The number of entries in the color map. Note: this is not the size of the `colorMap` parameter.

colorMap

Color component values in red, green, blue, alpha order; the alpha component is optional, and may not be present.

start

The starting position in `colorMap` array.

hasalpha

If `hasalpha` is `true`, alpha components are present in `colorMap` array.

Throws

`ArrayIndexOutOfBoundsException`

If `size` is invalid.

Description

Constructs an `IndexColorModel` object with the given component settings. The size of `colorMap` must be at least `3*size+start`, if `hasalpha` is `false`; if `hasalpha` is `true`, `colorMap.length` must be at least `4*size+start`.

public IndexColorModel (int bits, int size, byte[] colorMap, int start, boolean hasalpha, int transparent)

Parameters

bits

The number of bits in a pixel.

size

The number of entries in the color map. Note: this is not the size of the `colorMap` parameter.

colorMap

Color component values in red, green, blue, alpha order; the alpha component is optional, and may not be present.

start

The starting position in `colorMap` array.

hasalpha

If `hasalpha` is `true`, alpha components are present in `colorMap` array.

transparent

Position of `colorMap` entry for transparent pixel entry.

Throws

`ArrayIndexOutOfBoundsException`

If `size` invalid.

Description

Constructs an `IndexColorModel` object with the given component settings. The size of `colorMap` must be at least `3*size+start`, if `hasalpha` is `false`; if `hasalpha` is `true`, `colorMap.length` must be at least `4*size+start`. The color map has a transparent pixel; its location is given by `transparent`.

public IndexColorModel (int bits, int size, byte[] red, byte[] green, byte[] blue)

Parameters

bits

The number of bits in a pixel.

size

The number of entries in the color map.

red

Red color component values.

green

Green color component values.

blue

Blue color component values.

Throws

`ArrayIndexOutOfBoundsException`

If `size` invalid.

Description

Constructs an `IndexColorModel` object with the given component settings. There is no alpha component. The length of the `red`, `green`, and `blue` arrays must be greater than `size`.

public IndexColorModel (int bits, int size, byte[] red, byte[] green, byte[] blue, byte[] alpha)

Parameters

bits

The number of bits in a pixel.

size

The number of entries in the color map.

red

Red color component values.

green

Green color component values.

blue

Blue color component values.

alpha

Alpha component values.

Throws

`ArrayIndexOutOfBoundsException`

If `size` is invalid.

`NullPointerException`

If `size` is positive and `alpha` array is `null`.

Description

Constructs an `IndexColorModel` object with the given component settings. The length of the `red`, `green`, `blue`, and `alpha` arrays must be greater than `size`.

public IndexColorModel (int bits, int size, byte[] red, byte[] green, byte[] blue, int transparent)

Parameters

bits

The number of bits in a pixel.

size

The number of entries in the color map.

red

Red color component values.

green

Green color component values.

blue

Blue color component values.

transparent

Position of transparent pixel entry.

Throws

`ArrayIndexOutOfBoundsException`

If `size` is invalid.

Description

Constructs an `IndexColorModel` object with the given component settings. The length of the `red`, `green`, `blue`, and `alpha` arrays must be greater than `size`. The color map has a transparent pixel; its location is given by `transparent`.

Instance Methods

getAlpha

public final int getAlpha (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current alpha setting of the pixel.

Overrides

`ColorModel.getAlpha(int)`

getAlphas

public final void getAlphas (byte[] alphas)

Parameters

alphas

The alpha values of the pixels in the color model.

Description

Copies the alpha values from the color map into the array `alphas[]`.

getBlue

public final int getBlue (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current blue setting of the pixel.

Overrides

`ColorModel.getBlue(int)`

getBlues

public final void getBlues (byte[] blues)

Parameters

blues

The blue values of the pixels in the color model.

Description

Copies the blue values from the color map into the array `blues[]`.

getGreen

public final int getGreen (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current green setting of the pixel.

Overrides

`ColorModel.getGreen(int)`

getGreens

public final void getGreens (byte[] greens)

Parameters

greens

The green values of the pixels in the color model.

Description

Copies the green values from the color map into the array `greens[]`.

getMapSize

public final int getMapSize()

Returns

The current size of the color map table.

getRed

public final int getRed (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current red setting of the pixel.

Overrides

`ColorModel.getRed(int)`

getReds

public final void getReds (byte[] reds)

Parameters

reds

The red values of the pixels in the color model.

Description

Copies the red values from the color map into the array `reds[]`.

getRGB

public final int getRGB (int pixel)

Parameters

pixel

A pixel encoded with this `ColorModel`.

Returns

The current combined red, green, and blue settings of the pixel.

Overrides

`ColorModel.getRGB(int)`

Description

Gets the color of `pixel` in the default RGB color model.

getTransparentPixel

public final int getTransparentPixel()

Returns

The array index for the transparent pixel in the color model.

See Also

`ColorModel`

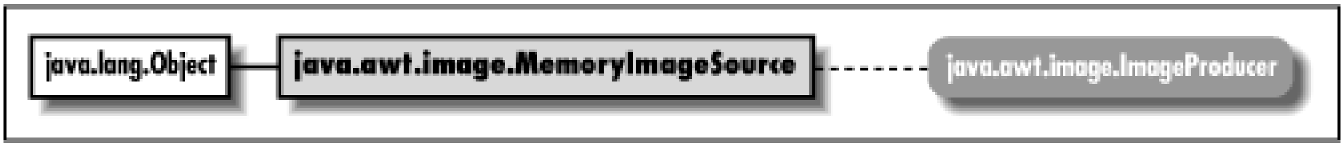
ImageProducer | BOOK INDEX | MemoryImageSource

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

MemoryImageSource

Name

MemoryImageSource



java.lang.Object
java.awt.image.MemoryImageSource
java.awt.image.ImageProducer

Description

The `MemoryImageSource` class allows you to create images completely in memory. You provide an array of data; it serves as an image producer for that data. In the 1.1 release, new methods support using this class for animation (notably `setAnimated()` and the various overrides of `newPixels()`).

Class Definition

```
public class java.awt.image.MemoryImageSource
    extends java.lang.Object
    implements java.awt.image.ImageProducer {
  // Constructors
  public MemoryImageSource (int w, int h, ColorModel cm,
      byte[] pix, int off, int scan);
  public MemoryImageSource (int w, int h, ColorModel cm,
      byte[] pix, int off, int scan, Hashtable props);
  public MemoryImageSource (int w, int h, ColorModel cm,
      int[] pix, int off, int scan);
  public MemoryImageSource (int w, int h, ColorModel cm,
      int[] pix, int off, int scan, Hashtable props);
  public MemoryImageSource (int w, int h, int[] pix,
      int off, int scan);
  public MemoryImageSource (int w, int h, int[] pix,
      int off, int scan, Hashtable props);
  // Instance Methods
  public synchronized void addConsumer (ImageConsumer ic);
  public synchronized boolean isConsumer (ImageConsumer ic);
  public void newPixels(); ★
  public synchronized void newPixels (int x, int y,
      int w, int h); ★
  public synchronized void newPixels (int x, int y,
      int w, int h, boolean framenotify); ★
  public synchronized void newPixels (byte[] newpix,
      ColorModel newmodel, int offset, int scansize); ★
  public synchronized void newPixels (int[] newpix,
      ColorModel newmodel, int offset, int scansize); ★
  public synchronized void removeConsumer (ImageConsumer ic);
  public void requestTopDownLeftRightResend (ImageConsumer ic);
  public synchronized void setAnimated (boolean animated); ★
  public synchronized void setFullBufferUpdates
      (boolean fullbuffers); ★
  public void startProduction (ImageConsumer ic);
}
```

Constructors

MemoryImageSource

public MemoryImageSource (int w, int h, ColorModel cm, byte[] pix, int off, int scan)

Parameters

w

Width of the image being created.

h

Height of the image being created.

cm

`ColorModel` of the image being created.

pix

Array of pixel information.

off

The offset of the first pixel in the array; elements prior to this pixel are ignored.

scan

The number of pixels per scan line in the array.

Description

Constructs a `MemoryImageSource` object with the given parameters to serve as an `ImageProducer` for a new image.

public MemoryImageSource (int w, int h, ColorModel cm, byte[] pix, int off, int scan, Hashtable props)

Parameters

w

Width of the image being created.

h

Height of the image being created.

cm

`ColorModel` of the image being created.

pix

Array of pixel information.

off

The offset of the first pixel in the array; elements prior to this pixel are ignored.

scan

The number of pixels per scan line in the array.

props

`Hashtable` of properties associated with image.

Description

Constructs a `MemoryImageSource` object with the given parameters to serve as an `ImageProducer` for a new image.

public MemoryImageSource (int w, int h, ColorModel cm, int[] pix, int off, int scan)

Parameters

w

Width of the image being created.

h

Height of the image being created.

cm

`ColorModel` of the image being created.

pix

Array of pixel information.

off

The offset of the first pixel in the array; elements prior to this pixel are ignored.

scan

The number of pixels per scan line in the array.

Description

Constructs a `MemoryImageSource` object with the given parameters to serve as an `ImageProducer` for a new image.

public MemoryImageSource (int w, int h, ColorModel cm, int[] pix, int off, int scan, Hashtable props)

Parameters

w

Width of the image being created.

h

Height of the image being created.

cm

`ColorModel` of the image being created.

pix

Array of pixel information.

off

The offset of the first pixel in the array; elements prior to this pixel are ignored.

scan

The number of pixels per scan line in the array.

props

Hashtable of properties associated with image.

Description

Constructs a MemoryImageSource object with the given parameters to serve as an ImageProducer for a new image.

public MemoryImageSource (int w, int h, int[] pix, int off, int scan)

Parameters

w

Width of the image being created.

h

Height of the image being created.

pix

Array of pixel information.

off

The offset of the first pixel in the array; elements prior to this pixel are ignored.

scan

The number of pixels per scan line in the array.

Description

Constructs a MemoryImageSource object with the given parameters to serve as an ImageProducer for a new image.

public MemoryImageSource (int w, int h, int[] pix, int off, int scan, Hashtable props)

Parameters

w

Width of the image being created.

h

Height of the image being created.

pix

Array of pixel information.

off

The offset of the first pixel in the array; elements prior to this pixel are ignored.

scan

The number of pixels per scan line in the array.

props

`Hashtable` of properties associated with image.

Description

Constructs a `MemoryImageSource` object with the given parameters to serve as an `ImageProducer` for a new image.

Class Methods

addConsumer

public synchronized void addConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` requesting image data.

Implements

`ImageProducer.addConsumer(ImageConsumer)`

Description

Registers an `ImageConsumer` as interested in `Image` information.

isConsumer

public synchronized boolean isConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to check.

Returns

`true` if `ImageConsumer` is registered with this `ImageProducer`, `false` otherwise.

Implements

`ImageProducer.isConsumer(ImageConsumer)`

newPixels

public synchronized void newPixels() ★

Description

Notifies the `MemoryImageSource` that there is new data available. The `MemoryImageSource` notifies all `ImageConsumer`s that there is new data, sending the full rectangle and notifying the consumers that the frame is complete.

public synchronized void newPixels (int x, int y, int w, int h, boolean framenotify) ★

Parameters

x

x coordinate of the top left corner of the new image data.

y

y coordinate of the top left corner of the new image data.

w

Width of the new image data.

h

Height of the new image data.

Description

Notifies the `MemoryImageSource` that there is new data available. The `MemoryImageSource` notifies all `ImageConsumer`s that there is new data in the rectangle described by `x`, `y`, `w`, and `h`. The consumers are notified that the frame is complete.

public synchronized void newPixels (int x, int y, int w, int h, boolean framenotify) ★

Parameters

x

x coordinate of the top left corner of the new image data.

y

y coordinate of the top left corner of the new image data.

w

Width of the new image data.

h

Height of the new image data.

framenotify

Determines whether this is a complete frame or not.

Description

Notifies the `MemoryImageSource` that there is new data available. The `MemoryImageSource` notifies all `ImageConsumer`s that there is new data in the rectangle described by `x`, `y`, `w`, and `h`. If `framenotify` is `true`, the consumers will also be notified that a frame is complete.

public synchronized void newPixels (byte[] newpix, ColorModel newmodel, int offset, int scansize) ★

Parameters

newpix

New array of image data.

newmodel

The color model to use for the new data.

offset

Offset into the data array

scansize

Size of each line.

Description

Changes the image data for this `MemoryImageSource` and notifies its `ImageConsumer`s that new data is available.

public synchronized void newPixels (int[] newpix, ColorModel newmodel, int offset, int scansize) ★

Parameters

newpix

New array of image data.

newmodel

The color model to use for the new data.

offset

Offset into the data array

scansize

Size of each line.

Description

Changes the image data for this `MemoryImageSource` and notifies its `ImageConsumer`s that new data is available.

removeConsumer

public void removeConsumer (ImageConsumer ic)

Parameters

ic

`ImageConsumer` to remove.

Implements

`ImageProducer.removeConsumer(ImageConsumer)`

Description

Removes an `ImageConsumer` from registered consumers for this `ImageProducer`.

requestTopDownLeftRightResend

public void requestTopDownLeftRightResend (ImageConsumer ic)

Parameters

ic

`ImageConsumer` requesting image data.

Implements

`ImageProducer.requestTopDownLeftRightResend(ImageConsumer)`

Description

Requests the retransmission of the `Image` data in top-down, left-to-right order.

setAnimated

public void setAnimated (boolean animated) ★

Parameters

animated

Flag indicating whether this image is animated.

Description

To use this MemoryImageSource for animation, call `setAnimated(true)`. The `newPixels()` methods will not work otherwise.

setFullBufferUpdates

public void setFullBufferUpdates (boolean fullbuffers) ★

Parameters

fullbuffers

`true` to send full buffers; `false` otherwise.

Description

This method is only important for animations; i.e., you should call `setAnimated(true)` before using this function. If you do request to send full buffers, then any rectangle parameters passed to `newPixels()` will be ignored and the entire image will be sent to the consumers.

startProduction

public void startProduction (ImageConsumer ic)

Parameters

ic

`ImageConsumer` requesting image data.

Implements

`ImageProducer.startProduction(ImageConsumer)`

Description

Registers `ImageConsumer` as interested in Image information and tells `ImageProducer` to start sending the image data immediately.

PixelGrabber

Name

PixelGrabber

[Graphic: Figure from the text]

Description

The `PixelGrabber` class is an `ImageConsumer` that captures the pixels from an image and saves them in an array.

Class Definition

```
public class java.awt.image.PixelGrabber
    extends java.lang.Object
    implements java.awt.image.ImageConsumer {
  // Constructors
  public PixelGrabber (Image img, int x, int y, int w, int h,
      boolean forceRGB); ★
  public PixelGrabber (Image image, int x, int y, int width,
      int height, int[] pixels, int offset, int scansize);
  public PixelGrabber (ImageProducer ip, int x, int y, int width,
      int height, int[] pixels, int offset, int scansize);
  // Instance Methods
  public synchronized void abortGrabbing(); ★
  public synchronized ColorModel getColorModel(); ★
  public synchronized int getHeight(); ★
  public synchronized Object getPixels(); ★
  public synchronized int getStatus(); ★
  public synchronized int getWidth(); ★
  public boolean grabPixels() throws InterruptedException;
  public synchronized boolean grabPixels (long ms)
      throws InterruptedException;
  public synchronized void imageComplete (int status);
  public void setColorModel (ColorModel model);
  public void setDimensions (int width, int height);
  public void setHints (int hints);
  public void setPixels (int x, int y, int width, int height,
      ColorModel model, byte[] pixels, int offset, int scansize);
  public void setPixels (int x, int y, int width, int height,
      ColorModel model, int[] pixels, int offset, int scansize);
  public void setProperties (Hashtable properties);
  public synchronized void startGrabbing(); ★
  public synchronized int status(); ☆
}
```

Constructors

PixelGrabber

public PixelGrabber (Image img, int x, int y, int w, int h, boolean forceRGB) ★

Parameters

img

`Image` to use as source of pixel data.

x

x-coordinate of top-left corner of pixel data.

y

y-coordinate of top-left corner of pixel data.

w

Width of pixel data.

h

Height of pixel data.

forceRGB

`true` to force the use of the RGB color model; `false` otherwise.

Description

Constructs a `PixelGrabber` instance to grab the specified area of the image.

public PixelGrabber (Image image, int x, int y, int width, int height, int[] pixels, int offset, int scansize)

Parameters

image

`Image` to use as source of pixel data.

x

x-coordinate of top-left corner of pixel data.

y

y-coordinate of top-left corner of pixel data.

width

Width of pixel data.

height

Height of pixel data.

pixels

Where to store pixel data when `grabPixels()` called.

offset

Offset from beginning of each line in pixels array.

scansize

Size of each line of data in pixels array.

Description

Constructs a `PixelGrabber` instance to grab the specified area of the image and store the pixel data from this area in the array `pixels[]`.

public PixelGrabber (ImageProducer ip, int x, int y, int width, int height, int[] pixels, int offset, int scansize)

Parameters

ip

`ImageProducer` to use as source of pixel data.

x

x-coordinate of top-left corner of pixel data.

y

y-coordinate of top-left corner of pixel data.

width

Width of pixel data.

height

Height of pixel data.

pixels

Where to store pixel data when `grabPixels()` called.

offset

Offset from beginning of each line in pixels array.

scansize

Size of each line of data in pixels array.

Description

Constructs a `PixelGrabber` instance to grab data from the specified area of the image generated by an `ImageProducer` and store the pixel data from this area in the array `pixels[]`.

Instance Methods

abortGrabbing

public synchronized void abortGrabbing() ★

Description

Stops the `PixelGrabber`'s image-grabbing process.

getColorModel

public synchronized ColorModel getColorModel() ★

Returns

The color model the `PixelGrabber` is using for its array.

getHeight

public synchronized int getHeight() ★

Returns

> The height of the grabbed image, or -1 if the height is not known.

getPixels

public synchronized Object getPixels() ★

Returns

> The array of pixels.

Description

> Either a byte array or an integer array is returned, or `null` if the size and format of the image are not yet known. Because the `PixelGrabber` may change its mind about what `ColorModel` it's using, different calls to this method may return different arrays until the image acquisition is complete.

getStatus

public synchronized int getStatus() ★

Returns

> A combination of `ImageObserver` flags indicating what data is available.

getWidth

public synchronized int getWidth() ★

Returns

> The width of the grabbed image, or -1 if the width is not known.

grabPixels

public boolean grabPixels() throws InterruptedException

Throws

`InterruptedException`

If image grabbing is interrupted before completion.

Returns

`true` if the image has completed loading, `false` if the loading process aborted or an error occurred.

Description

Starts the process of grabbing the pixel data from the source and storing it in the array `pixels[]` from constructor. Returns when the image is complete, loading aborts, or an error occurs.

public synchronized boolean grabPixels (long ms) throws InterruptedException

Parameters

ms

Milliseconds to wait for completion.

Returns

`true` if image has completed loading, `false` if the loading process aborted, or an error or a timeout occurred.

Throws

`InterruptedException`

If image grabbing is interrupted before completion.

Description

Starts the process of grabbing the pixel data from the source and storing it in the array `pixels[]` from constructor. Returns when the image is complete, loading aborts, an error occurs, or a timeout occurs.

imageComplete

public synchronized void imageComplete (int status)

Parameters

status

Image loading completion status flags.

Implements

`ImageConsumer.imageComplete(int)`

Description

Called by the `ImageProducer` to indicate that the image has been delivered.

setColorModel

void setColorModel (ColorModel model)

Parameters

model

The color model for the image.

Implements

`ImageConsumer.setColorModel(ColorModel)`

Description

Does nothing.

setDimensions

void setDimensions (int width, int height)

Parameters

width

Width for image.

height

Height for image.

Implements

`ImageConsumer.setDimensions(int, int)`

Description

Does nothing.

setHints

void setHints (int hints)

Parameters

hints

Image consumption hints.

Implements

`ImageConsumer.setHints(int)`

Description

Does nothing.

setPixels

void setPixels (int x, int y, int width, int height, ColorModel model, byte[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Implements

`ImageConsumer.setPixels(int, int, int, int, ColorModel, byte[], int, int)`

Description

Called by the `ImageProducer` to deliver pixel data from the image.

void setPixels (int x, int y, int width, int height, ColorModel model, int[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Implements

`ImageConsumer.setPixels(int, int, int, int, ColorModel, int[], int, int)`

Description

Called by the `ImageProducer` to deliver pixel data from the image.

setProperties

void setProperties (Hashtable properties)

Parameters

properties

The properties for the image.

Implements

`ImageConsumer.setProperties(Hashtable)`

Description

Does nothing.

startGrabbing

public synchronized void startGrabbing() ★

Description

Starts the `PixelGrabber`'s image-grabbing process.

status

public synchronized int status () ☆

Returns

> The `ImageObserver` flags OR'ed together representing the available information about the image. Replaced by `getStatus()`.

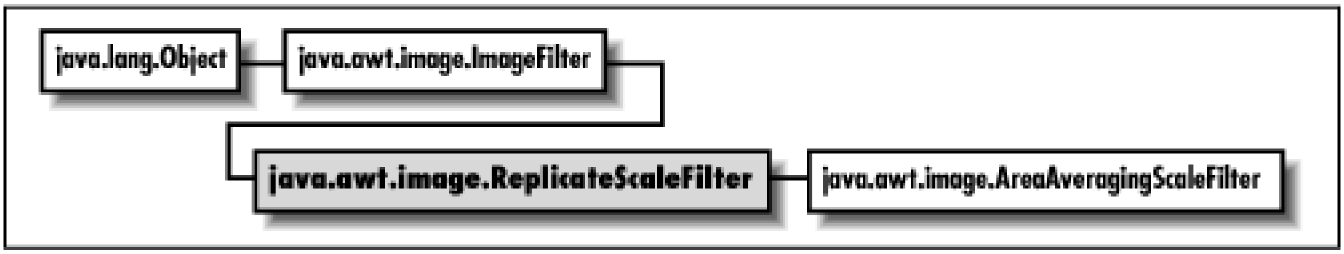
MemoryImageSource | BOOK INDEX | ReplicateScaleFilter ★

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ReplicateScaleFilter ★

Name

ReplicateScaleFilter ★



java.lang.Object
java.awt.image.ImageFilter
java.awt.image.ReplicateScaleFilter
java.awt.image.AreaAveragingScaleFilter

Description

The `ReplicateScaleFilter` class uses a simple-minded algorithm to scale an image. If the image is to be reduced, rows and columns of pixels are removed. If the image is to be expanded, rows and columns are duplicated (replicated).

Class Definition

```
public class ReplicateScaleFilter
    extends java.awt.image.ImageFilter {
  // Variables
  protected int destHeight;
  protected int destWidth;
  protected Object outpixbuf;
  protected int srcHeight;
  protected int srcWidth;
  protected int[] srccols;
  protected int[] srcrows;
  // Constructor
  public ReplicateScaleFilter(int width, int height);
  // Instance Methods
  public void setDimensions (int w, int h);
  public void setPixels(int x, int y, int w, int h, ColorModel model,
      byte[] pixels, int off, int scansize);
  public void setPixels(int x, int y, int w, int h, ColorModel model,
      int[] pixels, int off, int scansize);
  public void setProperties(Hashtable props);
}
```

Variables

destHeight

protected int destHeight

Height of the scaled image.

destWidth

protected int destWidth

Width of the scaled image.

outpixbuf

protected Object outpixbuf

An internal buffer.

srcHeight

protected int srcHeight

Height of the original image.

srcWidth

protected int srcWidth

Width of the original image.

srccols

protected int[] srccols

Internal array used to map incoming columns to outgoing columns.

srcrows

protected int[] srcrows

Internal array used to map incoming rows to outgoing rows.

Constructor

ReplicateScaleFilter

public ReplicateScaleFilter (int width, int height)

Parameters

> *width*
>
> > Width of scaled image.
>
> *height*
>
> > Height of scaled image.

Description

> Constructs a `ReplicateScaleFilter` that scales the original image to the specified size. If both `width` and `height` are -1, the destination image size will be set to the source image size. If either one of the parameters is -1, it will be set to preserve the aspect ratio of the original image.

Instance Methods

setDimensions

public void setDimensions (int w, int h)

Parameters

w

Width of the source image.

h

Height of the source image.

Overrides

`ImageFilter.setDimensions(int, int)`

Description

Sets the size of the source image.

setPixels

void setPixels (int x, int y, int w, int h, ColorModel model, byte[] pixels, int off, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

w

Width of the rectangle of pixel data delivered with this method call.

h

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

off

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ImageFilter.setPixels(int, int, int, int, ColorModel, byte[], int, int)`

Description

Receives a rectangle of image data from the `ImageProducer`; scales these pixels and delivers them to any `ImageConsumer`s.

void setPixels (int x, int y, int w, int h, ColorModel model, int[] pixels, int off, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

w

Width of the rectangle of pixel data delivered with this method call.

h

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

off

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ImageFilter.setPixels(int, int, int, int, ColorModel, int[], int, int)`

Description

Receives a rectangle of image data from the `ImageProducer`; scales these pixels and delivers them to any `ImageConsumer`s.

setProperties

public void setProperties (Hashtable props)

Parameters

props

The properties for the image.

Overrides

`ImageFilter.setProperties(Hashtable)`

Description

Adds the "rescale" image property to the properties list.

RGBImageFilter

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

RGBImageFilter

Name

RGBImageFilter

[Graphic: Figure from the text]

Description

`RGBImageFilter` is an abstract class that helps you filter images based on each pixel's color and position. In most cases, the only method you need to implement in subclasses is `filterRGB()`, which returns a new pixel value based on the old pixel's color and position. `RGBImageFilter` cannot be used to implement filters that depend on the value of neighboring pixels, or other factors aside from color and position.

Class Definition

```
public abstract class java.awt.image.RGBImageFilter
    extends java.awt.image.ImageFilter {
  // Variables
  protected boolean canFilterIndexColorModel;
  protected ColorModel newmodel;
  protected ColorModel oldmodel;
  // Instance Methods
  public IndexColorModel filterIndexColorModel (IndexColorModel icm);
  public abstract int filterRGB (int x, int y, int rgb);
  public void filterRGBPixels (int x, int y, int width,
      int height, int[] pixels, int off, int scansize);
  public void setColorModel (ColorModel model);
  public void setPixels (int x, int y, int width, int height,
      ColorModel model, byte[] pixels, int offset, int scansize);
  public void setPixels (int x, int y, int width, int height,
      ColorModel model, int[] pixels, int offset, int scansize);
  public void substituteColorModel (ColorModel oldModel,
      ColorModel newModel);
}
```

Variables

canFilterIndexColorModel

protected boolean canFilterIndexColorModel

Setting the `canFilterIndexColorModel` variable to `true` indicates the filter can filter `IndexColorModel` images. To filter an `IndexColorModel`, the filter must depend only on color, not on position.

newmodel

protected ColorModel newmodel

A place to store a new `ColorModel`.

origmodel

protected ColorModel origmodel

A place to store an old `ColorModel`.

Instance Methods

filterIndexColorModel

public IndexColorModel filterIndexColorModel (IndexColorModel icm)

Parameters

icm

Color model to filter.

Returns

Filtered color model.

Description

Helper method for `setColorModel()` that runs the entire color table of `icm` through the `filterRGB()` method of the subclass. Used only if `canFilterIndexColorModel` is `true`, and the image uses an `IndexColorModel`.

filterRGB

public abstract int filterRGB (int x, int y, int rgb)

Parameters

x

x-coordinate of pixel data.

y

y-coordinate of pixel data.

rgb

Color value of pixel to filter.

Returns

New color value of pixel.

Description

Subclasses implement this method to provide a filtering function that generates new pixels.

filterRGBPixels

public void filterRGBPixels (int x, int y, int width, int height, int[] pixels, int off, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data within entire image.

y

y-coordinate of top-left corner of pixel data within entire image.

width

Width of pixel data within entire image.

height

Height of pixel data within entire image.

pixels

Image data.

off

Offset from beginning of each line in pixels array.

scansize

Size of each line of data in pixels array.

Description

Helper method for `setPixels()` that filters each element of the `pixels` buffer through the subclass's `filterRGB()` method.

setColorModel

public void setColorModel (ColorModel model)

Parameters

model

The color model for the image.

Overrides

`ImageFilter.setColorModel(ColorModel)`

Description

Sets the image's color model.

setPixels

public void setPixels (int x, int y, int width, int height, ColorModel model, byte[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ImageFilter.setPixels(int, int, int, int, ColorModel, byte[], int, int)`

Description

Called by the `ImageProducer` to deliver a rectangular block of pixels for filtering.

public void setPixels (int x, int y, int width, int height, ColorModel model, int[] pixels, int offset, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

width

Width of the rectangle of pixel data delivered with this method call.

height

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

offset

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ImageFilter.setPixels(int, int, int, int, ColorModel, int[], int, int)`

Description

Called by the `ImageProducer` to deliver a rectangular block of pixels for filtering.

substituteColorModel

public void substituteColorModel (ColorModel oldModel, ColorModel newModel)

Parameters

oldModel

New value for `origmodel` variable.

newModel

New value for `newmodel` variable.

Description

Helper method for `setColorModel()` to initialize the protected variables `newmodel` and `origmodel`.

See Also

`ColorModel`, `ImageFilter`

Description

`CheckboxMenuItemPeer` is an interface that defines the basis for checkbox menu items.

Interface Definition

```
public abstract interface java.awt.peer.CheckboxMenuItemPeer
   extends java.awt.peer.MenuItemPeer {
  // Interface Methods
  public abstract void setState (boolean condition);
}
```

Interface Methods

setState

public abstract void setState (boolean condition)

Parameters

condition

New state for checkbox menu item's peer.

Description

Changes the state of checkbox menu item's peer.

See Also

`MenuComponentPeer`, `MenuItemPeer`

CheckboxPeer

Name

CheckboxPeer

[Graphic: Figure from the text]

Description

`CheckboxPeer` is an interface that defines the basis for checkbox components.

Interface Definition

```
public abstract interface java.awt.peer.CheckboxPeer
   extends java.awt.peer.ComponentPeer {
  // Interface Methods
  public abstract void setCheckboxGroup (CheckboxGroup group);
  public abstract void setLabel (String label);
  public abstract void setState (boolean state);
}
```

Interface Methods

setCheckboxGroup

public abstract void setCheckboxGroup (CheckboxGroup group)

Parameters

group

New group to put the checkbox peer in.

Description

Changes the checkbox group to which the checkbox peer belongs; implicitly removes the peer from its old group, if any.

setLabel

public abstract void setLabel (String label)

Parameters

label

New text for label of checkbox's peer.

Description

Changes the text of the label of the checkbox's peer.

setState

public abstract void setState (boolean state)

Parameters

state

New state for the checkbox's peer.

Description

Changes the state of the checkbox's peer.

  // Interface Methods
  public abstract void add (String item, int index); ★
  public abstract void addItem (String item, int position); ☆
  public abstract void remove (int index); ★
  public abstract void select (int position);
}
```

Interface Methods

add

public abstract void add (String item, int index) ★

Parameters

item

Text of the entry to add.

index

Position in which to add the entry; position 0 is the first entry in the list.

Description

Adds a new entry to the available choices at the designated position.

addItem

public abstract void addItem (String item, int position) ☆

Parameters

item

Text of the entry to add.

position

Position in which to add the entry; position 0 is the first entry in the list.

Description

Adds a new entry to the available choices at the designated position.

remove

public abstract void remove (int index) ★

Parameters

index

Position of the item to remove.

Description

Removes an entry at the given position.

select

public abstract void select (int position)

Parameters

position

Position to make selected entry.

Description

Makes the given entry the selected one for the choice's peer.

  public abstract ColorModel getColorModel();
  public abstract FontMetrics getFontMetrics (Font f);
  public abstract Graphics getGraphics();
  public abstract Point getLocationOnScreen(); ★
  public abstract Dimension getMinimumSize(); ★
  public abstract Dimension getPreferredSize(); ★
  public abstract Toolkit getToolkit();
  public abstract boolean handleEvent (Event e);
  public abstract void hide(); ☆
  public abstract boolean isFocusTraversable(); ★
  public abstract Dimension minimumSize(); ☆
  public abstract void paint (Graphics g);
  public abstract Dimension preferredSize (); ☆
  public abstract boolean prepareImage (Image image, int width, int height,
    ImageObserver observer);
  public abstract void print (Graphics g);
  public abstract void repaint (long tm, int x, int y, int width, int height);
  public abstract void requestFocus();
  public abstract void reshape (int x, int y, int width, int height); ☆
  public abstract void setBackground (Color c);
  public abstract void setBounds (int x, int y, int width, int height); ★
  public abstract void setCursor (Cursor cursor); ★
  public abstract void setEnabled (boolean b); ★
  public abstract void setFont (Font f);
  public abstract void setForeground (Color c);
  public abstract void setVisible (boolean b); ★
  public abstract void show(); ☆
}
```

Interface Methods

checkImage

public abstract int checkImage (Image image, int width, int height, ImageObserver observer)

Parameters

image

`Image` to check.

width

Horizontal size to which the image will be scaled.

height

Vertical size to which the image will be scaled.

observer

An `ImageObserver` to monitor image loading; normally, the object on which the image will be rendered.

Returns

`ImageObserver` flags ORed together indicating status.

Description

Checks status of image construction.

createImage

public abstract Image createImage (ImageProducer producer)

Parameters

producer

An object that implements the `ImageProducer` interface to create a new image.

Returns

Newly created image instance.

Description

Creates an `Image` based upon an `ImageProducer`.

public abstract Image createImage (int width, int height)

Parameters

width

Horizontal size for in-memory `Image`.

height

Vertical size for in-memory `Image`.

Returns

Newly created image instance.

Description

Creates an in-memory `Image` for double buffering.

disable

public abstract void disable() ☆

Description

Disables component so that it is unresponsive to user interactions. Replaced by `setEnabled(false)`.

dispose

public abstract void dispose()

Description

Releases resources used by peer.

enable

public abstract void enable() ☆

Description

Enables component so that it is responsive to user interactions. Replaced by `setEnabled(true)`.

getColorModel

public abstract ColorModel getColorModel()

Returns

`ColorModel` used to display the current component.

getFontMetrics

public abstract FontMetrics getFontMetrics (Font f)

Parameters

f

A font whose metrics are desired.

Returns

Font sizing information for the desired font.

getGraphics

public abstract Graphics getGraphics()

Throws

InternalException

If acquiring a graphics context is unsupported

Returns

Component's graphics context.

getLocationOnScreen

public abstract Point getLocationOnScreen() ★

Returns

The location of the component in the screen's coordinate space.

getMinimumSize

public abstract Dimension getMinimumSize() ★

Returns

> The minimum dimensions of the component.

getPreferredSize

public abstract Dimension getPreferredSize() ★

Returns

> The preferred dimensions of the component.

getToolkit

public abstract Toolkit getToolkit()

Returns

> `Toolkit` of `Component`.

handleEvent

public abstract boolean handleEvent (Event e)

Parameters

> *e*
>
> > `Event` instance identifying what caused the method to be called.

Returns

> `true` if the peer handled the event, `false` to propagate the event to the parent container.

Description

> High-level event handling routine.

hide

public abstract void hide() ☆

Description

Hides the component. Replaced by `setVisible(false)`.

isFocusTraversable

public abstract boolean isFocusTraversable() ★

Returns

`true` if the peer can be tabbed onto, `false` otherwise.

Description

Determines if this peer is navigable using the keyboard.

minimumSize

public abstract Dimension minimumSize() ☆

Returns

The minimum dimensions of the component. Replaced by `getMinimumSize()`.

paint

public abstract void paint (Graphics g)

Parameters

g

Graphics context of the component.

Description

Draws something in graphics context.

preferredSize

public abstract Dimension preferredSize() ☆

Returns

The preferred dimensions of the component. Replaced by `getPreferredSize()`.

prepareImage

public abstract boolean prepareImage (Image image, int width, int height, ImageObserver observer)

Parameters

image

`Image` to load.

width

Horizontal size to which the image will be scaled.

height

Vertical size to which the image will be scaled.

observer

An `ImageObserver` to monitor image loading; normally, the object on which the image will be rendered.

Returns

`true` if the image has already loaded, `false` otherwise.

Description

Forces the image to start loading.

print

public abstract void print (Graphics g)

Parameters

g

Graphics context of component.

Description

Print something from the graphics context.

repaint

public abstract void repaint (long tm, int x, int y, int width, int height)

Parameters

tm

Millisecond delay allowed before repaint.

x

Horizontal origin of bounding box to redraw.

y

Vertical origin of bounding box to redraw.

width

Width of bounding box to redraw.

height

Height of bounding box to redraw.

Description

Requests scheduler to redraw portion of component within a time period.

requestFocus

public abstract void requestFocus()

Description

Requests this `Component` gets the input focus.

reshape

public abstract void reshape (int x, int y, int width, int height) ☆

Parameters

x

New horizontal position for component.

y

New vertical position for component.

width

New width for component.

height

New height for component.

Description

Relocates and resizes the component's peer. Replaced by `setBounds(int, int, int, int)`.

setBackground

public abstract void setBackground (Color c)

Parameters

c

New color for the background.

Description

Changes the background color of the component.

setBounds

public abstract void setBounds (int x, int y, int width, int height) ★

Parameters

x

New horizontal position for component.

y

New vertical position for component.

width

New width for component.

height

New height for component.

Description

Relocates and resizes the component's peer.

setCursor

public abstract void setCursor (Cursor cursor) ★

Parameters

cursor

New cursor.

Description

Changes the cursor of the component.

setEnabled

public abstract void setEnabled (boolean b) ★

Parameters

b

`true` to enable the peer; `false` to disable it.

Description

Enables or disables the peer.

setFont

public abstract void setFont (Font f)

Parameters

f

New font for the component.

Description

Changes the font used to display text in the component.

setForeground

public abstract void setForeground (Color c)

Parameters

c

New foreground color for the component.

Description

Changes the foreground color of the component.

setVisible

public abstract void setVisible (boolean b) ★

Parameters

b

`true` to show the peer; `false` to hide it.

Description

Shows or hides the peer.

show

public abstract void show() ☆

Description

Makes the peer visible. Replaced by `setVisible(true)`.

Description

`ContainerPeer` is an interface that defines the basis for containers.

Interface Definition

```
public abstract interface java.awt.peer.ContainerPeer
   extends java.awt.peer.ComponentPeer {
  // Interface Methods
  public abstract void beginValidate(); ★
  public abstract void endValidate(); ★
  public abstract Insets getInsets(); ★
  public abstract Insets insets(); ☆
}
```

Interface Methods

beginValidate

public abstract void beginValidate() ★

Description

> Notifies the peer that the `Container` is going to validate its contents.

endValidate

public abstract void endValidate() ★

Description

> Notifies the peer that the `Container` is finished validating its contents.

getInsets

public Insets getInsets() ★

Returns

> Current `Insets` of container's peer.

insets

public Insets insets() ☆

Returns

> Current `Insets` of container's peer. Replaced by `getInsets()`.

  public abstract void setFilenameFilter (FilenameFilter filter);
}
```

Interface Methods

setDirectory

public abstract void setDirectory (String directory)

Parameters

directory

Initial directory for file dialog's peer.

Description

Changes the directory displayed in the file dialog's peer.

setFile

public abstract void setFile (String file)

Parameters

file

Initial filename for the file dialog's peer.

Description

Changes the default file selection for the file dialog's peer.

setFilenameFilter

public abstract void setFilenameFilter (FilenameFilter filter)

Parameters

filter

Initial filter for file dialog's peer.

Description

Changes the current filename filter of the file dialog's peer.

  public abstract void setMenuBar (MenuBar bar);
  public abstract void setResizable (boolean resizable);
  public abstract void setTitle (String title);
}
```

Interface Methods

setIconImage

public abstract void setIconImage (Image image)

Parameters

image

New image to use for frame peer's icon.

Description

Changes the icon associated with the frame's peer.

setMenuBar

public abstract void setMenuBar (MenuBar bar)

Parameters

bar

New `MenuBar` to use for the frame's peer.

Description

Changes the menu bar of the frame.

setResizable

public abstract void setResizable (boolean resizable)

Parameters

resizable

`true` if the frame's peer should allow resizing, `false` to prevent resizing.

Description

Changes the resize state of the frame's peer.

setTitle

public abstract void setTitle (String title)

Parameters

title

New title to use for the frame's peer.

Description

Changes the title of the frame's peer.

  public abstract void select (int position);
  public abstract void setMultipleMode (boolean b); ★
  public abstract void setMultipleSelections (boolean value); ☆
}
```

Interface Methods

add

public abstract void add (String item, int index) ★

Parameters

item

Text of an entry to add to the list.

index

Position in which to add the entry; position 0 is the first entry in the list.

Description

Adds a new entry to the available choices of the list's peer at the designated position.

addItem

public abstract void addItem (String item, int index) ☆

Parameters

item

Text of an entry to add to the list.

index

Position in which to add the entry; position 0 is the first entry in the list.

Description

Adds a new entry to the available choices of the list's peer at the designated position. Replaced by `add(String, int)`.

clear

public abstract void clear() ☆

Description

Clears all the entries out of the list's peer. Replaced by `removeAll()`.

delItems

public abstract void delItems (int start, int end)

Parameters

start

Starting position of entries to delete.

end

Ending position of entries to delete.

Description

Removes a set of entries from the list's peer.

deselect

public abstract void deselect (int index)

Parameters

index

Position to deselect.

Description

Deselects entry at designated position, if selected.

getMinimumSize

public abstract Dimension getMinimumSize (int rows) ★

Parameters

rows

Number of rows within list's peer to size.

Returns

The minimum dimensions of a list's peer of the given size.

getPreferredSize

public abstract Dimension getPreferredSize (int rows) ★

Parameters

rows

Number of rows within list's peer to size.

Returns

The preferred dimensions of a list's peer of the given size.

getSelectedIndexes

public abstract int[] getSelectedIndexes()

Returns

> Array of positions of currently selected entries in list's peer.

makeVisible

public abstract void makeVisible (int index)

Parameters

> *index*
>
> > Position to make visible on screen.

Description

> Ensures an item is displayed on the screen in the list's peer.

minimumSize

public abstract Dimension minimumSize (int rows) ☆

Parameters

> *rows*
>
> > Number of rows within list's peer to size.

Returns

> The minimum dimensions of a list's peer of the given size. Replaced by `getMinimumSize(int)`.

preferredSize

public abstract Dimension preferredSize (int rows) ☆

Parameters

rows

Number of rows within list's peer to size.

Returns

The preferred dimensions of a list's peer of the given size. Replaced by `getPreferredSize(int)`.

removeAll

public abstract void removeAll() ★

Description

Clears all the entries out of the list's peer.

select

public abstract void select (int position)

Parameters

position

Position to select; 0 indicates the first item in the list.

Description

Makes the given entry the selected item for the list's peer; deselects other selected entries if multiple selections are not enabled.

setMultipleMode

public abstract void setMultipleMode (boolean value) ★

Parameters

value

`true` to allow multiple selections within the list's peer; `false` to disallow multiple selections.

Description

Changes list peer's selection mode.

setMultipleSelections

public abstract void setMultipleSelections (boolean value) ☆

Parameters

value

`true` to allow multiple selections within the list's peer; `false` to disallow multiple selections.

Description

Changes list peer's selection mode. `Replaced by setMultipleMode(boolean)`.

LightweightPeer ★ | BOOK INDEX | MenuBarPeer

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

MenuBarPeer

Name

MenuBarPeer

[Graphic: Figure from the text]

Description

`MenuBarPeer` is an interface that defines the basis for menu bars.

Interface Definition

```
public abstract interface java.awt.peer.MenuBarPeer
   extends java.awt.peer.MenuComponentPeer {
  // Interface Methods
  public abstract void addHelpMenu (Menu m);
  public abstract void addMenu (Menu m);
  public abstract void delMenu (int index);
}
```

Interface Methods

addHelpMenu

public abstract void addHelpMenu (Menu m)

Parameters

m

Menu to designate as the help menu with the menu bar's peer.

Description

Sets a particular menu to be the help menu of the menu bar's peer.

addMenu

public abstract void addMenu (Menu m)

Parameters

m

Menu to add to the menu bar's peer

Description

Adds a menu to the menu bar's peer.

delMenu

public abstract void delMenu (int index)

Parameters

index

Menu position to delete from the menu bar's peer.

Description

Deletes a menu from the menu bar's peer.

See Also

`Menu`, `MenuComponentPeer`

MenuComponentPeer

Name

MenuComponentPeer

[Graphic: Figure from the text]

Description

`MenuComponentPeer` is an interface that defines the basis for all menu GUI peer interfaces.

Interface Definition

```
public abstract interface java.awt.peer.MenuComponentPeer {
  // Interface Methods
  public abstract void dispose();
}
```

Interface Methods

dispose

public abstract void dispose()

Description

Releases resources used by peer.

MenuItemPeer

Name

MenuItemPeer

[Graphic: Figure from the text]

Description

`MenuBarPeer` is an interface that defines the basis for menu bars.

Interface Definition

```
public abstract interface java.awt.peer.MenuItemPeer
   extends java.awt.peer.MenuComponentPeer {
  // Interface Methods
  public abstract void disable(); ☆
  public abstract void enable(); ☆
  public abstract void setEnabled (boolean b); ★
  public abstract void setLabel (String label);
}
```

Interface Methods

disable

public abstract void disable() ☆

Description

> Disables the menu item's peer so that it is unresponsive to user interactions. Replaced by `setEnabled(false)`.

enable

public abstract void enable() ☆

Description

> Enables the menu item's peer so that it is responsive to user interactions. Replaced by `setEnabled(true)`.

setEnabled

public abstract void setEnabled (boolean b) ★

Parameters

> *b*
>
> > `true` to enable the peer; `false` to disable it.

Description

> Enables or disables the menu item's peer.

setLabel

public abstract void setLabel (String label)

Parameters

label

New text to appear on the menu item's peer.

Description

Changes the label of the menu item's peer.

public abstract interface java.awt.peer.MenuPeer
   extends java.awt.peer.MenuItemPeer {
  // Interface Methods
  public abstract void addItem (MenuItem item);
  public abstract void addSeparator();
  public abstract void delItem (int index);
}
```

Interface Methods

addItem

public abstract void addItem (MenuItem item)

Parameters

item

`MenuItem` to add to the menu's peer

Description

Adds a menu item to the menu's peer.

addSeparator

public abstract void addSeparator()

Description

Adds a menu separator to the menu's peer.

delItem

public abstract void delItem (int index)

Parameters

index

`MenuItem` position to delete from the menu's peer.

Description

Deletes a menu item from the menu's peer.

   extends java.awt.peer.MenuPeer {
  // Interface Methods
  public abstract void show (Event e);
}
```

Interface Methods

show

public abstract void show (Event e)

Parameters

e

A mouse down event that begins the display of the popup menu.

Description

Shows the peer at the location encapsulated in `e`.

See Also

`Event, MenuPeer`

ScrollbarPeer

Name

ScrollbarPeer

[Graphic: Figure from the text]

Description

`ScrollbarPeer` is an interface that defines the basis for scrollbar components.

Interface Definition

public abstract interface java.awt.peer.ScrollbarPeer
   extends java.awt.peer.ComponentPeer {
  // Interface Methods
  public abstract void setLineIncrement (int amount);
  public abstract void setPageIncrement (int amount);
  public abstract void setValues (int value, int visible, int minimum, int maximum);
}
```

Interface Methods

setLineIncrement

public abstract void setLineIncrement (int amount)

Parameters

amount

New line increment amount.

Description

Changes the line increment amount for the scrollbar's peer.

setPageIncrement

public abstract void setPageIncrement (int amount)

Parameters

amount

New paging increment amount.

Description

Changes the paging increment amount for the scrollbar's peer.

setValues

public abstract void setValues (int value, int visible, int minimum, int maximum)

Parameters

value

New value for the scrollbar's peer.

visible

New slider width.

minimum

New minimum value for the scrollbar's peer.

maximum

New maximum value for the scrollbar's peer.

Description

Changes the settings of the scrollbar's peer to the given amounts.

See Also

```

ScrollPanePeer ★

Name

ScrollPanePeer ★

[Graphic: Figure from the text]

Description

`ScrollPanePeer` is an interface that defines the basis for a scrolling container.

Interface Definition

```
public abstract interface java.awt.peer.ScrollPanePeer
   extends java.awt.peer.ContainerPeer {
  // Interface Methods
  public abstract void childResized (int w, int h);
  public abstract int getHScrollbarHeight();
  public abstract int getVScrollbarWidth();
  public abstract void setScrollPosition (int x, int y);
  public abstract void setUnitIncrement (Adjustable adj, int u);
  public abstract void setValue (Adjustable adj, int v);
}
```

Interface Methods

childResized

public abstract void childResized (int w, int h)

Parameters

w

The new child width.

h

The new child height.

Description

Tells the peer that the child has a new size.

getHScrollbarHeight

public abstract int getHScrollbarHeight()

Returns

Height that a horizontal scrollbar would occupy.

Description

The height is returned regardless of whether the scrollbar is showing or not.

getVScrollbarWidth

public abstract int getVScrollbarWidth()

Returns

Width that a vertical scrollbar would occupy.

Description

The width is returned regardless of whether the scrollbar is showing or not.

setScrollPosition

public abstract void setScrollPosition (int x, int y)

Parameters

x

The new horizontal position.

y

The new vertical position.

Description

Changes the coordinate of the child component that is displayed at the origin of the `ScrollPanePeer`.

setUnitIncrement

public abstract void setUnitIncrement (Adjustable adj, int u)

Parameters

adj

The `Adjustable` object to change.

u

The new value.

Description

Changes the unit increment of the given `Adjustable` object.

setValue

public abstract void setValue (Adjustable adj, int v)

Parameters

adj

The `Adjustable` object to change.

v

The new value.

Description

Changes the value of the given `Adjustable` object.

TextAreaPeer

Name

TextAreaPeer

[Graphic: Figure from the text]

Description

`TextAreaPeer` is an interface that defines the basis for text areas.

Interface Definition

```
public abstract interface java.awt.peer.TextAreaPeer
   extends java.awt.peer.TextComponentPeer {
  // Interface Methods
  public abstract Dimension getMinimumSize (int rows, int columns); ★
  public abstract Dimension getPreferredSize (int rows, int columns); ★
  public abstract void insert (String string, int position); ★
  public abstract void insertText (String string, int position); ☆
  public abstract Dimension minimumSize (int rows, int columns); ☆
  public abstract Dimension preferredSize (int rows, int columns); ☆
  public abstract void replaceRange (String string, int startPosition, int
endPosition); ★
  public abstract void replaceText (String string, int startPosition, int
endPosition); ☆
}
```

Interface Methods

getMinimumSize

public abstract Dimension getMinimumSize (int rows, int columns) ★

Parameters

rows

Number of rows within the text area's peer.

columns

Number of columns within the text area's peer.

Returns

The minimum dimensions of a text area's peer of the given size.

getPreferredSize

public abstract Dimension getPreferredSize (int rows, int columns) ★

Parameters

rows

Number of rows within the text area's peer.

columns

Number of columns within the text area's peer.

Returns

The preferred dimensions of a text area's peer of the given size.

insert

public abstract void insert (String string, int position) ★

Parameters

string

Content to place within the text area's peer.

position

Location at which to insert the content.

Description

Places additional text within the text area's peer.

insertText

public abstract void insertText (String string, int position) ☆

Parameters

string

Content to place within the text area's peer.

position

Location at which to insert the content.

Description

Places additional text within the text area's peer. Replaced by `insert(String, int)`.

minimumSize

public abstract Dimension minimumSize (int rows, int columns) ☆

Parameters

rows

Number of rows within the text area's peer.

columns

Number of columns within the text area's peer.

Returns

The minimum dimensions of a text area's peer of the given size. Replaced by `getMinimumSize(int, int)`.

preferredSize

public abstract Dimension preferredSize (int rows, int columns) ☆

Parameters

rows

Number of rows within the text area's peer.

columns

Number of columns within the text area's peer.

Returns

The preferred dimensions of a text area's peer of the given size. Replaced by `getPreferredSize(int, int)`.

replaceRange

public abstract void replaceRange (String string, int startPosition, int endPosition) ★

Parameters

string

New content to place in the text area's peer.

startPosition

Starting position of the content to replace.

endPosition

Ending position of the content to replace.

Description

Replaces a portion of the text area peer's content with the given text.

replaceText

public abstract void replaceText (String string, int startPosition, int endPosition) ☆

Parameters

string

New content to place in the text area's peer.

startPosition

Starting position of the content to replace.

endPosition

Ending position of the content to replace.

Description

Replaces a portion of the text area peer's content with the given text. Replaced by `replaceRange(String, int, int)`.

  public abstract void select (int selectionStart, int selectionEnd);
  public abstract void setCaretPosition (int pos); ★
  public abstract void setEditable (boolean state);
  public abstract void setText (String text);
}
```

Interface Methods

getCaretPosition

public abstract int getCaretPosition() ★

Returns

> The current position of the caret (text cursor).

getSelectionEnd

public abstract int getSelectionEnd()

Returns

> The ending cursor position of any selected text.

getSelectionStart

public abstract int getSelectionStart()

Returns

> The initial position of any selected text.

getText

public abstract String getText()

Returns

> The current contents of the text component's peer.

select

public abstract void select (int selectionStart, int selectionEnd)

Parameters

selectionStart

Beginning position of the text to select.

selectionEnd

Ending position of the text to select.

Description

Selects text in the text component's peer.

selectCaretPosition

public abstract void selectCaretPosition (int pos)

Parameters

pos

New caret position.

Description

Changes the position of the caret (text cursor).

setEditable

public abstract void setEditable (boolean state)

Parameters

state

`true` if the user can change the contents of the text component's peer (i.e., `true` to make the peer editable); `false` to make the peer read-only.

Description

Allows you to change the current editable state of the text component's peer.

setText

public abstract void setText (String text)

Parameters

text

New text for the text component's peer .

Description

Sets the content of the text component's peer.

  public abstract void setEchoChar (char echoChar); ★
  public abstract void setEchoCharacter (char c); ☆
}
```

Interface Methods

getMinimumSize

public abstract Dimension getMinimumSize (int rows) ★

Parameters

rows

Number of rows within the text field's peer.

Returns

The minimum dimensions of a text field's peer of the given size.

getPreferredSize

public abstract Dimension getPreferredSize (int rows) ★

Parameters

rows

Number of rows within the text field's peer.

Returns

The preferred dimensions of a text field's peer of the given size.

minimumSize

public abstract Dimension minimumSize (int rows) ☆

Parameters

rows

Number of rows within the text field's peer.

Returns

Replaced by `getMinimumSize(int)`.

preferredSize

public abstract Dimension preferredSize (int rows) ☆

Parameters

rows

Number of rows within the text field's peer.

Returns

Replaced by `getPreferredSize(int)`.

setEchoChar

public abstract void setEchoChar (char c) ★

Parameters

c

The character to display for all input.

Description

Changes the character that is displayed to the user for every character he or she types in the text field.

setEchoCharacter

public abstract void setEchoCharacter (char c) ☆

Parameters

c

The character to display for all input.

Description

Replaced by `setEchoChar(char)`.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

C.2 Test Program

The test program, `compList`, listed in Source Code shows the events peers pass along to the Java run-time system. You can then examine the output to see how the run-time system reacts to the different events. When you run `compList`, the screen looks something like the one in Figure C.1.

Figure C.1: Test program

[Graphic: Figure C-1]

How to Use the Program

Java does not have an automated record and playback feature, so the work is left for you to do. The program displays 10 components: `Label`, `Button`, `Scrollbar`, `List`, multiselection `List`, `Choice`, `Checkbox`, `TextField`, `TextArea`, and `Canvas` (the black box in Figure C.1). Basically, you must manually trigger every event for every component.

For *every* component on the screen (except Done), do the following:

With the mouse

Move the cursor over the object, press the mouse button and release, and drag the cursor over the object.

With the keyboard

Press and release an alphabetic key, press and release the Home and End keys, arrow keys, and function keys. Do this for every component, even for components like `Button` and `Label` that have no logical reason for using keyboard events.

For items with choices

Select and deselect a few choices; double-click and single-click selections.

For the scrollbar

Click on each arrow, drag the slider, and click in the paging area (the space between each arrow and the slider).

For the text field

Press Enter.

When finished

Press the Done button, and analyze the results. Run the program again (without exiting), and check the results again. Try to trigger any specific events that you expect but didn't appear in the output from the first pass. Generating some events requires a little work. For example, on a Macintosh, in order to get the `MOUSE_UP` and `MOUSE_DRAG` events, you must do a `MOUSE_DOWN` off the component; otherwise, the `MOUSE_DOWN`/`MOUSE_UP` combination turns into an `ACTION_EVENT`, if that component can generate it.

NOTE:

The SunTest business unit of Sun Microsystems has an early version of a record and playback Java GUI testing tool called JavaSTAR. Information about it is available at http://www.suntest.com/JavaSTAR/JavaSTAR.html. In the future, it may be possible to use JavaSTAR to help automate this process.

Source Code

The following is the source code for the test program:

```
import java.awt.*;
import java.util.*;
import java.applet.*;
public class compList extends Applet {
    Button done = new Button ("Done");
    Hashtable values = new Hashtable();
    public void init () {
        add (new Label ("Label"));
        add (new Button ("Button"));
        add (new Scrollbar (Scrollbar.HORIZONTAL, 50, 25, 0, 255));
        List l1 = new List (3, false);
        l1.addItem ("List 1");
        l1.addItem ("List 2");
        l1.addItem ("List 3");
        l1.addItem ("List 4");
        l1.addItem ("List 5");
        add (l1);
        List l2 = new List (3, true);
        l2.addItem ("Multi 1");
        l2.addItem ("Multi 2");
        l2.addItem ("Multi 3");
        l2.addItem ("Multi 4");
        l2.addItem ("Multi 5");
        add (l2);
        Choice c = new Choice ();
        c.addItem ("Choice 1");
        c.addItem ("Choice 2");
        c.addItem ("Choice 3");
        c.addItem ("Choice 4");
        c.addItem ("Choice 5");
        add (c);
        add (new Checkbox ("Checkbox"));
        add (new TextField ("TextField", 10));
        add (new TextArea ("TextArea", 3, 20));
        Canvas c1 = new Canvas ();
        c1.resize (50, 50);
        c1.setBackground (Color.blue);
        add (c1);
        add (done);
    }
    public boolean handleEvent (Event e) {
        if (e.target == done) {
            if (e.id == Event.ACTION_EVENT) {
                System.out.println (System.getProperty ("java.vendor"));
                System.out.println (System.getProperty ("java.version"));
                System.out.println (System.getProperty ("java.class.version"));
                System.out.println (System.getProperty ("os.name"));
                System.out.println (values);
            }
        }else {
            Vector v;
            Class c = e.target.getClass();
            v = (Vector)values.get(c);
            if (v == null)
                v = new Vector();
            Integer i = new Integer (e.id);
            if (!v.contains (i)) {
                v.addElement (i);
                values.put (c, v);
            }
        }
        return super.handleEvent (e);
    }
}
```

An HTML document to display the applet in a browser should look something like the following:

```
<APPLET code="compList.class" height=300 width=300>
</APPLET>
```

Examining Results

The results of the program are sent to standard output when you click on the Done button. What happens to the output depends on the platform. It may be sent to a log file (Internet Explorer), the Java Console (Netscape Navigator), or the command line (appletviewer). The following is sample output from Internet Explorer 3.0 on a Windows 95 platform.

```
Microsoft Corp.
1.0.2
45.3
Windows 95
{class java.awt.Canvas=[504, 503, 1004, 501, 506, 502, 505, 1005,
401, 402, 403, 404], class java.awt.Choice=[1001, 401, 402, 403,
404], class java.awt.Checkbox=[1001, 402, 401, 403, 404], class
compList=[504, 503, 501, 506, 502, 505, 1004, 1005], class java.
awt.TextField=[401, 402, 403, 404], class java.awt.List=[701,
1001, 401, 402, 403, 404, 702], class java.awt.Scrollbar=[602,
605, 604, 603, 601], class java.awt.TextArea=[401, 402, 403, 404],
class java.awt.Button=[1001, 401, 402, 403, 404]}
```

In addition to some identifying information about the run-time environment, the program displays a list of classes and the events they passed. The integers represent the event constants of the `Event` class; for example, `Canvas` received events with identifiers 504, 503, etc. The events are not sorted, so you can see the order in which they were sent. Unfortunately, you have to look up these constants in the source code yourself. The class listed as `compList` is the applet itself and shows you the events that the `Applet` class receives.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

D.2 A Brief Tour of sun.awt.image

The classes in `sun.awt.image` do the behind-the-scenes work for rendering an image from a file or across the network. This information is purely for the curious; you should never have to work with these classes yourself.

`Image`

The `Image` class in this package represents a concrete `Image` instance. It contains the basis for the `Image` class that is actually used on the run-time platform, which exists in the package for the specific environment. For instance, the `sun.awt.win32` package includes the `W32Image` (Java 1.0), the `sun.awt.windows` package includes `WImage` (Java 1.1), while the `sun.awt.motif` package includes the `X11Image`, and the `sun.awt.macos` package includes the `MacImage`.

`ImageRepresentation`

The `ImageRepresentation` is the `ImageConsumer` that watches the creation of the image and notifies the `ImageObserver` when it is time to update the display. It plays an important part in the overall control of the `Image` production process.

Image sources

A Java image can come from three different sources: memory (through `createImage()`), local disk, or the network (through `getImage()`).

- `OffScreenImageSource` implements `ImageProducer` for a single framed image in memory. When an `Image` created from an `OffScreenImageSource` is drawn with `drawImage()`, the `ImageObserver` parameter can be `null` since all the image information is already in memory and there is no need for periodic updating as more is retrieved from disk. You can get the graphics context of `OffScreenImageSource` images and use the context to draw on the image area. This is how double buffering works.

- `InputStreamImageSource` implements `ImageProducer` for an image that comes from disk or across the network. When an `Image` created from an `InputStreamImageSource` is drawn with `drawImage()`, the `ImageObserver` parameter should be the component being drawn on (usually `this`) since the image information will be loaded periodically with the help of the `ImageObserver` interface). This class determines how to decode the image type and initializes the `ImageDecoder` to one of `GifImageDecoder`, `JPEGImageDecoder`, or `XbmImageDecoder`, although that can be overridden by a subclass. It can use a `ContentHandler` to work with unknown image types.

- `FileImageSource` is a subclass of `InputStreamImageSource` for images that come from the filesystem. It uses the filename to determine the type of image to decode and checks the security manager to ensure that access is allowed.

- `URLImageSource` is a subclass of `InputStreamImageSource` for images that are specified by a URL.

- `ByteArrayImageSource` (Java 1.1 only) is a subclass of `InputStreamImageSource` for images that are created by calling `Toolkit.createImage(byte[])`.

Image decoders

An `ImageDecoder` is utilized to convert the image source to an image object. If there is no decoder for an image type, it can be read in with the help of a `ContentHandler` or your own class that implements `ImageProducer`, like the `PPMImageDecoder` shown in *Chapter 12, Image Processing*.

- `GifImageDecoder` reads in an image file in the GIF format.

- `JPEGImageDecoder` reads in an image file in the JPEG format.

- `XbmImageDecoder` reads in an image file in the XBM format. Although XBM support is not required by the language specification, support is provided with Netscape Navigator, Internet Explorer, HotJava, and the Java Developer's Kit from Sun.

`ImageFetcher`

The `ImageFetcher` class fetches the actual image from its source. This class creates a separate daemon thread to fetch each image. The thread is run at a higher priority than the default but not at the maximum priority.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.2 New Language Features in Java 1.1

Although Java 1.1 is a massive new release, there are relatively few changes to the Java language in this version. The new features of the language are quite significant, however, as they add useful functionality and make the Java language even more elegant. Here is a brief summary of the new features of the Java language in Java 1.1:

- The addition of inner classes is the largest change to the Java language in Java 1.1. With this new feature, classes can be defined as members of other classes, just like variables and methods. Classes can also be defined within blocks of Java code, just like local variables. A class that is declared inside of another class may have access to the instance variables of the enclosing class; a class declared within a block may have access to the local variables and/or formal parameters of that block.

  Inner classes include: nested top-level classes and interfaces, member classes, local classes, and anonymous classes. The various types of inner clases are described in Inner Classes. The syntax for nested top-level and member classes is covered in Nested Top-Level and Member Classes, while the syntax for nested top-level interfaces is covered in Nested Top-Level Interfaces. The syntax for local classes is described in Local Classes. The syntax for an anonymous class is part of an allocation expression, as covered in Allocation Expressions.

- Java 1.1 provides the ability to declare `final` local variables, method parameters, and `catch` clause parameters. `final` local variables, method parameters, and `catch` parameters are needed to allow local classes to access these entities within the scope of their blocks. The syntax for `final` local variables is described in Local Variables, while `final` method parameters are covered in Method formal parameters. The new syntax for the `catch` clause is described in The try Statement.

- Instance initializers are blocks of code that execute when an instance of a class is created. Instance initializers have been added in Java 1.1 to allow anonymous classes to perform any necessary initialization, since anonymous classes can not define any constructors. The syntax for instance initializers is covered in Instance Initializers.

- As of Java 1.1, `final` variable declarations do not have to include initializers. A `final` variable declaration that does not include an initializer is called a blank final. The functionality of blank finals is described in Variable modifiers and Final local variables.

- A class literal is a new kind of primary expression that can be used to obtain a `Class` object for a particular data type. Class literals have been added to support the new Reflection API in Java 1.1. The syntax for class literals is covered in Class Literals.

- An anonymous array is an array created and initialized without using a variable initializer. The syntax for an anonymous array is part of an allocation expression, as described in Allocation Expressions.

A "Hello World" Program | BOOK INDEX | Compiling a Java Source File

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.3 Compiling a Java Source File

The interface for the Java compiler in Sun's Java Development Kit (JDK) is the command line. To compile a Java program, run the program *javac* with the name of the source file specified as a command-line argument. For example, to compile the "Hello World" program, issue the following command:

```
C:\> javac HelloWorld.java
```

The Java compiler, *javac*, requires that the name of a Java source file end with a *.java* extension. If the source file contains a class or interface that is declared with the keyword `public`, the filename must be the name of that class or interface. There can be at most one such class or interface in a source file.

In an environment such as Windows 95 that does not distinguish between uppercase and lowercase letters in a filename, you still need to be sure that the case of the filename exactly matches the case used in the `public` class or interface declaration. If you use a filename with the incorrect case, the compiler will be able to compile the file but it will complain about an incorrect filename.

The compiler produces a compiled class file with the same name as the `public` class or interface declaration; the file extension used for a compiled Java file is *.class*.

If the *javac* compiler complains that it is unable to find some classes, it may mean that an environment variable named `CLASSPATH` has not been set properly. The exact setting needed for `CLASSPATH` varies depending on the operating system and its directory structure. However, the value of `CLASSPATH` always specifies a list of directories in which the compiler should search for Java classes.

1.4 Running a Java Application

To run a Java application, you invoke the Java interpreter, *java*, with one or more arguments. The first argument is always the name of a Java class. Here is how to run the "Hello World" application:

```
C:\> java HelloWorld
```

The capitalization of the class name must match the name used in the class declaration in the source file. The interpreter loads the specified class and then calls its `main()` method.

A class can belong to a particular package. This allows the class to prevent classes in other packages from accessing its declared variables and methods. If a class is not specified as part of a package, it automatically becomes part of the default package. Because the `HelloWorld` class is part of the default package, you do not need to include the package name as part of the class name on the command line. If the `HelloWorld` class were part of a package called `student.language`, however, you would have to include the package name on the command line. For example, you would run the application as follows:

```
C:\> java student.language.HelloWorld
```

Any additional arguments specified on the command line are passed to the `main()` method in its `String[]` parameter. For the "Hello World" application, the `String[]` parameter is an empty array. If, however, there were command-line arguments, the first array element, `String[0]`, would correspond to the first command-line argument specified after the class name, `String[1]` would correspond to the next command-line element, and so on. The name of the class does not appear as an element in the array of parameters passed to the `main()` method. This is different than in C/C++, where the first element in the array of command-line arguments identifies the program name and the second element is the first command-line argument.

1.5 Notational Conventions

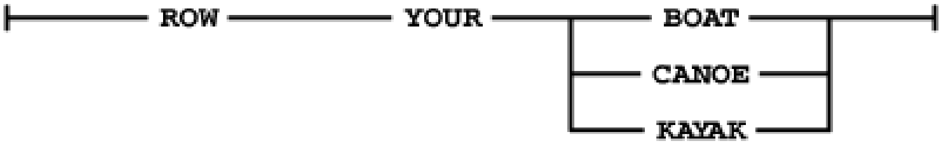
One of the topics of this manual is the *syntax* of Java: the way that identifiers such as `foobar`, operators such as `+`, and punctuation such as `;` can be put together to form a valid Java program. This book also talks about *lexical structure* : the sequences of characters that can be put together to form valid numbers, identifiers, operators, and the like.

To describe syntax and lexical structure, many language reference manuals use a notation called BNF. BNF notation is very helpful to language implementors because it defines language constructs in a way that can easily be turned into a working language parser. Unfortunately, however, BNF can be difficult for human beings to understand. This reference manual uses a different notation, called a *railroad diagram*, to describe syntax and lexical structure. Railroad diagrams are much easier for people to understand. A railroad diagram provides a visual means of specifying the sequence of words, symbols, and punctuation that can be used to write a syntactic construct or a lexical structure.

Here is a simple example:

The idea is to follow the lines from left to right. The sequence of words or symbols that you pass along the way is the sequence of words or symbols that the railroad diagram specifies. The primary rule when navigating railroad diagrams is that you can follow lines from left to right only, unless there is an arrow pointing to the left. In the above example, there are no arrows, so there is only one way to navigate through the diagram. Therefore, the above railroad diagram specifies exactly one sequence of words: `ROW YOUR BOAT`.

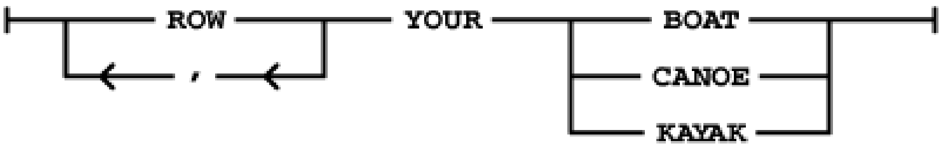
The next example provides you with a choice of sequences:



You can navigate the above diagram with one of three sequences:

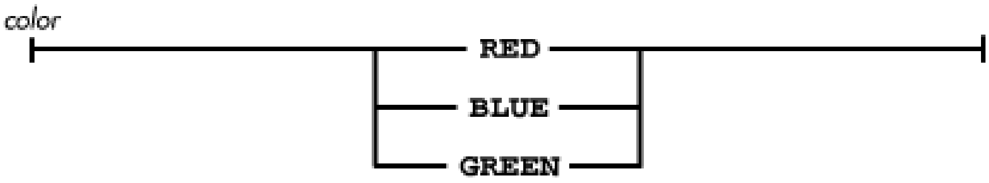
- `ROW YOUR BOAT`
- `ROW YOUR CANOE`
- `ROW YOUR KAYAK`

The following example contains an arrow:

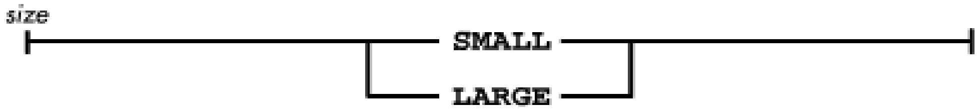


In the above diagram, there is a left-pointing arrow on the line under the word `ROW`. That arrow means that the line can only be traversed from right to left. The line with the arrow provides a loop that allows the word `ROW` to be repeated one or more times, separated by commas. This allows a sequence like: `ROW,ROW,ROW YOUR BOAT`.

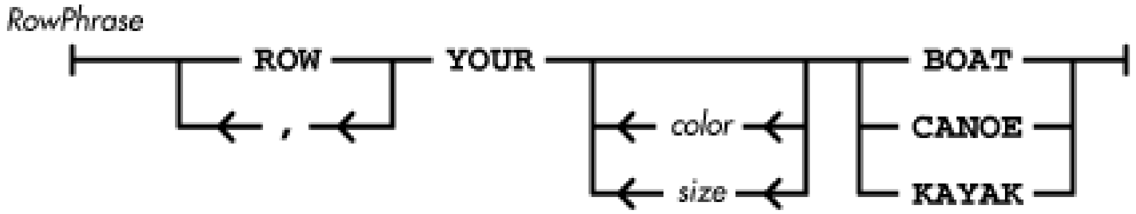
The railroad diagrams shown so far lack a feature that is typically needed to make them useful: a name. A name allows one railroad diagram to refer to another diagram. The following railroad diagram defines a construct named *color* :



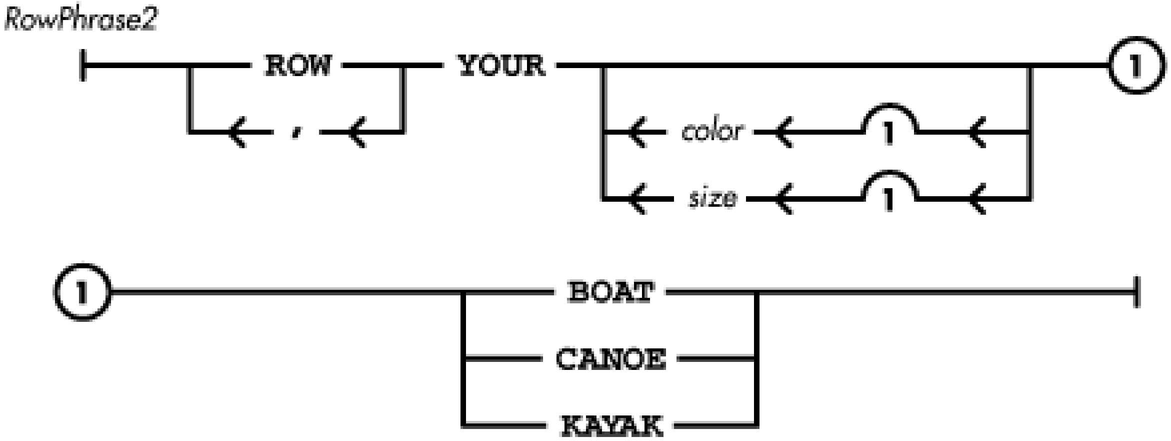
To further illustrate this point, let's look at two more railroad diagrams. The first diagram defines a construct named *size* :



The second railroad diagram is similar to previous ones except that now it allows an optional color or size to precede `BOAT`, `CANOE`, or `KAYAK`. The diagram does this by referring to the names of the railroad diagrams that define these things:



In the diagrams in this book, the font for words such as ROW that are directly contained in railroad diagrams is different from the font used for words like *color* that are names of railroad diagrams. The preceding railroad diagram allows *size* and *color* to occur more than once. The next diagram limits size and color to at most one occurrence:



The lines that refer to the *size* and *color* diagrams both have semi-circles with the number one under them. The semi-circles represent bridges that collapse if crossed more than a certain number of times. The number under the semi-circle is the number of times a bridge can be crossed. Adding bridges that can be crossed only once creates a railroad diagram that permits no more than one occurrence of *color* and *size*.

The other new feature introduced in the above railroad diagram is a circle enclosing a number. These circles are connectors used when a diagram does not fit across a page. The numbered connector at the right end of one part of a railroad diagram attaches to a connector with a matching number at the left end of another part of the railroad diagram.

2.2 Tokenization

The tokenization phase of lexical analysis in Java handles breaking down the lines of Unicode source code into comments, white space, and tokens. The rule that defines the overall lexical organization of Java programs is *TokenStream:*

[Graphic: Figure from the text]

References Comments; Identifiers; Keywords; Literals; Operators; Separators; White Space

Identifiers

An *identifier* is generally used as the name for a thing in a program. A few identifiers are reserved by Java for special uses; these are called *keywords*.

From the viewpoint of lexical analysis, an identifier is a sequence of one or more Unicode characters. The first character must be a letter, underscore, or dollar sign. The other characters must be letters, numbers, underscores, or dollar signs. An identifier can't have the same Unicode character sequence as a keyword:

[Graphic: Figure from the text]

For example, `foo21`, `_foo`, and `$foo` are all valid identifiers; `3foo` is not a valid identifier. There is no limit to the length of an identifier in Java. Although `$` is a legal character in an identifier, you should avoid using it to eliminate confusion with compiler-generated identifiers.

A *UnicodeDigit* is a Unicode character that is classified as a digit by `Character.isDigit()`.

A *UnicodeLetter* is a Unicode character code that is classified as a letter by `Character.isLetter()`.

Two identifiers are the same if they have the same length and if corresponding characters in each identifier have the same Unicode character code. It is possible, however, to have identifiers that are distinct to a Java compiler, but not to the human eye. For example, the Java compiler recognizes lowercase Latin `a' (`\u0061`) and lowercase Cyrillic `a' (`\u0430`) as different characters, although they may well be visually indistinguishable.

References Character; Keywords

Keywords

Keywords are identifiers that have a special meaning to Java. Because of their special meanings, keywords are not available for use as names of things defined in programs. A *Keyword* is one of the following:

```
abstract
boolean
break
byte
case
catch
char
class
default
do
double
else
extends
false
final
finally
goto
if
implements
import
instanceof
int
interface
long
null
package
private
protected
public
return
short
static
synchronized
this
throw
throws
transient
true
try
void
```

```
const    float   native    super    volatile
continue for     new       switch   while
```

The keywords `const` and `goto` are not currently used for any purpose in Java, although they may be assigned meaning in future versions of the Java language.

References Identifiers

Literals

A *literal* is a token that represents a constant value of a primitive data type or a `String` object:

[Graphic: Figure from the text]

References Boolean literals; Character literals; Floating-point literals; Integer literals; String literals

Integer literals

An integer literal represents an integer constant:

[Graphic: Figure from the text]

NonZeroDigit is defined as one of the following characters: `1`, `2`, `3`, `4`, `5`, `6`, `7`, `8`, or `9`.

OctalDigit is defined as one of the following characters: `0`, `1`, `2`, `3`, `4`, `5`, `6`, or `7`.

Integer literals that begin with a non-zero digit are in base 10 and are called *decimal literals*. Integer literals that begin with `0x` are in base 16 and are called *hexadecimal literals*. Integer literals that begin with `0` followed by `0-7` are in base 8 and are called *octal literals*.

If an integer literal ends with `L` or `l`, its type is `long`; otherwise its type is `int`.

Integer literals cannot begin with a `+` or a `-`. If either of these characters precedes an integer literal, it is treated as a unary operator, a separate token in its own right.

Here are some examples of `int` literals:

```
0
92
0642
0xDeadBeef
```

Here are some examples of `long` literals:

```
0L
1414213562373l
0x2000000000L
075204l
```

Note that the preceding examples end with either an uppercase or lowercase "L". They do not end with the digit 1 (one).

Decimal literals of type `int` may not be greater than 2147483647, which represents 2^31-1. Decimal literals of type `long` may not be greater than 9223372036854775807L, which represents 2^63-1. Decimal literals cannot be used directly to represent negative values. To represent negative values using a decimal literal, you must use the decimal literal in conjunction with the unary minus operator. For example, representing -321 requires the use of a unary minus and a decimal literal. To represent the `int` -2147483648, use `0x80000000`. To represent the `long` -9223372036854775808L, use `0x8000000000000000L`.

Hexadecimal and octal literals may be positive or negative because they represent either a 32-bit (`int`) or 64-bit (`long`) two's-complement quantity. Two's complement is a binary encoding technique that represents both positive and negative values. The range of values that can be represented by `int` hexadecimal and octal literals is shown in Table 2-1.

Table 2.1: Minimum and Maximum int Literals

Representation	**Minimum Value**	**Maximum Value**
Hexadecimal	`0x80000000`	`0x7fffffff`
Octal	`020000000000`	`017777777777`
Base 10 equivalent	`-2147483648`	`2147483647`

The range of values that can be represented by `long` hexadecimal and octal literals is shown in Table 2-2.

Table 2.2: Minimum and Maximum long Literals

Representation	**Minimum Value**	**Maximum Value**
Hexadecimal	`0x8000000000000000L`	`0x7fffffffffffffffL`
Octal	`01000000000000000000000L`	`0777777777777777777777L`
Base 10 equivalent	`-9223372036854775808`	`9223372036854775807`

References **UNKNOWN XREF**; **UNKNOWN XREF**; Integer types; Conversion to Unicode; Unary Operators

Floating-point literals

A floating-point literal represents a constant value of type `float` or `double` :

[Graphic: Figure from the text]

A floating-point literal must minimally contain at least one digit and either a decimal point or an exponent.

The data type of a floating-point literal is `float` if and only if the suffix `f` or `F` appears at the end of the literal. If there is no suffix or the suffix is `d` or `D`, the data type is `double`.

Floating-point literals cannot begin with a `+` or a `-`. If either of these precedes a floating-point literal, it is treated as a separate token, a unary operator.

Here are some examples of `float` literals:

```
23e4f
1.E2f
.31416e1F
2.717f
7.63e+9f
```

Here are some examples of `double` literals:

```
23e4
1.E2
.31415e1D
2.717
7.53e+9d
```

The ranges of values that can be represented by `float` and `double` literals are shown in Table 2-3.

Table 2.3: Minimum and Maximum Floating-Point Literals

Representation	**Minimum Value**	**Maximum Value**
float	`1.40239846e-45f`	`3.40282347e38f`
double	`4.94065645841246544e-324`	`1.79769313486231570e308`

Floating-point literals that exceed these limits are treated as errors by the Java compiler. The special floating-point values positive infinity, negative infinity, and not-a-number are available as predefined constants in Java, as part of the `Float` and `Double` classes.

References **UNKNOWN XREF**; Floating-point types; Unary Operators; Double; Float

Boolean literals

There are two `boolean` literal values, represented by the keywords `true` and `false:`

[Graphic: Figure from the text]

References Boolean Type

Character literals

A character literal represents a constant value of type `char` (an unsigned 16-bit quantity). A character literal consists of either the character being represented, or an equivalent escape sequence, enclosed in single quotes:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

Here are some examples of character literals:

```
'c'
'n'
'\\'
'\u0138'
```

The character sequence `\u`*xxxx* is not defined above as a valid *Escape*, even though it can be used as a legal character literal. This sequence of characters is defined as an *EscapedSourceCharacter*, which is handled during the pre-processing phase, before tokenization takes place. As a result, the tokenization phase never sees an *EscapedSourceCharacter*. Tokenization sees only the single Unicode character that replaces the *EscapedSourceCharacter* during pre-processing.

The translations of the different types of escape sequences supported in Java are shown in Table 2-4.

Table 2.4: Java Escape Sequences

Escape Sequence	**Unicode Equivalent**	**Meaning**
`\b`	`\u0008`	Backspace
`\t`	`\u0009`	Horizontal tab
`\n`	`\u000a`	Linefeed
`\f`	`\u000c`	Form feed
`\r`	`\u000d`	Carriage return
`\"`	`\u0022`	Double quote

\'	\u0027	Single quote
\\	\u005c	Backslash
\xxx	\u0000 to \u00ff	The character corresponding to the octal value *xxx*

A character literal representing a carriage return character can be written only as '\r'; a character literal representing a linefeed character can be written only as '\n'. During the pre-processing that precedes token recognition, these characters are classified as line terminators, so neither carriage return (\u000d) nor linefeed (\u000a) characters in Java source code can ever be seen by the Java compiler as being part of a character literal.

If a backslash that is not part of a legal *Escape* appears in a character literal, it is flagged as an error. This is different from languages like C++ that ignore backslashes in character literals that are not part of an escape.

References Conversion to Unicode; Integer types; **UNKNOWN XREF**

String literals

A string literal represents a constant string value and consists of the characters in the string or the equivalent escapes:

[Graphic: Figure from the text]

Here are some examples of string literals:

```
""                           // the empty string
"Hello World"
"This has \"escapes\"\n"     // a string literal with escapes
```

There is no primitive type for representing strings in Java. Instead, each string literal becomes a reference to a String object. If two or more string literals consist of the same sequence of characters, they refer to the same String object. Using one String object to represent multiple string literals works because, once created, the contents of a String object cannot be changed.

For a string literal to contain a carriage return or linefeed character, the carriage return or linefeed must be written as \r or \n. Neither carriage return (\u000d) nor linefeed (\u000a) characters in Java source code can ever be seen by the Java compiler as part of a string literal. These characters are classified as line terminators during the pre-processing phase that precedes token recognition. For the same reason, `\u` Unicode escapes for carriage return and linefeed characters cannot be directly used in string literals.

If a backslash that is not part of a legal *Escape* appears in a string literal it is flagged as an error. This is different from languages like C++ that ignore backslashes in string literals that are not part of an escape.

Because operations on strings are generally based on the length of the string, Java does not automatically supply a NUL character (`\u0000`) at the end of a string literal. For the same reason, it is not customary for Java programs to put a NUL character at the end of a string.

References *Escape* 2.2.3.4; Specially supported classes; String; StringBuffer; String Concatenation Operator +

Separators

A *separator* is any one of the punctuation tokens in the following railroad diagram:

[Graphic: Figure from the text]

Separator tokens are used to separate other types of tokens. Thus, separators are a part of a higher-level syntactic construct. Although separators have syntactic significance, they do not imply any operation on data.

Operators

An operator is a token that implies an operation on data. Java has both assignment and non-assignment operators:

[Graphic: Figure from the text]

A *NonAssignmentOperator* is one of the following:

```
+ - <= ^   ++
< * >= %   --
  / != ?   >>
! & == :   >>
~ | && >>>
```

An *AssignmentOperator* is one of the following:

```
=   -=  *=
/=  |=  &=
^=  +=  %=
<<= >>= >>>=
```

Unlike C/C++, Java does not have a comma operator. Java does allow a comma to be used as a separator in the header portion of `for` statements, however. Java also omits a number of other operators found in C and C++. Most notably, Java does not include operators for accessing physical memory as an array of bytes, such as `sizeof`, `unary & (address of)`, `unary * (contents of)`, or `-> (contents of field)`.

Comments

Java supports three styles of comments:

- A standard C-style comment, where all of the characters between `/*` and `*/` are ignored.
- A single-line comment, where all of the characters from `//` to the end of the line are ignored.
- A documentation comment that begins with `/**` and ends with `*/`. These comments are similar to standard C-style comments, but the contents of a documentation comment can be extracted to produce automatically generated documentation.

The formal definition of a comment is:

[Graphic: Figure from the text]

C-style comments and documentation comments do not nest. For example, consider the following arrangement of comments:

```
/*   ...   /*   ...   */   ...   */
```

The Java compiler interprets the first `*/` to be the end of the comment, so that what follows is a syntax error.

However, in a single-line comment (i.e., one that starts with `//`), the sequences `/*`, `/**`, and `*/` have no special meaning. Similarly, in a C-style comment or a documentation comment (i.e., comments that begin with `/*` or `/**`), the sequence `//` has no special meaning.

In order to comment out large chunks of code, you need to adopt a commenting style. The C/C++ practice of using `#if` to comment out multiple lines of code is not available for Java programs because Java does not have a conditional compilation mechanism. If you use C-style comments in your code, you'll need to use the `//` style of comment to comment out multiple lines of code:

```
///*
// * Prevent instantiation of RomanNumeral objects without
// * parameters.
// */
//    private RomanNumeral() {
//        super();
//    }
```

The `/*  */` style of comment cannot be used to comment out the lines in the above example because the example already contains that style of comment, and these comments do not nest.

If, however, you stick to using the `//` style of comment in your code, you can use C-style comments to comment out large blocks of code:

```
/*
```

```
*// Prevent instantiation of RomanNumeral objects without
*// parameters.
*    private RomanNumeral() {
*        super();
*     }
*/
```

Which style you choose is less important than using it consistently, so that you avoid inadvertently nesting comments in illegal ways.

References Documentation Comments; Division of the Input Stream into Lines

White Space

White space denotes characters such as space, tab, and form feed that do not have corresponding glyphs, but alter the position of following glyphs. White space and comments are discarded. The purpose of white space is to separate tokens from each other:

[Graphic: Figure from the text]

SpaceCharacter is equivalent to `\u0020`.

HorizontalTabCharacter is equivalent to `\u0009` or `\t`.

FormFeedCharacter is equivalent to `\u000C` or `\f`.

EndOf FileMarker is defined as `\u001A`. Also known as Control-Z, this is the last character in a pre-processed compilation unit. It is treated as white space if it is the last character in a file, to enhance compatibility with older MS-DOS programs and other operating environments that recognize `\u001A` as an end-of-file marker.

3.2 Reference Types

Java is an object-oriented language. An object is a collection of variables and associated methods that is described by a class. The concepts in this section that relate to objects are discussed in detail in Object-Orientation Java Style.

The name of a class can be used as a type, so you can declare an object-type variable or specify that a method returns an object. If you declare a variable using the name of a class for its type, that variable can contain a *reference* to an object of that class. Such a variable does not contain an actual object, but rather a reference to the class instance, or object, the variable refers to. Because using a class name as a type declares a reference to an object, such types are called *reference types*. Java also allows the use of an interface name to specify a reference type. In addition, array types in Java are reference types because Java treats arrays as objects.

The two main characteristics of objects in Java are that:

- Objects are always dynamically allocated. The lifetime of the storage occupied by an object is determined by the program's logic, not by the lifetime of a procedure call or the boundaries of a block. The lifetime of the storage occupied by an object refers to the span of time that begins when the object is created and ends at the earliest time it can be freed by the garbage collector.

- Objects are not contained by variables. Instead, a variable contains a reference to an object. A reference is similar to what is called a pointer in other languages. If there are two variables of the same reference type and one variable is assigned to the other, both variables refer to the same object. If the information in that object is changed, the change is visible through both variables.

Java references are very similar to pointers in C/C++, but they are not at all related to the C++ notion of a reference. The main difference between Java references and C++ pointers is that Java does not allow any arithmetic to be done with references. This, coupled with Java's lack of any way to explicitly deallocate the storage used by reference type values, guarantees that a reference can never point to an illegal address.

The formal definition of a reference type is:

[Graphic: Figure from the text]

It is possible to cause a reference variable to contain a reference to nothing by assigning the special value represented by the keyword `null` to the variable. The value `null` can be assigned to any reference variable without a type cast.

Java does not allow reference types to be cast to primitive data types or primitive data types to be type cast to reference types. In particular, unlike C/C++, there is no conversion between integer values and references.

The only operation that Java provides for reference-type variables is the ability to fetch the referenced object. However, Java does not provide an operator to fetch the object referenced by a reference variable. Instead, the object fetch operation is performed implicitly by the following operations:

- A field expression that accesses a variable or method of a class or interface object
- A field expression that accesses an element of an array object
- A type comparison operation that uses the `instanceof` operator

References Array Types; *ClassOrInterfaceName* 4.1.6; Class Types; Field Expressions; Interface Types; null; Object-Orientation Java Style; Primitive Types; The instanceof Operator

Class Types

The name of a class can be used to specify the type of a reference. If a variable is declared as a class type, the variable either contains `null` or a reference to an object of that class or a subclass of that class. It is not allowed to contain any other kinds of values. For example:

```
class Shape { ... }
class Triangle extends Shape { ... }
...
Shape s;
Triangle t;
...
s = t;
```

This example declares a class called `Shape` and a subclass of `Shape` called `Triangle`. The code later declares a reference variable called `s` that can contain a reference to a `Shape` object and another variable called `t` that can contain a reference to a `Triangle` object. The value of `s` can be assigned to the value of `t` because an object is not only an instance of its declared class, but also an instance of every superclass of its declared class. Since instances of the `Triangle` class are also instances of its superclass `Shape`, the Java compiler has no problem with `s = t`.

However, saying `t = s` generates an error message from the compiler. Java does not allow a reference variable declared as a class type to contain a reference to a superclass of the declared class. The assignment `t = s` is illegal because `Shape` is a superclass of `Triangle`. The assignment can be accomplished if `s` is first cast to a reference to `Triangle`:

```
t = (Triangle)s;
```

The cast operation ensures that the object referenced by `s` is a class type that is either `Triangle` or a descendant of `Triangle`. When you cast an object reference to a subclass of the reference type, you are saying that you want to treat the object being referenced as an instance of the specified subclass. If the compiler cannot determine whether the argument of a cast will be of the required type, the compiler generates runtime code that ensures that the argument really is an instance of the specified subclass. At runtime, if the class of the object being referenced is not an instance of the specified subclass, a `ClassCastException` is thrown.

References Casts; Classes; Class Declarations; Object Allocation Expressions; Runtime exceptions

Specially supported classes

Java provides special support for the `String` and `StringBuffer` classes. All string literals are compiled into `String` objects. The result of a string concatenation operation is a `String` object. An intermediate `StringBuffer` object is used to compute the result of a concatenation operation. Because operations on strings are generally based on the length of the string, Java does not automatically supply a NUL character (`\u0000`) at the end of a string literal. For the same reason, it is not customary for Java programs to put a NUL character at the end of a string.

Java also provides special support for the `Object` class. This class is the ultimate superclass of all other classes in Java. If a class is declared without its superclass being specified, the language automatically specifies `Object` as its superclass.

The `throw` statement in Java is special, in that it requires the use of a `Throwable` object.

References Object; String; StringBuffer; String Concatenation Operator +; String literals; The throw Statement; Throwable

Interface Types

The name of an interface can be used to specify the type of a reference. A reference variable declared using an interface name as its type can only reference instances of classes that implement that interface. For example, Java provides an interface called `Runnable`. Java also provides a class called `Thread` that implements `Runnable`. This means that the following assignment is allowed:

```
Runnable r;
r = new Thread();
```

The Java compiler does not allow a value to be assigned to a variable declared using an interface type unless the compiler can be sure that the object referenced by the value implements the specified interface. Casting a reference variable to an interface type allows the variable to be assigned to that interface type, because the cast operation provides its own guarantee that the object implements the specified interface. Unless the compiler is able to determine the actual class of the object that will be referenced at runtime, the cast produces code that verifies at runtime that the object being cast really does implement the specified interface. At runtime, if the object being cast does not implement the required interface, a `ClassCastException` is thrown.

References Casts; Interfaces; Interface Declarations; Object Allocation Expressions; Runtime exceptions

Array Types

An array is a special kind of object that contains values called *elements*. Array elements are similar to variables in that they contain values that can be used in expressions and set by assignment operations. Elements differ from variables, however, in that they do not have names. Instead, they are identified by non-negative integers. The elements in an array are identified by a contiguous range of integers from 0 to one less than the number of elements in the array. The elements of an array must all contain the same type of value; the type of the array is specified when the array is created.

An array-type variable is declared as follows:

```
int [] a;
```

This declaration specifies that the variable `a` refers to an array of `int` values. Java actually allows two styles of array declarations: the one shown above and a style that is more like that used in C/C++. In other words, you can put the square brackets after the variable name instead of after the type:

```
int a[];
```

Technically, all arrays in Java are one-dimensional. However, Java does allow you to declare an array of arrays, which is a more flexible data structure than a multi-dimensional array. The additional flexibility comes from the fact that the arrays in an array of arrays do not have to be the same length. Because arrays of arrays are typically used to represent multi-dimensional arrays, this book refers to them as multi-dimensional arrays, even though that is not precisely correct.

A multi-dimensional array is declared using multiple pairs of square brackets, as in the following examples:

```
int [][] d2;       // Refers to a 2-dimensional array
int [][][] d3;     // Refers to a 3-dimensional array
```

When you declare a variable to refer to a multi-dimensional array, the number of dimensions in the array is determined by the number of pairs of square brackets. Whether the brackets follow the type name or the variable name is not important. Thus, the above variables could have been declared like this:

```
int [] d2[],       // Refers to a 2-dimensional array
       d3[][];     // Refers to a 3-dimensional array
```

The actual length of each dimension of an array object is specified when the array object is created, not when the array variable is declared. An array object is not created at the same time that an array variable is declared. An array object is created with the `new` operator. Here are some examples:

```
int j[] = new int[10];          // An array of 10 ints
int k[][] = new float[3][4];  // An array of 3 arrays of 4 floats
```

The arrays contained in an array of arrays can also be of different lengths:

```
int a[][] = new int [3][];
a[0] = new int [5];
a[1] = new int [6];
a[2] = new int [7];
```

Although the first `new` operator is creating a two-dimensional array, only the length of one dimension is specified. In this case, just the array of arrays is created. The subarrays are created by the subsequent `new` operators.

The expression used to specify the length of an array does not have to be a constant. Consider the following example:

```
int[] countArray(int n){
    int[] a = new int[n];
    for (int i=0; i<n; i++) {
        a[i]=i+1;
    }
    return a;
}
```

The number of elements in an array object is fixed at the time that the array object is created and cannot be changed.[2] Every array object has a public variable called `length` that contains the number of elements in the array. The variable `length` is `final`, which means that its value cannot be changed by assignment.

> [2] The standard class `java.util.Vector` implements an array-like object with a length that can be changed.

The Java notion of arrays is fundamentally different than that of C/C++. Subscripting a Java array does not imply pointer arithmetic, so there is no danger of an out-of-range index accessing memory that shouldn't be accessed. Array objects in Java detect out-of-range subscripts; when they do they throw an `ArrayIndexOutOfBoundsException`. And unlike C/C++, arrays of type `char` are not strings in Java. Instead, Java uses the `String` class to support strings.

Although array objects are reference types, array objects are different from other kinds of objects. The `Object` class is the parent class of all array objects, but array objects do not really belong to a class of their own. An array object inherits all of the variables and methods of the `Object` class. Every array also defines the variable `length`, but there is no class declaration for an array type.

References Variable initializers; Array Allocation Expressions; Index Expressions; Object; String

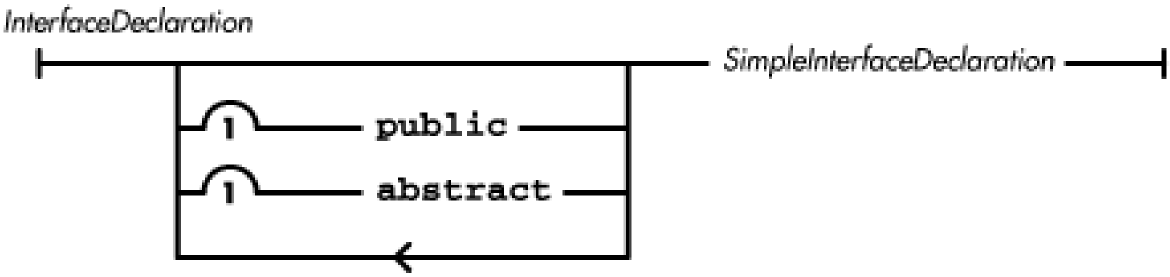
5.5 Interface Declarations

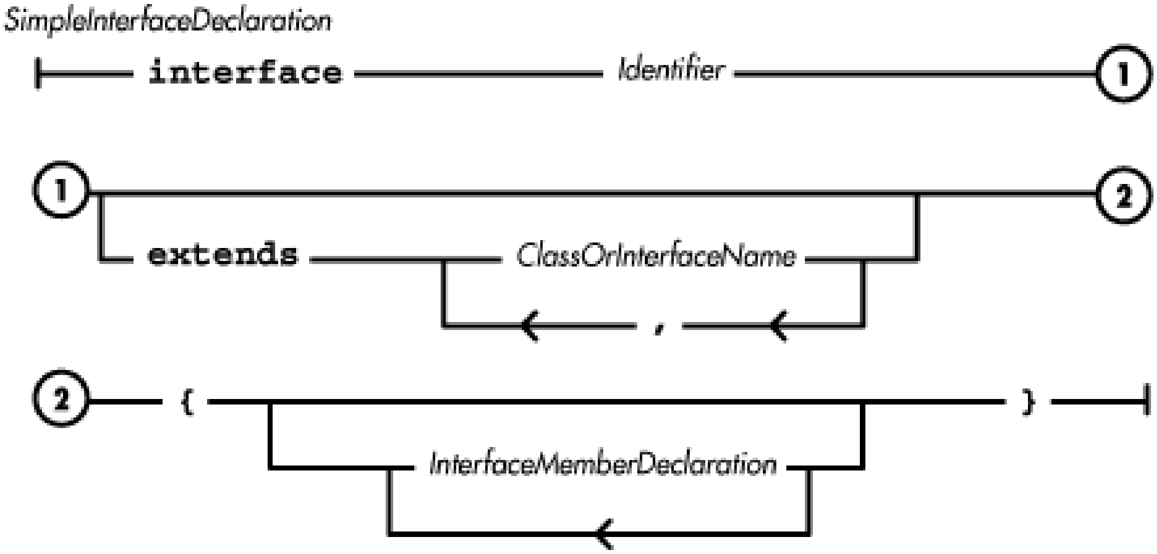
An interface declaration creates a reference type in Java. An interface declaration is similar to a class declaration, with the following two very important differences.

- All of the methods in an interface are implicitly `abstract`. Every method declaration in an interface specifies the formal parameters and return type of the method, but it does not include an implementation of the method.
- All of the variables in an interface are implicitly `static` and `final`.

Interfaces are most useful for declaring that an otherwise unrelated set of classes have a common set of methods. For example, if you want to store a variety of objects in a database, you might want all of those objects to have fetch and store methods. The fetch and store methods of each object require different implementations, so it makes sense to declare the fetch and store methods in an interface declaration. Then any class that needs fetch and store methods can implement the interface.

The formal definition for an interface declaration is:





While the above diagram may seem complicated, an interface declaration is really made up of five distinct things:

- Optional modifiers that specify attributes of the class
- The keyword `interface`
- An identifier that names the interface
- An optional `extends` clause that specifies the super interfaces of the declared interface
- Any number of interface member declarations, which can include variables and methods

Here are some sample interface declarations:

```
interface Dyn {
    double squeeze();
}
interface Press extends Dyn {
    double squeeze(double theta);
}
```

Here is an example of a class that implements `Press`:

```
class Clamp implements Press {
      ...
    double squeeze() {
        return squeeze(0);
    }
    double squeeze(double theta) {
        return force*Math.cos(theta);
    }
      ...
}
```

Since the `Press` interface extends the `Dyn` interface, the `Clamp` class must implement the methods declared in both `Dyn` and `Press`.

References Class Declarations; *ClassOrInterfaceName* 4.1.6; Identifiers; Interfaces; Interface Members

Interface Modifiers

The keywords `public` and `abstract` can appear as modifiers at the beginning of an interface declaration. In this situation, these modifiers have the following meanings:

`public`

> If an interface is declared `public`, it can be referenced by any class or interface. If the `public` modifier is not used, however, the interface can only be referenced by classes and interfaces in the same package. A single source file, or compilation unit, can only declare one `public` class or interface (see Compilation Units for an exception to this rule).

`abstract`

> An interface is implicitly `abstract`; so all of the methods in an interface are implicitly `abstract`. Including the `abstract` modifier in an interface declaration is permitted, but it does not change the meaning of the interface declaration.

References Compilation Units; Inner interface modifiers; Interface method modifiers; Interface variable modifiers

Interface Name

The identifier that follows the keyword `interface` is the name of the interface. This identifier can be used as a reference type wherever the interface is accessible.

References Interface Types

Interface Inheritance

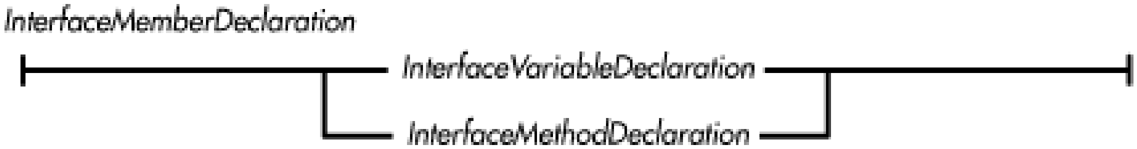
The extends clause specifies any super-interfaces of the interface being declared; the extends keyword can be followed by the names of one or more interfaces. If an interface has an extends clause, the clause can only name other interfaces.

Including an interface in the extends clause of another interface means that the declared interface inherits the variables and methods declared in the super-interface. A class that implements the declared interface must implement all of the methods in the declared interface, as well as all of the methods inherited from the super-interface.

If an interface declaration does not include an extends clause, the interface does not extend any other interfaces.

Interface Members

The members of an interface can be variables or methods; an interface cannot have constructors, static initializers, instance initializers, nested top-level classes or interfaces, or member classes:

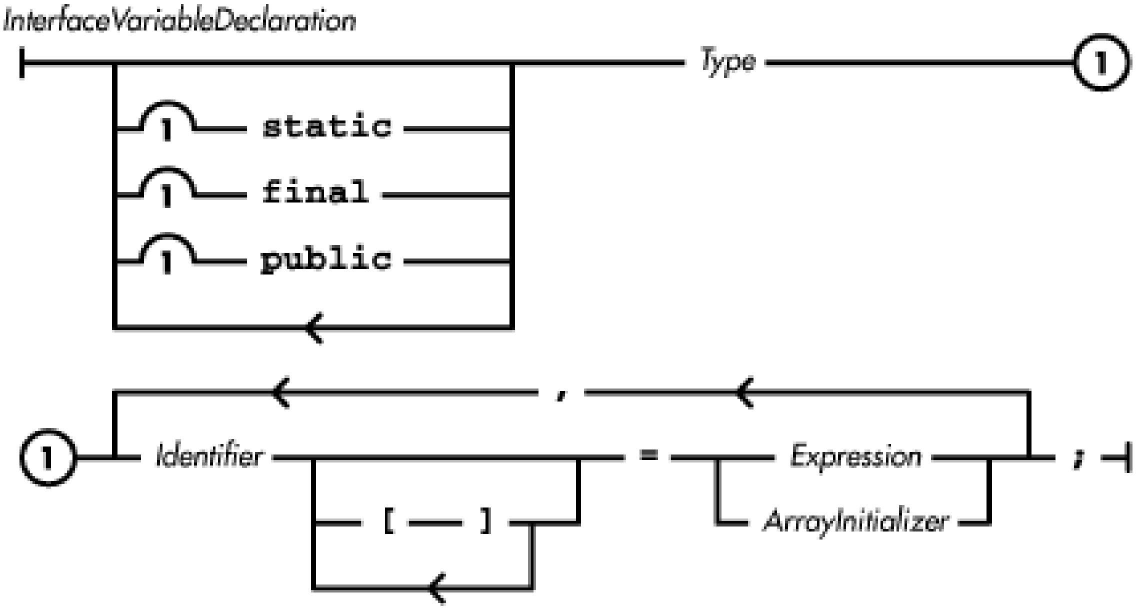


InterfaceMemberDeclaration
InterfaceVariableDeclaration
InterfaceMethodDeclaration

References Interface Methods; Interface Variables

Interface Variables

Any field variables declared in an interface are implicitly static and final. In other words, field variables in an interface are named constants. Every field variable declaration in an interface must contain an initializer that sets the value of the named constant:



A variable declaration in an interface is made up of three distinct things:

- Optional modifiers that specify attributes of the variable.
- A type, which can be either a primitive type or a reference type.
- Any number of identifiers that name variables. Each name must be followed by an initializer that sets the value of the constant.

References Variable initializers; *Expression* 4; Identifiers; *Type* 3

Interface variable modifiers

Variables in an interface are implicitly `static` and `final`. Including these modifiers in a variable declaration is permitted, but it is not necessary and it does not change the meaning of the variable declaration. Thus, by definition, all variables in an interface are named constants.

If an interface is declared `public`, a field variable declared in the interface is `public`, even if it is declared with the `private` or `protected` modifier. If an interface is not declared `public`, however, any field variables in the interface have the default accessibility, which means that they are only accessible in classes and interfaces in the same package.

It is an error to declare a field variable in an interface with the `transient` or `volatile` modifier.

References Interface Modifiers; Variable modifiers

Interface variable type

If the interface variable declaration uses a primitive type, the variable contains a constant value of the specified primitive type. If the declaration uses a reference type, the variable contains a constant reference to the specified type of object. The presence of square brackets in a variable declaration, after either the type or variable name, indicates that the variable contains a reference to an array.

References Array Types; Primitive Types; Reference Types

Interface variable name

The identifier that follows the variable type is the name of the variable. This identifier can be used anywhere that the variable is accessible.

It is an error to declare two field variables with the same name in the same interface. It is also an error to declare a field variable with the same name as a method declared in the same interface or any of its super-interfaces.

An interface that extends another interface inherits all of the variables in its super-interface. Any class that implements an interface has access to all of the variables defined in that interface, as well as the variables inherited from super-interfaces.

If a field variable is declared with the same name as a variable declared in a super-interface, the variable in the super-interface is considered to be shadowed. If a variable is shadowed in an interface, it cannot be accessed as a field of that interface. However, a shadowed variable can be accessed by casting a reference to an object that implements the interface to a reference to the appropriate super-interface in which the variable is not shadowed. For example:

```
interface A {
    int x = 4;
}
interface B extends A {
    int x = 7;
}
class Z implements B {
    Z() {
        int i = x;              // i gets the value of B's x
        int h = ((A)this).x;    // h gets the value of A's x
    }
}
```

The variable x in interface A is shadowed by the variable x in interface B. Class Z implements interface B, so a reference to x produces the value 7, as defined in interface B. However, it is possible to access the shadowed variable by casting this to a reference to interface A.

In some situations, an interface may inherit multiple field variables with the same name. This leads to a single, ambiguous variable name. For example:

```
interface A {
    int x = 4;
}
interface B {
    int x = 43;
}
interface C extends A, B {
    int y = 22;
}
class Z implements C {
    public static void main (String[] argv) {
        System.out.println(x);        // Ambiguous
    }
}
```

In this example, the interface `C` inherits two variables named `x`. This is fine, as long as `C` does not refer to the variable `x` by its simple name in any of its declarations. If `C` needs to use `x`, it must qualify the name with the appropriate interface name (e.g., `A.x`). Class `Z` implements interface `C`, so it also has access to two variables named `x`. As a result, the use of `x` in `main()` is ambiguous. This problem can be resolved by qualifying the variable name with the appropriate interface name (e.g., `B.x`).

A class that implements multiple interfaces can also inherit multiple field variables with the same name. Again, this leads to a single, ambiguous variable name:

```
interface A {
    int x = 4;
}
interface B {
    int x = 43;
}
class Z implements A, B {
    public static void main (String[] argv) {
        System.out.println(x);        // Ambiguous
    }
}
```

The class `Z` implements both interface `A` and interface `B`, so it inherits two variables named `x`. As a result, the use of `x` in `main()` is ambiguous. This problem can again be resolved by qualifying the variable name with the appropriate interface name (e.g., `B.x`).

References Field Expressions; Identifiers; Interface method name

Interface variable initializers

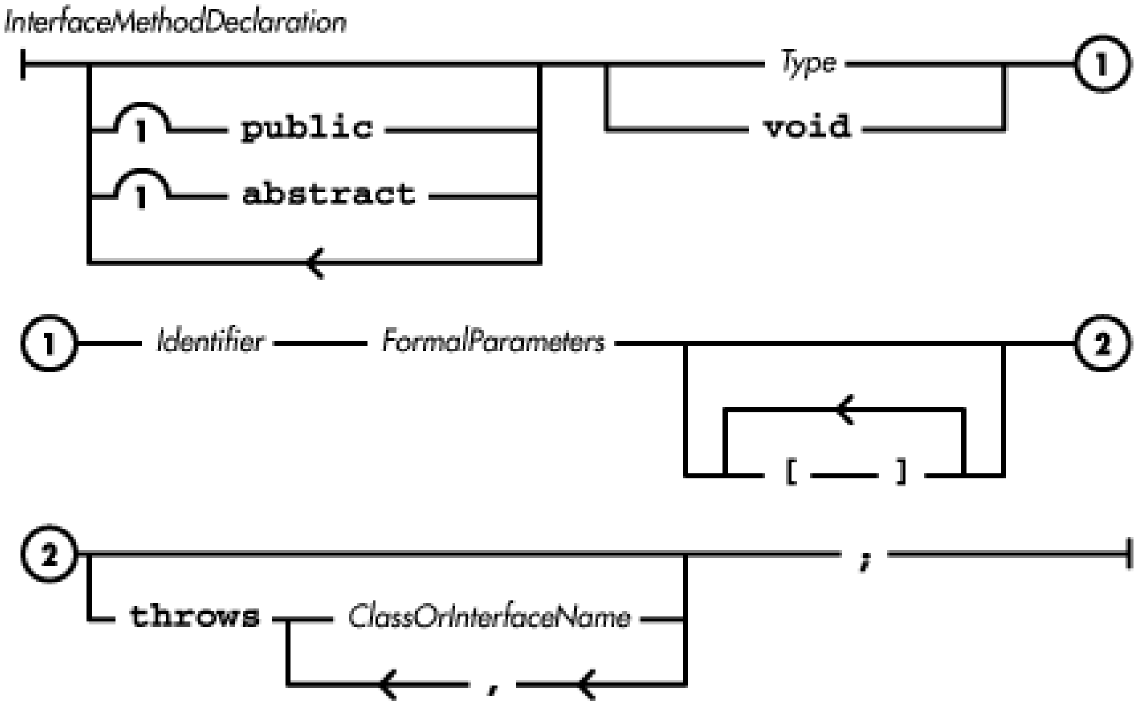
Every variable declaration in an interface must include an initializer that sets the value of the constant. The initializer does not, however, have to be a constant expression. If the variable is of a non-array type, the expression in the initializer is evaluated and the variable is set to the result of the expression, as long as the result is assignment-compatible with the variable. If the variable is of an array type, the initializer must be an array initializer.

The initializer for a variable in an interface cannot refer to any variables that are declared after its own declaration.

References Variable initializers; Array Types; Assignment Operators; Constant Expressions; *Expression* 4

Interface Methods

Any methods declared in an interface are implicitly `abstract`. In other words, methods in an interface do not have a specified implementation:



A method declaration in an interface is made up of six distinct things:

- Optional modifiers that specify attributes of the method
- A type that specifies the type of value returned by the method
- An identifier that names the method
- A list of formal parameters that specifies the values that are passed to the method
- An optional `throws` clause that specifies any exceptions that can be thrown by the method
- A semicolon, since the method declaration does not include an implementation

References *ClassOrInterfaceName* 4.1.6; Exception Handling 9; Method formal parameters; Identifiers; *Type* 3

Interface method modifiers

Methods in an interface are implicitly `abstract`. Including this modifier in a method declaration is permitted, but it is not necessary and it does not change the meaning of the method declaration. Thus, by definition, none of the methods in an interface has a specified implementation.

If an interface is declared `public`, a method declared in the interface is `public`, even if it is declared with the `private` or `protected` modifier. If the interface is not declared `public`, however, any methods in the interface have the default accessibility, which means that they are only accessible in classes and interfaces in the same package.

It is an error to declare a method in an interface with the `static`, `final`, `native`, or `synchronized` modifier. These modifiers are not allowed because defining a method in an interface is not meant to imply anything about the nature of the implementation, other than the return type of the method and the types of the formal parameters. A class that implements the interface has control over the implementation of the methods and can use any of these modifiers when they are appropriate for the implementation.

References Interface Modifiers; Method modifiers

Interface method return type

A method declaration in an interface must specify the type of value returned by the method. The return value can be of a primitive type or of a reference type. The presence of square brackets in a method declaration, after either the return type or the formal parameters, indicates that the method returns a reference to the specified type of array. If the method does not return a value, the declaration uses `void` to indicate that. The return type comes before the name of the method in the method declaration.

References Array Types; Method return type; Primitive Types; Reference Types

Interface method name

The identifier that follows the return type is the name of the method. This identifier can be used anywhere that the method is accessible.

It is an error to declare two methods that have the same name, the same number of parameters, and the same type for each corresponding parameter in the same interface. It is also an error to declare a method with the same name as a variable declared in the same interface or any of its super-interfaces.

An interface that extends another interface inherits all of the methods in its super-interface. Any class that implements an interface must provide an implementation for each of the methods defined in that interface, as well as each of the methods inherited from super-interfaces.

If an interface inherits methods from multiple super-interfaces that have the same name, formal parameters, and return type, there is no problem. The various super-interfaces are in agreement about the method. The interface can also override the inherited methods by declaring a method with the same name, formal parameters, and return type. In any case, a class that implements the interface has to provide a single implementation for the method.

However, if an interface inherits methods from multiple super-interfaces that have the same name and same formal parameters, but different return types, a compile-time error results. By the same token, if the interface attempts to override an inherited method with a method that has the same name and same formal parameters, but a different return type, a compile-time error results.

If an interface inherits methods from multiple super-interfaces that have the same name but different formal parameters, there is no problem. The methods are simply considered overloaded in the interface. The interface can even declare additional methods that have the same name but different formal parameters. A class that implements the interface simply has to provide an implementation for each of the overloaded methods.

References Identifiers; Interface variable name; Method Call Expression

Interface method formal parameters

The formal parameters in a method declaration specify a list of variables to which values are assigned when the method is called. If a method has no formal parameters, the parentheses must still appear in the method declaration. The presence of square brackets in a formal parameter declaration, either as part of a reference type or after the name of a formal parameter, indicates that the formal parameter is an array type.

References Array Types; Method formal parameters; Method formal parameters; *Type* 3

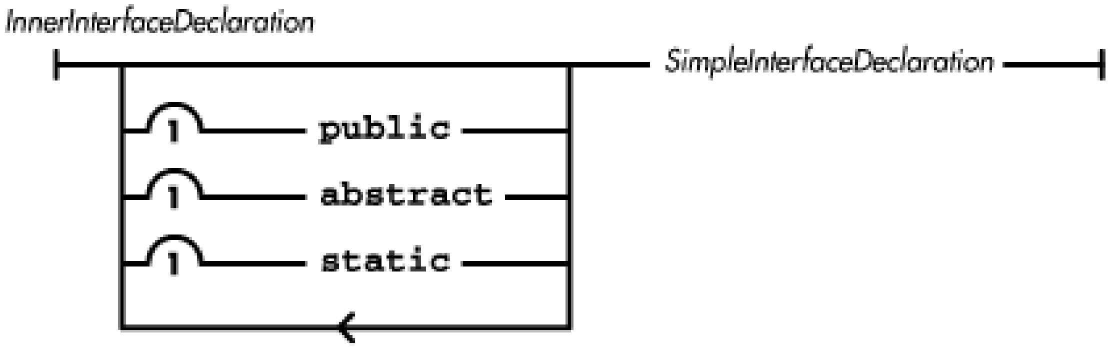
Interface method throws clause

If a method is expected to throw any exceptions, the method declaration must declare that fact in a `throws` clause. If the declaration of a method in an interface contains a `throws` clause, any method in a sub-interface that overrides that method cannot include any classes in its `throws` clause that are not declared in the overridden method.

References Exception Handling 9; Method throws clause

Nested Top-Level Interfaces

Nested top-level interfaces are interfaces that are declared inside of another class. Just as with a top-level interface declaration, the declaration of a nested top-level interface creates a reference type in Java. Here's the formal definition of a nested top-level interface:



A nested top-level interface can be accessed outside of its enclosing class by qualifying its name with the name of its enclosing class, as follows:

`EnclosingClass.InnerInterface`

The syntax for declaring nested top-level interfaces is not supported prior to Java 1.1.

References Nested top-level classes and interfaces; *SimpleInterfaceDeclaration* 5.5

Inner interface modifiers

The keywords `public`, `abstract`, and `static` can be used in the declaration of a nested top-level interface. In this situation, these modifiers have the following meanings:

`public`

> If a nested top-level interface is declared `public`, it is accessible from any class or interface that can access the enclosing class. If the `public` modifier is not used, however, the nested top-level interface can only be referenced by classes and interfaces in the same package as the enclosing class.

`abstract`

> A nested top-level interface is implicitly `abstract`; thus, all of the methods in the interface are implicitly `abstract`. Including the `abstract` modifier in a nested top-level interface declaration is permitted, but it does not change the meaning of the interface declaration.

`static`

> A nested top-level interface is implicitly `static`. Including the `static` modifier in a nested top-level interface declaration is permitted, but it does not change the meaning of the interface declaration.

References Interface Modifiers

Inner interface members

The remainder of a nested top-level interface declaration is the same as that for a top-level interface declaration, which is described in Interface Declarations.

5.4 Class Declarations

A class declaration creates a reference type in Java. The class declaration also specifies the implementation of the class, including its variables, constructors, and methods. The formal definition of a class declaration is:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

[Graphic: Figure from the text]

While the above diagram may seem complicated, a class declaration is really made up of six distinct things:

- Optional modifiers that specify attributes of the class
- The keyword `class`
- An identifier that names the class
- An optional `extends` clause that specifies the superclass of the declared class
- An optional `implements` clause that specifies the interfaces implemented by the declared class
- Any number of member declarations, which can include variables, methods, constructors, static initializers, instance initializers, nested top-level classes and interfaces, and member classes

References Classes; *ClassOrInterfaceName* 4.1.6; Class Members; Identifiers

Class Modifiers

The keywords public, abstract, and final can appear as modifiers at the beginning of a class declaration. In this situation, these modifiers have the following meanings:[3]

> [3] Version 1.0 of Java included a private protected access specification; this specification has been removed as of version 1.0.2 of the language.

public

> If a class is declared public, it can be referenced by any other class. If the public modifier is not used, however, the class can only be referenced by other classes in the same package. A single source file, or compilation unit, can only declare one public class or interface (see Compilation Units for an exception to this rule).

abstract

> If a class is declared abstract, no instances of the class may be created. A class declared abstract may contain abstract methods. Classes not declared abstract may not contain abstract methods and must override any abstract methods they inherit with methods that are not abstract. Furthermore, classes that implement an interface and are not declared abstract must contain or inherit methods that are not abstract that have the same name, number of parameters, and corresponding parameter types as the methods declared in the interfaces that the class implements.

final

> If a class is declared final, it cannot be subclassed. In other words, it cannot appear in the extends clause of another class.
>
> You want to declare a class final if it is important to ensure the exact properties and behavior of that class. Many of the classes in the java.lang package are declared final for that reason. In addition, the compiler can often optimize operations on final classes. For example, the compiler can optimize operations involving the String class because it can safely assume the exact logic of String methods. The compiler does not have to account for the possibility of methods of a final class being overridden in a subclass.

References Compilation Units; Inner class modifiers; Local class modifiers; Method modifiers; Variable modifiers

Class Name

The identifier that follows the keyword class is the name of the class. This identifier can be used as a reference type wherever the class is accessible.

References Class Types

Class Inheritance

The `extends` clause specifies the superclass of the class being declared. If a class is declared without an `extends` clause, the class `Object` is its implicit superclass. The class inherits all of the accessible methods and variables of its superclass.

If a class is declared `final`, it cannot appear in an `extends` clause for any other class.

The `implements` clause specifies any interfaces implemented by the class being declared. Unless it is an `abstract` class, the class (or one of its superclasses) must define implementations for all of the methods declared in the interfaces.

References Inheritance; Interfaces; Interface Declarations; Object

Class Members

Fields are the variables, methods, constructors, static (load-time) initializers, instance initializers, nested top-level classes and interfaces, and member classes that are declared as part of a class:

[Graphic: Figure from the text]

A member declaration causes the member to be defined throughout the entire class and all of its subclasses. This means that it is not a problem to have forward references to members, or in other words, you can use members in a class before you have defined them. For example:

```
class foo {
    void doIt() {
        countIt();
    }
    void countIt() {
        i++;
    }
    int i;
}
```

References Constructors; Nested Top-Level and Member Classes; Nested Top-Level Interfaces; Instance Initializers; Methods; Static Initializers; Variables

Variables

A variable that is declared as a member in a class is called a *field variable*. A field variable is different from a local variable, which is declared within a method or a block. The formal definition of a variable declaration is:

[Graphic: Figure from the text]

While the above diagram may seem complicated, a variable declaration is really made up of four distinct things:

- Optional modifiers that specify attributes of the variable.

- A type, which can be either a primitive type or a reference type.
- Any number of identifiers that name variables. Each name can be followed by pairs of square brackets to indicate an array variable.
- An optional initializer for each variable declared.

Here are some examples of variable declarations:

```
int x;
public static final double[] k, m[];
```

References Variable initializers; *Expression* 4; Identifiers; Local Variables; *Type* 3

Variable modifiers

The modifiers `public`, `protected`, and `private` can be used in the declaration of a field variable to specify the accessibility of the variable. In this situation, the modifiers have the following meanings:[4]

> [4] Version 1.0 of Java included a `private protected` access specification; this specification has been removed as of version 1.0.2 of the language.

`public`

> A field variable that is declared `public` is accessible from any class.

`protected`

> A field variable that is declared `protected` is accessible to any class that is part of the same package as the class in which the variable is declared. Such a field variable is also accessible to any subclass of the class in which it is declared; this occurs regardless of whether or not the subclass is part of the same package.

`private`

> A field variable that is declared `private` is only accessible in the class in which it is declared. Such a field variable is not accessible to other classes. In particular, a field variable that is declared `private` is not accessible in subclasses of the class in which it is declared.

If a field variable is not declared with any of the access modifiers, the variable has the default accessibility. Default access is often called "friendly" access because it is similar to `friendly` access in

C++. A variable with default access is accessible in any class that is part of the same package as the class in which the variable is declared. However, a friendly variable is not accessible to classes outside of the package in which it is declared, even if the desired classes are subclasses of the class in which it is declared.

The keywords `static`, `final`, `transient`, and `volatile` can also be used in the declaration of a field variable. These modifiers have the following meanings:

`static`

> A field variable that is declared with the `static` modifier is called a *class variable*. There is exactly one copy of each class variable associated with the class; every instance of the class shares the single copy of the class's `static` variables. Thus, setting the value of a class variable changes the value of the variable for all objects that are instances of that class or any of its subclasses.
>
> For example, if you want to count how many instances of a class have been instantiated, you can write:

```
class Foo {
    ...
    static int fooCount = 0;
    Foo() {
        fooCount++;
    }
    ...
}
```

> A field variable that is not declared with the `static` modifier is called an *instance variable*. There is a distinct copy of each instance variable associated with every instance of the class. Thus, setting the value of an instance variable in one object does not affect the value of that instance variable in any other object.

`final`

> If a field variable is declared with the `final` modifier, the variable is a named constant value. As such, it must be assigned an initial value. Any assignment to a `final` variable, other than the one that provides its initial value, is a compile-time error. The initial value for a `final` variable is typically provided by an initializer that is part of the variable's declaration. For example:

```
final int X = 4;
```

A `final` field variable that is not initialized in its declaration is called a *blank final*. Blank finals are not supported prior to Java 1.1. A blank final that is declared `static` must be assigned a value exactly once in a static initializer. A blank final that is not declared `static` must be assigned a value exactly once in an instance initializer or exactly once in each constructor. The compiler uses flow analysis that takes `if` statements and iteration statements into account to ensure that a blank final is assigned a value exactly once. Thus, it is possible to have multiple assignments to a blank final, so long as exactly one of them can be executed. For example, here is an instance initializer that sets the value of a blank final:

```
{
    final int DAYS_IN_YEAR;
    if (isLeapYear(new Date()))
        DAYS_IN_YEAR = 366;
    else
        DAYS_IN_YEAR = 365;
    ...
}
```

Note that the meaning of `final` in a variable declaration is very different from the meaning of `final` in a method or class declaration. In particular, if a class contains a `final` variable, you can declare a variable with the same name in a subclass of that class without causing an error.

`transient`

The `transient` modifier is used to indicate that a field variable is not part of the persistent state of an object. The `java.io.ObjectOutputStream` class defines `write()` methods that output a representation of an object that can be read later to create a copy of the object. These `write()` methods do not include field variables that are declared `transient` in the representation of an object.

`volatile`

The `volatile` modifier is used to tell the compiler that a field variable will be modified asynchronously by methods that are running in different threads. Each time the variable is accessed or set, it is fetched from or stored into global memory in a way that avoids the assumption that a version of the variable in a cache or a register is consistent with the version in global memory.

References Class Modifiers; Inner class modifiers; Local class modifiers; Method modifiers

Variable type

A field variable declaration must always specify the type of the variable. If the declaration of a field variable uses a primitive type, the variable contains a value of the specified primitive type. If the declaration uses a reference type, the variable contains a reference to the specified type of object.

The presence of square brackets in a variable declaration, after either the type or variable name, indicates that the variable contains a reference to an array. For example:

```
int a[];        // a is an array of int
int[] b;        // b is also an array of int
```

It is also possible to declare a variable to contain an array of arrays, or more generally, arrays nested to any level. Each pair of square brackets in the declaration corresponds to a dimension of the array; it makes no difference whether the brackets appear after the type or the variable name. For example:

```
int[][][] d3;      // Each of these is an array of
int[][] f3[];      // arrays of arrays of integers
int[] g3[][];
int h3[][][];
int[] j3, k3[];    // An array and an array of arrays
```

References Array Types; Primitive Types; Reference Types

Variable name

The identifier that follows the variable type is the name of the variable. This identifier can be used anywhere that the variable is accessible.

It is an error to declare two field variables with the same name in the same class. It is also an error to declare a field variable with the same name as a method declared in the same class or any of its superclasses.

If a field variable is declared with the same name as a variable declared in a superclass, the variable in the superclass is considered to be *shadowed*. If a variable is shadowed in a class, it cannot be accessed as a field of that class. However, a shadowed variable can be accessed by casting a reference to an object of that class to a reference to the appropriate superclass in which the variable is not shadowed. For example:

```
class A {
    int x = 4;
}
class B extends A {
    int x = 7;
    B () {
        int i = x;             // i gets the value of B's x
        int h = ((A)this).x;   // h gets the value of A's x
    }
}
```

Alternatively, if a variable is shadowed in a class but not in its immediate superclass, the methods of the class can access the shadowed variable using the keyword `super`. In the above example, this would look as follows:

```
int h = super.x;        // h gets the value of A's x
```

If a method is declared with the same name and parameters as a method in a superclass, the method in the superclass is considered to be overridden. Note that variable shadowing is different than method overriding. The most important difference is that using a reference to an instance of an object's superclass does not provide access to overridden methods. Overriding is described in detail in Method name.

References Field Expressions; Identifiers; Inheritance; Method name

Variable initializers

A variable declaration can contain an initializer. However, if a variable is declared to be `final`, it must either have an initializer or be initialized exactly once in a static initializer, instance initializer, or constructor. If the variable is of a non-array type, the expression in the initializer is evaluated and the variable is set to the result of the expression, as long as the result is assignment-compatible with the variable. If the variable is of an array type, the initializer must be an array initializer:

[Graphic: Figure from the text]

Each expression or array initializer in an array initializer is evaluated and becomes an element of the array produced by the initializer. The variable is set to the array produced by the initializer, as long as the assignment is assignment-compatible. Here are some examples of actual array initializers:

```
short a[] = {2,5,8,2,11};    // array of 5 shorts
int s[][] = { {3,45,8},      // array of 4 arrays
              {12,9,33},     // of 3 ints
```

```
               {7,22,53},
               {33,1,2} };
```

Note that a trailing comma is allowed within an array initializer. For example, the following is legal:

```
int x[] = {2,23,4,};
```

Any initializers for class variables (i.e., `static` variables) are evaluated when the class is loaded. The initializer for a class variable cannot refer to any instance variables in the class. An initializer for a `static` variable cannot refer to any `static` variables that are declared after its own declaration. The initial value of a class variable can also be set in a static initializer for the class; static initializers are described in Static Initializers.

Any initializers for instance variables are evaluated when a constructor for the class is called to create an instance of the class. Every class has at least one constructor that explicitly or implicitly calls one of the constructors of its immediate superclass before it does anything else. When the superclass's constructor returns, any instance variable initializers (and instance initializers) are evaluated before the constructor does anything else. The initial value of an instance variable can also be set in an instance initializer; instance initializers are described in Instance Initializers. Of course, it is also possible to set the initial values of instance variables explicitly in a constructor. Constructors are described in Constructors.

If a variable declaration does not contain an initializer, the variable is set to a default value. The actual value is determined by the variable's type. Table 5-1 shows the default values used for the various types in Java.

Table 5.1: Default Values for Field Variables

Type	**Default Value**
`byte`	`0`
`char`	`'\u0000'`
`short`	`0`
`int`	`0`
`long`	`0L`
`float`	`0.0F`
`double`	`0.0`
`boolean`	`false`
Object reference	`null`

For an array, every element of the array is set to the appropriate default value, based on the type of elements in the array.

Here are some examples of variable declarations, with and without initializers:

```
int i,j;                 // initialized to zero
long k = 243L;
double d = k*1.414;
String s;                // initialized to null
char c[] = new char[123];
float f[] = { 3.2f, 4.7f, 9.12f, 345.9f};
Double dbl = new Double(382.3748);
java.io.File fl = new File("/dev/null");
Object o = fl;
```

Methods

A method is a piece of executable code that can be called as a subroutine or a function. A method can be passed parameters by its caller; the method can also return a result to its caller. In Java, a method can only be declared as a field in a class. The formal definition of a method declaration is:

[Graphic: Figure from the text]

While the above diagram may seem complicated, a method declaration is really made up of six distinct things:

- Optional modifiers that specify attributes of the method

- A type that specifies the type of value returned by the method
- An identifier that names the method
- A list of formal parameters that specifies the values that are passed to the method
- An optional `throws` clause that specifies any exceptions that can be thrown by the method
- A block that defines the functionality of the method

Here are some examples of method declarations:

```
public static void main(String[] argv) {
    System.out.println( argv[0] );
}
int readSquare(DataInputStream d) throws IOException {
    int i = d.readInt();
    return i*i;
}
int filledArray(int length, int value) [] {
    int [] array = new int [length];
    for (int i = 0; i < length; i++ ) {
        array[i] = value;
    }
    return array;
}
```

Unlike C/C++, Java only allows method declarations that fully specify the type and number of parameters that the method can be called with.

References Blocks; *ClassOrInterfaceName* 4.1.6; Exception Handling 9; Method formal parameters; Identifiers; *Type* 3

Method modifiers

The modifiers `public`, `protected`, and `private` can be used in the declaration of a method to specify the accessibility of the method. In this situation, the modifiers have the following meanings:

`public`

> A method that is declared `public` is accessible from any class.

`protected`

> A method that is declared `protected` is accessible in any class that is part of the same package as the class in which the method is declared. Such a method is also accessible to any subclass of the class in which it is declared, regardless of whether or not the subclass is part of the same package.

`private`

> A method that is declared `private` is only accessible in the class in which it is declared. Such a method is not accessible in other classes. In particular, a method that is declared `private` is not accessible in subclasses of the class in which it is declared. A method cannot be declared both `private` and `abstract`.

If a method is not declared with any of the access modifiers, it has the default accessibility. Default access is often called "friendly" access because it is similar to `friendly` access in C++. A method with default access is accessible in any class that is part of the same package as the class in which the method is declared. However, a friendly method is not accessible to classes outside of the package in which it is declared, even if the classes are subclasses of the class in which it is declared.

The keywords `static`, `final`, `abstract`, `native`, and `synchronized` can also be used in the declaration of a method. These modifiers have the following meanings:

`static`

> A method that is declared with the `static` modifier is called a *class method*. Class methods are not associated with an instance of a class. This means that a class method cannot directly refer to other, non-`static` methods or variables in its class, unless the method or variable is accessed through an explicit object reference. In addition, the keywords `this` and `super` are treated as undefined variables within `static` methods. A method that is declared `static` is also implicitly `final`, or in other words, `static` methods cannot be overridden. A method that is declared `static` cannot also be declared `abstract`.
>
> Because `static` methods are not associated with a class instance, you do not need an instance of a class to invoke such a method. For example, the `Math` class contains a collection of mathematical methods that can be called using the class name:
>
> ```
> Math.tan(x)
> ```
>
> A method that is not declared with the `static` modifier is called an *instance method*. Instance methods are associated with an instance of a class, so an instance method may contain direct

references to any other methods or variables in its class.

`final`

A method that is declared with the `final` modifier cannot be overridden. In other words, if a method in a class is declared `final`, no subclass of that class can declare a method with the same name, number of parameters, and parameter types as the `final` method. Although `final` methods cannot be overridden, declaring a method to be `final` in no way prevents it from being overloaded.

`abstract`

If a method is declared with the `abstract` modifier, the declaration must end with a semicolon rather than a block. An `abstract` method declaration specifies the name, number and type of parameters, and return type of the method; it does not specify the implementation of the method. If a class contains an `abstract` method, the class must also be declared `abstract`. If a non-`abstract` class inherits an `abstract` method, the class must override the method and provide an implementation.

An `abstract` method cannot also be declared either `private` or `static` because neither `private` nor `static` methods can be overridden. A `private` method cannot be overridden because it is not inherited by its subclasses; a `static` method cannot be overridden because it is implicitly `final`.

`native`

If a method is declared with the `native` modifier, the declaration must end with a semicolon rather than a block. A `native` method is implemented in a platform-specific way using a language other than Java, such as C++. Because the implementation of a `native` method is not done in Java, Java requires the semicolon in place of an implementation.

Because the implementation of a `native` method is platform-specific, you should avoid using native methods in classes that are expected to run on different kinds of clients. Native methods also require an installation process, which is another reason to avoid them for use on clients.

`synchronized`

If a method is declared with the `synchronized` modifier, a thread must obtain a lock before it can invoke the method. If the method is not declared `static`, the thread must obtain a lock associated with the object used to access the method. If the method is declared `static`, the thread must obtain a lock associated with the class in which the method is declared.

> A synchronized method is one of two mechanisms for providing single-threaded access to the contents of a class or object. The other mechanism is the `synchronized` statement. Of the two, a synchronized method is usually the preferred mechanism. If all access to instance data that is shared by multiple threads is through `synchronized` methods, the integrity of the instance data is guaranteed, no matter what the callers of the methods do. On the other hand, if instance data shared by multiple threads is directly accessible outside of the class that defines it or its subclasses, providing single-threaded access to the data requires the use of `synchronized` statements.

References Class Modifiers; Inner class modifiers; Local class modifiers; Variable modifiers

Method return type

A method declaration must always specify the type of value returned by the method. The return value can be of a primitive type or of a reference type. If the method does not return a value, it should be declared with its return type specified as `void`. The return type comes before the name of the method in the method declaration.

The presence of square brackets in a method declaration, after either the return type or the formal parameters, indicates that the method returns a reference to the specified type of array.

For example:

```
int a()[] {...};        // a returns an array of int
int[] b() {...};        // b also returns an array of int
```

It is also possible to declare that a method returns a reference to an array of arrays, or more generally, arrays nested to any level. Each pair of square brackets in the declaration corresponds to a dimension of the array; it makes no difference whether the brackets appear after the return type or the formal parameters. For example:

```
int[][][] d3() {...};    // Each of these returns an array of
int[][] f3()[] {...};    // arrays of arrays of integers
int[] g3()[][] {...};
int h3()[][][] {...};
```

If a method is declared with the `void` return type, any `return` statement that appears within the method must not contain a return value. Because a method with a `void` return type does not return a value, such a method can only be called from an expression statement that consists of a method call expression.

On the other hand, if a method is declared with a return type other than `void`, it must return through an explicit `return` statement that contains a return value that is assignment-compatible with the return type of the method.

References Array Types; Expression Statements; Primitive Types; Reference Types; The return Statement

Method name

The identifier that follows the return type is the name of the method. This identifier can be used anywhere that the method is accessible.

It is an error to declare two methods that have the same name, the same number of parameters, and the same type for each corresponding parameter in the same class. It is also an error to declare a method with the same name as a variable declared in the same class or any of its superclasses.

A method is said to be *overloaded* if there is more than one accessible method in a class with the same name, but with parameters that differ in number or type.[5] This situation can arise if two or more such methods are declared in the same class. It can also occur when at least one of the methods is defined in a superclass and the rest are in a subclass.

> [5] Although Java supports overloaded methods, it does not allow programs to define overloaded operators. While it is true that the `+` operator is defined in an overloaded way, that operator is part of the language specification and it is the only overloaded operator.

Overloaded methods aren't required to have the same return type. For example:

```
int max(int x, int y){return x>y ? x : y;}
double max(double x, double y){return x>y ? x : y;}
```

A method that is inherited from a superclass is said to be *overridden* if a method in the inheriting class has the same name, number of parameters, and types of parameters as the inherited method. If the overridden method returns `void`, the overriding method must also return `void`. Otherwise, the return type of the overriding method must be the same as the type of the overridden method.

An overriding method can be more accessible than the overridden method, but it cannot be less accessible. In other words, a subclass cannot hide things that are visible in its superclass, but it can make visible things that are hidden. An object is considered to be an instance of its own class, as well as an instance of each of its superclasses. As a result, you can use an object reference to call a method in an object and not worry about whether the object is actually an instance of a subclass of the type of the reference. If a subclass were allowed to override methods of its superclass with methods that were less accessible, you would no longer be able to use a reference without regard to the actual type of the object being referenced.

For example, `Object` is the superclass of `String`. This means that a variable declared to contain a reference to an `Object` may actually refer to a `String`. The `Object` class defines a `public` method called `hashCode()`, so a reference to the `Object` class can be used to call the `hashCode()` method of whatever subclass of `Object` it refers to. Allowing a subclass of `Object` to declare a `private hashcode()` method would be inconsistent with this usage.

Table 5-2 shows the access modifiers that are permitted for an overriding method, based on the access allowed for the overridden method.

Table 5.2: Permitted Access Modifiers for Overriding Methods

		Access declared for overridden method		
		no modifier	**`protected`**	**`public`**
Access for overriding method	`private`	not allowed	not allowed	not allowed
	no modifier	allowed	not allowed	not allowed
	`protected`	allowed	allowed	not allowed
	`public`	allowed	allowed	allowed

If a method in the superclass is declared `private`, it is not inherited by the subclass. This means that a method in the subclass that has the same name, number of parameters, and types of parameters does not override the `private` method in the superclass. As a result, the method in the subclass can have any return type and there are no restrictions on its accessibility.

Non-`static` methods must be called through an object reference. If a non-`static` method is called with no explicit object reference, it is implicitly called using the object reference `this`. At compile-time, the type of the object reference is used to determine the combinations of method names and parameters that are accessible to the calling expression (see Method Call Expression). At runtime, however, the actual type of the object determines which of the methods is called. If the actual object is an instance of a subclass of the referenced class and the subclass overrides the method being called, the overriding method in the subclass is invoked.

In other words, the actual type of the object is used to determine which method to call, not the type of the reference to that object. This means that you cannot simply cast an object reference to a superclass of the class of the actual object to call to an overridden method. Instead, you use the keyword `super` to access an overridden method in the superclass. For example:

```
class A {
    void doit() {
        ...
    }
}
class B extends A {
    void doit() {
        super.doit();      // calls overridden A.doit()
    }
    public static void main(String argv[]) {
        B b = new B();
        ((A)b).doit();     // calls B.doit()
    }
}
```

The `doit()` method in class `B` calls the overridden `doit()` method in class `A` using the `super` construct. But, in `main()`, the `doit()` method in class `B` is invoked because casting a reference does not provide access to overridden methods.

References Identifiers; Inheritance; Method Call Expression; Variable name

Method formal parameters

The formal parameters in a method declaration specify a list of variables to which values are assigned when the method is called:

[Graphic: Figure from the text]

Within the block that contains the implementation of the method, the method's formal parameters are treated as local variables; the name of each formal parameter is available as an identifier in the method's implementation. Formal parameters differ from local variables only in that their declaration and value come from outside the method's block.

If a formal parameter is declared `final`, any assignment to that parameter generates an error. The syntax for declaring `final` parameters is not supported prior to Java 1.1.

If a method has no formal parameters, the parentheses must still appear in the method declaration.

Here's an example of a method declaration with formal parameters:

```
abstract int foo(DataInputStream d, Double[] values, int weights[]) ;
```

The presence of square brackets in a formal parameter declaration, either as part of a reference type or after the name of a formal parameter, indicates that the formal parameter is an array type. For example:

```
foo(int a[],    // a is an array of int
    int[] b)    // b is also an array of int
```

It is also possible to declare that a formal parameter is an array of arrays, or more generally, arrays nested to any level. Each pair of square brackets in the declaration corresponds to a dimension of the array; it makes no difference whether the brackets appear with the type or after the name of the formal parameter. For example:

```
int[][][] d3        // Each of these is an array of
int[][] f3[]        // arrays of arrays of integers
int[] g3[][]
int h3[][][]
```

References Array Types; Blocks; Identifiers; Local Variables; *Type* 3

Method throws clause

If a method is expected to throw any exceptions, the method declaration must declare that fact in a `throws` clause. Java requires that most types of exceptions either be caught or declared, so bugs caused by programmers forgetting to handle particular types of exceptions are uncommon in Java programs.

If a method implementation contains a `throw` statement, or if the method calls another method declared with a `throws` clause, there is the possibility that an exception will be thrown from within the method. If the exception is not caught, it will be thrown out of the method to its caller. Any exception that can be thrown out of a method in this way must be listed in a `throws` clause in the method declaration, unless the exception is an instance of `Error`, `RuntimeException`, or a subclass of one of those classes. Subclasses of the `Error` class correspond to situations that are not easily predicted, such as the system running out of memory. Subclasses of `RuntimeException` correspond to many common runtime problems, such as illegal casts and array index problems. The classes listed in a `throws` clause must be `Throwable` or any of its subclasses; the `Throwable` class is the superclass of all objects that can be thrown in Java.

Consider the following example:

```
import java.io.IOException;
class throwsExample {
    char[] a;
```

```
int position;
...
// Method explicitly throws an exception
int read() throws IOException {
    if (position >= a.length)
        throw new IOException();
    return a[position++];
}
// Method implicitly throws an exception
String readUpTo(char terminator) throws IOException {
    StringBuffer s = new StringBuffer();
    while (true) {
        int c = read(); // Can throw IOException
        if (c == -1 || c == terminator) {
            return s.toString();
        }
        s.append((char)c);
    }
    return s.toString():
}
// Method catches an exception internally
int getLength() {
    String s;
    try {
        s = readUpTo(':');
    } catch (IOException e) {
        return 0;
    }
    return s.length();
}
// Method can throw a RuntimeException
int getAvgLength() {
    int count = 0;
    int total = 0;
    int len;
    while (true){
        len = getLength();
        if (len == 0)
            break;
        count++;
        total += len;
    }
    return total/count; // Can throw ArithmeticException
    }
}
```

The method `read()` can throw an `IOException`, so it declares that fact in its `throws` clause. Without that `throws` clause, the compiler would complain that the method must either declare `IOException` in its `throws` clause or catch it. Although the `readUpTo()` method does not explicitly throw any exceptions, it calls the `read()` method that does throw an `IOException`, so it declares that fact in its `throws` clause. Whether explicitly or implicitly thrown, the requirement to catch or declare an exception is the same. The `getLength()` method catches the `IOException` thrown by `readUpTo()`, so it does not have to declare the exception. The final method, `getAvgLength()`, can throw an `ArithmeticException` if `count` is zero. Because `ArithmeticException` is a subclass of `RuntimeException`, the fact that it can be thrown out of `getAvgLength()` does not need to be declared.

If a method overrides another method, the overriding method cannot throw anything that the overridden method does not throw. Specifically, if the declaration of a method contains a `throws` clause, any method that overrides that method cannot include any classes in its `throws` clause that are not declared in the overridden method. This restriction avoids surprises. When a method is called, the Java compiler requires that all of the objects listed the method's `throws` clause are either caught by the calling method or declared in the calling method's `throws` clause. The requirement that an overriding method cannot include any class in its `throws` clause that is not in the overridden method's `throws` clause ensures that the guarantee made by the compiler is respected by the runtime environment.

References Exception Handling 9; The throw Statement; The try Statement

Method implementation

A method declaration must end with either a block or a semicolon. If either the `abstract` or `native` modifier is used in the declaration, the declaration must end with a semicolon. All other method declarations must end with a block that defines the implementation of the method.

References Blocks; Method modifiers

Constructors

A constructor is a special kind of method that is designed to set the initial values of an object's instance variables and do anything else that is necessary to create an object. Constructors are only called as part of the object creation process. The declaration of a constructor does not include a return type. The name of a constructor is always the same as the name of the class:

[Graphic: Figure from the text]

A constructor declaration is really made up of five distinct things:

- Optional modifiers that specify attributes of the constructor
- An identifier that names the constructor; this identifier must be the same as the name of the class
- A list of formal parameters that specifies the values that are passed to the constructor
- An optional `throws` clause that specifies any exceptions that can be thrown by the constructor
- A block that defines the functionality of the constructor

Here is an example that shows a class with some constructors:

```
class Construct {
    private Construct(Double[] values, int weights[]) {
    }
    public Construct(OutputStream o, Double[] values, int weights[])
                    throws IOException {
        this(values, weights);
        o.write(weights[0]);
    }
    public Construct() {
    }
}
```

References Blocks; *ClassOrInterfaceName* 4.1.6; Exception Handling 9; Method formal parameters; Identifiers; Object Creation

Constructor modifiers

The modifiers `public`, `protected`, and `private` can be used in the declaration of a constructor to specify the accessibility of the constructor. In this situation, the modifiers have the following meanings:

`public`

> A constructor that is declared `public` is accessible from any class.

`protected`

A constructor that is declared `protected` is accessible in any class that is part of the same package as the class in which the constructor is declared. Such a constructor is also accessible to any subclass of the class in which it is declared, regardless of whether or not the subclass is part of the same package.

`private`

A constructor that is declared `private` is accessible in the class in which it is declared. Such a constructor is not accessible in other classes. In particular, a constructor that is declared `private` is not accessible in subclasses of the class in which it is declared.

If a class is declared with at least one constructor, to prevent Java from providing a default `public` constructor, and all of the constructors are declared `private`, no other class can create an instance of the class. It makes sense to prevent the instantiation of a class if the class exists only to provide a collection of `static` methods. An example of this type of class is `java.lang.Math`.

`private` constructors can be used by `static` methods in the same class.

If a constructor is not declared with any of the access modifiers, the constructor has the default accessibility. Default access is often called "friendly" access because it is similar to `friendly` access in C++. A constructor with default access is accessible in any class that is part of the same package as the class in which the constructor is declared. However, a friendly constructor is not accessible in subclasses of the class in which it is declared.

References Class Modifiers; Inner class modifiers; Local class modifiers

Constructor name

A constructor has no name of its own. The identifier that appears in a constructor declaration must be the same as the name of the class in which the constructor is declared. This identifier can be used anywhere that the constructor is accessible.

References Class Types

Constructor return type

A constructor has no declared return type; it always returns an object that is an instance of its class. A `return` statement in a constructor is treated the same as it is in a method declared to return `void`; the `return` statement must not contain a return value. Note that it is not possible to explicitly declare a constructor to have the return type `void`.

References The return Statement

Constructor formal parameters

The formal parameters in a constructor declaration specify a list of variables to which values are assigned when the constructor is called. Within the block that contains the implementation of the constructor, the constructor's formal parameters are treated as local variables; the name of each formal parameter is available as an identifier in the constructor's implementation. Formal parameters differ from local variables only in that their declaration and value come from outside the constructor's block.

If a formal parameter is declared `final`, any assignment to that parameter generates an error. The syntax for declaring `final` parameters is not supported prior to Java 1.1.

If a constructor has no formal parameters, the parentheses must still appear in the constructor declaration.

The presence of square brackets in a formal parameter declaration, either as part of a reference type or after the name of a formal parameter, indicates that the formal parameter is an array type. For example:

```
Foo(int a[],    // a is an array of int
    int[] b)    // b is also an array of int
```

It is also possible to declare that a formal parameter is an array of arrays, or more generally, arrays nested to any level. Each pair of square brackets in the declaration corresponds to a dimension of the array; it makes no difference whether the brackets appear with the type or after the name of the formal parameter. For example:

```
int[][][] d3        // Each of these is an array of
int[][] f3[]        // arrays of arrays of integers
int[] g3[][]
int h3[][][]
```

References Array Types; Blocks; Method formal parameters; Local Variables

Constructor throws clause

If a constructor is expected to throw any exceptions, the constructor declaration must declare that fact in a `throws` clause. If a constructor implementation contains a `throw` statement, or if the constructor calls another constructor or method declared with a `throws` clause, there is the possibility that an exception will be thrown from within the constructor.

If the exception is not caught, it will be thrown out of the constructor to its caller. Any exception that can be thrown out of a constructor in this way must be listed in a `throws` clause in the constructor declaration, unless the exception is an instance of `Error`, `RuntimeException`, or a subclass of one of those classes.

Subclasses of the `Error` class correspond to situations that are not easily predicted, such as the system running out of memory. Subclasses of `RuntimeException` correspond to many common runtime problems, such as illegal casts and array index problems. The classes listed in a `throws` clause must be `Throwable` or any of its subclasses; the `Throwable` class is the superclass of all objects that can be thrown in Java.

References Exception Handling 9; The throw Statement; The try Statement

Constructor implementation

The block at the end of a constructor declaration contains the implementation of the constructor. The block is called the constructor body. The first statement in a constructor body is special; it is the only place that Java allows an explicit call to a constructor outside of an allocation expression. An explicit call to a constructor has a special form:

[Graphic: Figure from the text]

In an explicit constructor call, the keyword `this` can be used to specify a call to a constructor in the same class. The keyword `super` can be used to specify a call to a constructor in the immediate superclass.

For example:

```
class Square extends RegularPolygon {
    // Construct a square without specifying the length of the sides
    Square() {
        this(5);
    }
    // Construct a square with sides of a specified length
    Square(int len) {
        super(4,len);
    }
}
```

The first constructor simply calls the second constructor with the argument 5. The second constructor calls a constructor in the immediate superclass to create a four-sided regular polygon with sides of the given length.

Except for the constructors in the class `Object`, a constructor always begins by calling another constructor in the same class or in its immediate superclass. If the first statement in a constructor is not an explicit call to another constructor using `this` or `super` and the class is not `Object`, the compiler inserts a call to `super()` before the first statement in the constructor.

In other words, if a constructor does not begin with an explicit call to another constructor, it begins with an implicit call to the constructor of its immediate superclass that takes no argument. The result is constructor chaining: a constructor for each superclass of a class is called before the constructor of the class executes any of its own code. After all of the calls to the superclasses' constructors (explicit or implicit) have returned, any instance variables that have initializers are initialized, and finally the constructor executes its own code.

Constructor chaining places a restriction on the arguments that can be passed to a constructor in an explicit constructor call. The expressions provided as arguments must not refer to any instance variables of the object being created because these instance variables are not initialized until the superclass's constructor returns.

References *ArgumentList* 4.1.8; Object Allocation Expressions; this; super

The default constructor

If a class declaration does not contain any constructor declarations, Java supplies a default constructor for the class. The default constructor is `public`, it takes no arguments, and it simply calls the constructor of its class's superclass that takes no arguments. The default constructor is approximately equivalent to:

```
public MyClass() {
    super();
}
```

Because Java creates a default constructor only for a class that does not have any explicitly declared constructors, it is possible for the superclass of that class not to have a constructor that takes no arguments. If a class declaration does not contain a constructor declaration and its immediate superclass does not have a constructor that takes no arguments, the compiler issues an error message because the default constructor references a non-existent constructor in the superclass. The default constructor for the class `Object` does not contain a call to another constructor because class `Object` has no superclass.

References Object

Constructor inheritance

A subclass does not inherit constructors from its superclass, as it does normal methods. This is one important difference between regular methods and constructors: constructors are not inherited. However, a subclass can access a constructor in its superclass, as long as the constructor is accessible, based on any access modifiers used in its declaration.

This example illustrates the difference between inheritance and accessibility:

```
public class A {
    public A (int q) {
    }
}
public class B extends A {
    public B () {
        super(5);
    }
}
```

Although class `B` is a subclass of class `A`, `B` does not inherit the public constructor in `A` that takes a single argument. This means that if you try to create a new instance of `B` using an allocation expression with a single argument, you'll get an error message from the compiler. Here's an erroneous call:

```
B b1 = new B(9);
```

However, as shown in the example, the constructor in `B` can access the constructor in `A` using the keyword `super`.

The finalize method

A class declaration can include a special method that is called before an instance of the class is destroyed by the garbage collector. This method is called a *finalizer* ; it has the name `finalize()`. The `finalize()` method for a class must be declared with no parameters, a `void` return type, and no modifiers:

```
void finalize() {...}
```

If a class has a `finalize()` method, it is normally called by the garbage collector before an object of that class type is destroyed. A program can also explicitly call an object's `finalize()` method, but in this case, the garbage collector does not call the method during the object destruction process. If the garbage collector does call an object's `finalize()` method, the garbage collector does not immediately destroy the object because the `finalize()` method might do something that results in a reference to the object. Thus the garbage collector waits to destroy the object until it can again prove it is safe to do so. The next time the garbage collector decides it is safe to destroy the object, it does so without calling the finalizer again. In any case, a `finalize()` method is never called more than once by the garbage collector for a particular object.

A superclass of the class may also define a `finalize()` method, but Java does not provide a mechanism that automatically calls the superclass's `finalize()` method. If a class contains a `finalize()` method, it is a good idea for that method to call `super.finalize()` as the very last thing that it does. This technique ensures that the `finalize()` method of the superclass gets called. The technique even works if the superclass does not explicitly define a `finalize()` method, since every class inherits a default `finalize()` method from the `Object` class. This default `finalize` method does not do anything.

References Object Destruction

Static Initializers

A *static initializer* is a piece of code that is executed when a class is loaded. A static initializer is simply a block of code in a class declaration that is preceded by the keyword `static`:

[Graphic: Figure from the text]

A class is loaded when its definition is needed by another class. You can specifically request that a class be loaded by calling the `forName()` method of the `Class` class on the class you want to load. Alternatively, you can use the `loadClass()` method of a `ClassLoader` object to load a class directly.

When a class is loaded, a `Class` object is created to represent it and storage for the class's `static` variables is allocated. When a class is initialized, its static initializers and `static` variable initializers are evaluated in the order in which they appear in the class declaration. For example, here is a class that contains both static initializers and `static` variable initializers:

```
class foo {
    static int i = 4;
    static {
        i += 2;
        j = 5 * i;
    }
    static int j = 7;
    static double d;
    static frame f = new Frame();
    static { d = Math.tan(Math.PI/j); }
}
```

When the `foo` class is loaded, here is what happens. First, the variable `i` is set to 4. Then the first static initializer is executed. It increments `i` by 2, which makes it 6, and sets `j` to `5*i`, which is 30. Next, the variable `j` is set to 7 by its initializer; this overwrites the value that was set in the static initializer. The variable `f` is then set to the new `Frame` object created by its initializer. Finally, the second static initializer is executed. It sets the variable `d` to , which is .

Notice that the first static initializer uses the variable `j`, even though the variable is not declared until after the static initializer. A static initializer can refer to a `static` variable that is declared after the static initializer. However, the same is not true for `static` variable initializers. A `static` variable initializer cannot refer to any variables that are declared after its own declaration, or the compiler generates an error message. The following class declaration is erroneous:

```
class foo {
    static int x = y*3;    // error because y defined after x
    static int y;
}
```

If an exception is thrown out of a static initializer, the method that caused the class to be defined throws an `ExceptionInInitializerError`. This `ExceptionInInitializerError` contains a reference to the original exception that can be fetched by calling its `getException()` method.

References Blocks; Class; Errors; Variables

Instance Initializers

An *instance initializer* is a piece of code that is executed when an instance of a class is created.

Specifically, it is executed after the object's immediate superclass constructor returns, but before the constructor of the class itself runs. An instance initializer is simply a block of code in a class that is not in any method. Here is the formal syntax:

[Graphic: Figure from the text]

Every class has at least one constructor that explicitly or implicitly calls one of the constructors of its immediate superclass before it does anything else. When the superclass's constructor returns, any instance initializers and instance variable initializers are evaluated before the constructor does anything else. The instance initializers and instance variable initializers are evaluated in the order in which they appear in the class declaration. If an instance initializer throws an exception, the exception appears to have come from the constructor that called the superclass's constructor.

References Blocks; Constructors; Variable initializers

Nested Top-Level and Member Classes

Nested top-level classes and member classes are classes that are declared inside of another class. Just as with a top-level class declaration, the declaration of a nested top-level class or member class creates a reference type in Java. Here's the formal definition of a nested top-level or member class declaration:

[Graphic: Figure from the text]

A class declared inside of another class has access to all of the variables, methods, and other inner classes of the enclosing class. If a nested top-level or member class is not `private`, it can also be accessed outside of its enclosing class by qualifying its name with the name of its enclosing class, as follows:

`EnclosingClass.InnerClass`

The syntax for declaring nested top-level classes and member classes is not supported prior to Java 1.1.

References Nested top-level classes and interfaces; Member classes; Class Declarations

Inner class modifiers

The keywords `public`, `protected`, and `private` can be used in the declaration of a nested top-level or member class to specify the accessibility of the inner class. In this situation, the modifiers have the following meanings:

`public`

> A nested top-level or member class that is declared `public` is accessible from any class that can access the enclosing class.

`protected`

> A nested top-level or member class that is declared `protected` is accessible from any class that is part of the same package as the enclosing class. Such an inner class is also accessible to any

subclass of the enclosing class, regardless of whether or not the subclass is part of the same package.

`private`

A nested top-level or member class that is declared `private` is only accessible from its enclosing class and other classes declared within the enclosing class. In particular, an inner class that is declared `private` is not accessible in subclasses of its enclosing class.

If a nested top-level or member class is not declared with any of the access modifiers, the class has the default accessability. Default access is often called "friendly" access because it is similar to `friendly` access in C++. An inner class with default access is accessible in any class that is part of the same package as the enclosing class. However, a friendly inner class is not accessible to classes outside of the package of the enclosing class, even if the desired classes are subclasses of the enclosing class.

The keywords `abstract`, `final`, and `static` can also be used in the declaration of a nested top-level or member class. These modifiers have the following meanings:

`abstract`

If a nested top-level or member class is declared `abstract`, no instances of the class may be created. An inner class declared `abstract` may contain `abstract` methods; classes not declared `abstract` may not contain `abstract` methods and must override any `abstract` methods they inherit with methods that are not `abstract`. Furthermore, classes that implement an interface and are not declared `abstract` must contain or inherit methods that are not `abstract`, that have the same name, have the same number of parameters, and have corresponding parameter types as the methods declared in the interfaces that the class implements.

`final`

If a nested top-level or member class is declared `final`, it cannot be subclassed. In other words, it connot appear in the `extends` clause of another class.

`static`

An inner class that is declared with the `static` modifier is called a nested top-level class. A class can only be declared with the `static` modifier if its enclosing class is a top-level class (i.e., it is not declared within another class). The code within a nested top-level class cannot directly access non-`static` variables and methods of its enclosing class.

An inner class that is not declared with the `static` modifier is called a member class. The code within a member class can access all of the variables and methods of its enclosing class, including private variables and methods.

References Class Modifiers; Local class modifiers

Inner class members

The body of a nested top-level or member class cannot declare any `static` variables, `static` methods, `static` classes, or static initializers. Beyond those restrictions, the remainder of the declaration is the same as that for a top-level class declaration, which is described in Class Declarations.

References Class Declarations; Constructors; Instance Initializers; Methods; Nested Top-Level and Member Classes; Static Initializers; Variables

4.6 Additive Operators

The additive operators in Java are binary operators that are used for addition and string concatenation (`+`) and subtraction (`-`). The additive operators appear in additive expressions.

[Graphic: Figure from the text]

The additive operators are equal in precedence and are evaluated from left to right.

References Multiplicative Operators; Order of Operations

Arithmetic Addition Operator +

The binary arithmetic addition operator `+` produces a pure value that is the sum of its operands. The arithmetic `+` operator may appear in an additive expression. The arithmetic addition operator never throws an exception.

Here is an example that uses the arithmetic addition operator:

```
int addThree (int x, int y, int z) {
    return x + y + z;
}
```

If the type of either operand of `+` is a reference to a `String` object, the operator is the string concatenation operator, not the arithmetic addition operator. The string concatenation operator is described in String Concatenation Operator +.

Otherwise, the types of both operands of the arithmetic addition operator must be arithmetic types, or a compile-time error occurs. The `+` operator may perform type conversions on its operands:

- If either operand is of type `double`, the other operand is converted to `double` and the operation produces a `double` value.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float` and the operation produces a `float` value.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.
- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

If the addition of integer data overflows, the value produced by `+` contains the low order bits of the sum and the sign of the value is the opposite of the mathematically correct sign, due to the limitations of the two's complement representation used for integer data.

The addition of floating-point data is governed by the following rules:

- If either operand is not-a-number (NaN), the sum is NaN.
- If one operand is positive infinity and the other is negative infinity, the sum is NaN.
- If both of the operands are positive infinity, the sum is positive infinity.
- If both of the operands are negative infinity, the sum is negative infinity.
- If one of the operands is an infinity value and the other operand is a finite value, the sum is the same infinity value as the operand.
- If one operand is positive zero and the other is negative zero; the sum is positive zero.

- If both operands are positive zero, the sum is positive zero.

- If both operands are negative zero, the sum is negative zero.

- If neither operand is NaN nor an infinity value, the sum is rounded to the nearest representable value. If the magnitude of the sum is too large to be represented, the operation overflows and an infinity value of the appropriate sign is produced. If the magnitude of the sum is too small to be represented, the operation underflows and a zero value of the appropriate sign is produced.

References Arithmetic Types; String Concatenation Operator +

Arithmetic Subtraction Operator -

The binary subtraction operator `-` produces a pure value that is the difference between its operands; it subtracts its right operand from its left operand. The arithmetic `-` operator may appear in an additive expression. The arithmetic subtraction operator never throws an exception.

Here is an example that uses the arithmetic subtraction operator:

```
int subThree (int x, int y, int z) {
    return x - y - z;
}
```

The types of both operands of the arithmetic subtraction operator must be arithmetic types, or a compile-time error occurs. The `-` operator may perform type conversions on its operands:

- If either operand is of type `double`, the other operand is converted to `double` and the operation produces a `double` value.

- Otherwise, if either operand is of type `float`, the other operand is converted to `float` and the operation produces a `float` value.

- Otherwise, if either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.

- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

For both integer and floating-point data, `a-b` always produces the same result as `a-(+b)`.

If the subtraction of integer data overflows, the value produced by `-` contains the low order bits of the difference and the sign of the value is the opposite of the mathematically correct sign, due to the limitations of the two's complement representation used for integer data.

The subtraction of floating-point data is governed by the following rules:

- If either operand is not-a-number (NaN), the difference is NaN.
- If the left operand is positive infinity and the right operand is negative infinity, the difference is positive infinity.
- If the left operand is negative infinity and the right operand is positive infinity, the difference is negative infinity.
- If both operands are positive infinity, the difference is NaN.
- If both operands are negative infinity, the difference is NaN.
- If the left operand is an infinity value and the right operand is a finite value, the difference is the same infinity value as the left operand.
- If the left operand is a finite value and the right argument is an infinity value, the difference is the opposite infinity value of the right operand.
- If both operands are either positive zero or negative zero, the difference is positive zero.
- If the left operand is positive zero and the right operand is negative zero, the difference is positive zero.
- If the left operand is negative zero and the right operand is positive zero, the difference is negative zero.
- If neither operand is NaN nor an infinity value, the difference is rounded to the nearest representable value. If the magnitude of the difference is too large to be represented, the operation overflows and an infinity value of the appropriate sign is produced. If the magnitude of the difference is too small to be represented, the operation underflows and a zero value of the appropriate sign is produced.

References Arithmetic Types

String Concatenation Operator +

The string concatenation operator `+` produces a pure value that is a reference to a `String` object that it creates. The `String` object contains the concatenation of the operands; the characters of the left operand precede the characters of the right operand in the newly created string. The string concatenation + operator may appear in an additive expression.

Here is an example of some code that uses the string concatenation operator:

```
// format seconds into hours, minutes, and seconds
String formatTime(int t) {
    int minutes, seconds;
    seconds = t%60;
    t /= 60;
    minutes = t%60;
    return t/60 + ":" + minutes + ":" + seconds;
}
```

If neither operand of + is a reference to a `String` object, the operator is the arithmetic addition operator, not the string concatenation operator. Note that Java does not allow a program to define overloaded operators. However, the language defines the + operator to have a meaning that is fundamentally different from arithmetic addition if at least one of its operands is a `String` object.

The way in which Java decides if + means arithmetic addition or string concatenation means that the use of parentheses can alter the meaning of the + operator. Consider the following code:

```
int x = 3, y = 4;
System.out.println("x = " + x + ", y = " + y);
System.out.println("\"??\" + x + y ==> " + "??" + x + y);
System.out.println("\"??\" + (x + y) ==> " + "??"+ (x + y));
```

In the output from this code, you can see that the addition of parentheses changes the meaning of the last + from string concatenation to arithmetic addition:

```
x = 3, y = 4
"??" + x + y ==> ??34
"??" + (x + y) ==> ??7
```

If one of the operands of + is a `String` object and the other is not, the operand that is not a `String` object is converted to one using the following rules:

- If the operand is an object reference that is `null`, it is converted to the string literal `"null"`.
- If the operand is a non-`null` reference to an object that is not a string, the object's `toString()` method is called. The result of the conversion is the string value returned by the object's

`toString()` method, unless the return value is `null`, in which case the result of the conversion is the string literal `"null"`. Since the `Object` class defines a `toString()` method, every class in Java has such a method.

- If the type of the operand is `char`, the operand is converted to a reference to a `String` object that has a length of one and contains that character.

- If the type of the operand is an integer type other than `char`, the operand is converted to a base 10 string representation of its value. If the value is negative, the string value starts with a minus sign; if it is positive there is no sign character. If the value is zero, the result of the conversion is `"0"`. Otherwise, the string representation of the integer does not have any leading zeros.

- If the type of the operand is a floating-point type, the exact string representation depends on the value being converted. If the absolute value of `d` is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

  Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

  In addition, the values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

  Note that the specification for this conversion has changed as of Java 1.1. Prior to that release, the conversion provided a string representation that was equivalent to the `%g` format of the `printf` function in C. In addition, the string representations of the infinity values, the zero values, and NaN are not specified prior to Java 1.1.

- If the type of the operand is `boolean`, the value is converted to a reference to either the string literal `"true"` or the string literal `"false"`.

Java uses the `StringBuffer` object to implement string concatenation. Consider the following code:

```
String s, s1,s2;
s = s1 + s2;
```

To compute the string concatenation, Java compiler generates code equivalent to:

```
s = new StringBuffer().append(s1).append(s2).toString();
```

Consider another expression:

```
s = 1 + s1 + 2
```

In this case, the Java compiler generates code equivalent to:

```
s = new StringBuffer().append(1).append(s1).append(2).toString()
```

No matter how many strings are being concatenated in an expression, the expression always produces exactly one `StringBuffer` object and one `String` object.[3] From an efficiency standpoint, if you concatenate more than two strings, it may be more efficient to do so in a single expression, rather than in multiple expressions.

[3] Although an optimizing compiler should be smart enough to combine multiple concatenation expressions when it is advantageous, the compiler provided with Sun's reference implementation of Java does not do this.

4.13 Assignment Operators

Assignment operators set the values of variables and array elements. An assignment operator may appear in an assignment expression:

[Graphic: Figure from the text]

The actual assignment operator in an assignment expression can be the simple assignment operator `=` or one of the compound assignment operators shown below. All of the assignment operators are equal in precedence. Assignment operators are evaluated from right to left, so `a=b=c` is equivalent to `a=(b=c)`.

The left operand of an assignment operator must be an expression that produces a variable or an array element. The left operand of an assignment operator cannot be an expression that evaluates to a pure value, or a compile-time error occurs. So, for example, the left operand cannot be a `final` variable, since a `final` variable evaluates to a pure value, not a variable.

The assignment operator itself produces a pure value, not a variable or an array element. The pure value produced by an assignment operator is the value of the variable or array element after it has been set by the assignment operation. The type of this pure value is the type of the variable or array element.

The simple assignment operator `=` just sets the value of a variable or array element. It does not imply any other computation. The right operand of the simple assignment operator can be of any type, as long as that type is assignment-compatible with the type of the left operand, as described in the next section. If the right operand is not assignment-compatible, a compile-time error occurs.

The compound assignment operators are:

```
+=  -=   *=
/=  |=   &=
^=  %=   <<=
>>= >>>=
```

Both of the operands of a compound assignment operator must be of primitive types, or a compile-time error occurs. The one exception is if the left operand of the `+=` operator is of type `String`; in this case the right operand can be of any type.

A compound assignment operator combines a binary operator with the simple assignment operator `=`. Thus, to be assignment-compatible, the right operand of a compound assignment operator must be of a type that complies with the rules for the indicated binary operation. Otherwise, a compile-time error occurs. An assignment expression of the form:

```
e1 op = e2
```

is approximately equivalent to:

```
e1 = (type) ((e1) op (e2))
```

where *type* is the type of the expression `e1`. The only difference is that `e1` is only evaluated once in the expression that uses the compound assignment operator.

For example, consider the following code fragment:

```
j = 0;
a[0] = 3;
a[1]=6;
a[j++] += 2;
```

After this code is executed, `j` equals 1 and `a[0]` is 5. Contrast this with the following code:

```
j = 0;
a[0] = 3;
a[1]=6;
a[j++] = a[j++] + 2;
```

After this code is executed, `j` equals 2 and `a[0]` is 8 because `j++` is evaluated twice.

Assignment Compatibility

Saying that one type of value is *assignment-compatible* with another type of value means that a value of the first type can be assigned to a variable of the second type. Here are the rules for assignment compatibility in Java:

- Every type is assignment-compatible with itself.
- The `boolean` type is not assignment-compatible with any other type.
- A value of any integer type can be assigned to a variable of any other integer type if the variable is of a type that allows it to contain the value without any loss of information.
- A value of any integer type can be assigned to a variable of any floating-point type, but a value of any floating-point type cannot be assigned to a variable of any integer type.
- A `float` value can be assigned to a `double` variable, but a `double` value cannot be assigned to a `float` variable.
- With a type cast, a value of any arithmetic type can be assigned to a variable of any other arithmetic type.
- Any reference can be assigned to a variable that is declared of type `Object`.
- A reference to an object can be assigned to a class-type reference variable if the class of the variable is the same class or a superclass of the class of the object.
- A reference to an object can be assigned to an interface-type reference variable if the class of the object implements the interface.
- A reference to an array can be assigned to an array variable if either of the following conditions is true:
  - Both array types contain elements of the same type.
  - Both array types contain object references and the type of reference contained in the elements of the array reference can be assigned to the type of reference contained in the elements of the variable.

Here's an example that illustrates the rules about assignment compatibility of arrays:

```
class Triangle extends Shape {...}
...
int[] i = new int[8];
int j[];
long l[];
short s[];
Triangle[] t;
Shape[] sh;
j = i;    // Okay
s = i;    // Error
l = i;    // Error
sh = t;   // Okay
t = sh;   // Error
```

Assigning `i` to `j` is fine because both variables are declared as references to arrays that contain `int` values. On the other hand, assigning `i` to `s` is an error because the variables are declared as references to arrays that contain different kinds of elements and these elements are not object references. Assigning `i` to `l` is an error for the same reason. Assigning `t` to `sh` is fine because the variables are declared as references to arrays that contain object references, and `sh[0]=t[0]` is legal. However, assigning `sh` to `t` is an error because `t[0]=sh[0]` is not legal.

It is not always possible for the compiler to determine if an assignment to an array element is legal; in these cases the assignment compatibility is checked at runtime. This situation can occur when a variable contains a reference to an array whose type of elements is specified by a class or interface name. In this case, it may not be possible to determine the actual type of the array elements until runtime. Consider the following example:

```
void foo (InputStream a[]) {
    a[0] = new FileInputStream("/dev/null");
}
```

Figure 4.1 shows the `InputStream` class and some of its subclasses in the `java.io` package.

Figure 4.1: InputStream and some of its classes

[Graphic: Figure 4-1]

Any array with elements that contain references to objects of class InputStream or any of its subclasses can be passed to the method foo() shown in the above example. For example:

```
FileInputStream f[] = new FileInputStream[3];
foo(f);
```

Since FileInputStream is a subclass of InputStream, the call to foo() does not cause any problems at runtime.

However, the following call to foo() is problematic:

```
DataInputStream f[] = new DataInputStream[3];
foo(f);
```

This call causes an ArrayStoreException to be thrown at runtime. Although DataInputStream is a subclass of InputStream, it is not a superclass of FileInputStream, so the array element assignment in foo() is not assignment-compatible.

4.10 Bitwise/Logical Operators

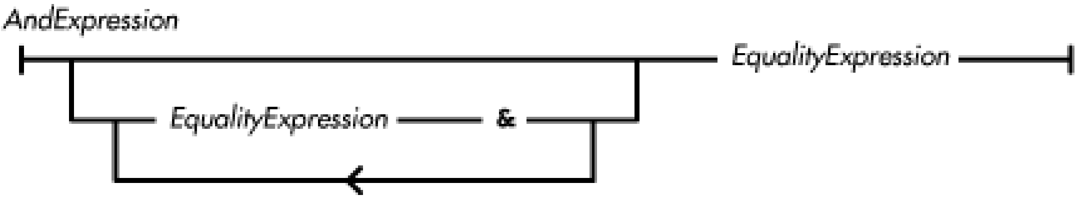
The bitwise/logical operators in Java are used for bitwise and logical AND (&), bitwise and logical exclusive OR (^), and bitwise and logical inclusive OR (|) operations. These operators have different precedence; the & operator has the highest precedence of the group and the | operator has the lowest. All of the operators are evaluated from left to right.

The unary operator ~ provides a bitwise negation operation.

References Bitwise Negation Operator ~; Order of Operations

Bitwise/Logical AND Operator &

The bitwise/logical AND operator & produces a pure value that is the AND of its operands. The & operator may appear in a bitwise or logical AND expression:



The bitwise/logical AND operator is evaluated from left to right. The operator never throws an exception.

Here is a code example that shows the use of the bitwise AND operator:

```
boolean isOdd(int x) {
    return (x & 1) == 1;
}
```

The operands of the bitwise/logical AND operator must both be of either an integer type or the type `boolean`, or a compile-time error occurs.

If both operands are of integer types, the operator performs a bitwise AND operation. The operator may perform type conversions on the operands:

- If either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.
- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

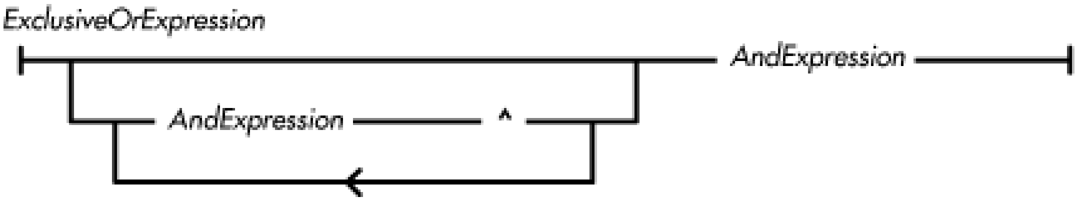
The bitwise AND operator produces a pure value that is the bitwise AND of its operands. If the corresponding bits in both of the converted operands are 1s, the corresponding bit in the result is a 1; otherwise the corresponding bit in the result is a 0.

If both operands are of type `boolean`, the operator performs a logical AND operation. The logical AND operation produces a pure value of type `boolean`. If both operands are `true`, the operation produces `true`; otherwise the operation produces `false`. This operator differs from the conditional AND operator (&&) because it always evaluates both of its operands, even if its left operand evaluates to `false`.

References Boolean AND Operator &&; Boolean Type; Equality Comparison Operators; Integer types; Order of Operations

Bitwise/Logical Exclusive OR Operator ^

The bitwise/logical exclusive OR operator ^ produces a pure value that is the exclusive OR of its operands. The ^ operator may appear in a bitwise or logical exclusive OR expression:



The bitwise/logical exclusive OR operator is evaluated from left to right. The operator never throws an exception.

The operands of the bitwise/logical exclusive OR operator must both be of either an integer type or the type `boolean`, or a compile-time error occurs.

If both operands are of integer types, the operator performs a bitwise exclusive OR operation. The operator may perform type conversions on the operands:

- If either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.
- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

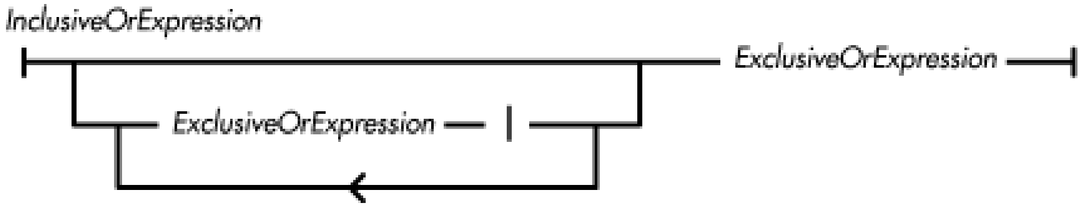
The bitwise exclusive OR operator produces a pure value that is the bitwise exclusive OR of its operands. If the corresponding bits in the converted operands are both 0 or both 1, the corresponding bit in the result is a 0; otherwise the corresponding bit in the result is a 1.

If both operands are of type `boolean`, the operator performs a logical exclusive OR operation. The logical exclusive OR operation produces a pure value of type `boolean`. If either, but not both, operands are `true`, the operation produces `true`; otherwise the operation produces `false`.

References Bitwise/Logical AND Operator &; Boolean Type; Integer types; Order of Operations

Bitwise/Logical Inclusive OR Operator |

The bitwise/logical inclusive OR operator `|` produces a pure value that is the inclusive OR of its operands. The `|` operator may appear in a bitwise or logical inclusive OR expression:



The bitwise/logical inclusive OR operator is evaluated from left to right. The operator never throws an exception.

Here is a code example that shows the use of the bitwise inclusive OR operator:

```
setFont("Helvetica", Font.BOLD | Font.ITALIC, 18);
```

The operands of the bitwise/logical inclusive OR operator must both be of either an integer type or the type `boolean`, or a compile-time error occurs.

If both operands are of integer types, the operator performs a bitwise inclusive OR operation. The operator may perform type conversions on the operands:

- If either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.
- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

The bitwise inclusive OR operator produces a pure value that is the bitwise inclusive OR of its operands. If the corresponding bits in either or both of the converted operands are 1s, the corresponding bit in the result is a 1; otherwise the corresponding bit in the result is a 0.

If both operands are of type `boolean`, the operator performs a logical inclusive OR operation. The logical inclusive OR operation produces a pure value of type `boolean`. If either or both operands are `true`, the operation produces `true`; otherwise the operation produces `false`. This operator differs from the conditional OR operator (`||`) because it always evaluates both of its operands, even if its left operand evaluates to `true`.

Byte

Name

Byte

Synopsis

Class Name:

> `java.lang.Byte`

Superclass:

> `java.lang.Number`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> New as of JDK 1.1

Description

The `Byte` class provides an object wrapper for a `byte` value. This is useful when you need to treat a `byte` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `byte` value for one of these arguments, but you can provide a reference to a `Byte` object that encapsulates the byte value. Furthermore, the Byte class is necessary as of JDK 1.1 to support the Reflection API and class literals.

The Byte class also provides a number of utility methods for converting byte values to other primitive types and for converting byte values to strings and vice versa.

Class Summary

```
public final class java.lang.Byte extends java.lang.Number {
  // Constants
  public static final byte MAX_VALUE;
  public static final byte MIN_VALUE;
  public static final Class TYPE;
  // Constructors
  public Byte(byte value);
  public Byte(String s);
  // Class Methods
  public static Byte decode(String nm);
  public static byte parseByte(String s);
  public static byte parseByte(String s, int radix);
  public static String toString(byte b);
  public static Byte valueOf(String s, int radix);
  public static Byte valueOf(String s);
  // Instance Methods
  public byte byteValue();
  public double doubleValue;
  public boolean equals(Object obj);
  public float floatValue
  public int hashCode();
  public int intValue();
  public long longValue();
  public short shortValue();
  public String toString();
}
```

Constants

MAX_VALUE

public static final byte MAX_VALUE= 127

The largest value that can be represented by a byte.

MIN_VALUE

public static final byte MIN_VALUE= -128

The smallest value that can be represented by a `byte`.

TYPE

public static final Class TYPE

The `Class` object that represents the primitive type `byte`. It is always true that `Byte.TYPE` == `byte.class`.

Constructors

Byte

public Byte(byte value)

Parameters

`value`

The `byte` value to be encapsulated by this object.

Description

Creates a `Byte` object with the specified byte value.

public Byte(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Byte` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `byte` literal.

Description

Constructs a `Byte` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

decode

public static Byte decode(String nm) throws NumberFormatException

Parameters

`nm`

A `String` representation of the value to be encapsulated by a `Byte` object. If the string begins with # or `0x`, it is a radix 16 representation of the value. If the string begins with `0`, it is a radix 8 representation of the value. Otherwise, it is assumed to be a radix 10 representation of the value.

Returns

A `Byte` object that encapsulates the given value.

Throws

`NumberFormatException`

If the `String` contains any non-digit characters other than a leading minus sign or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

This method returns a `Byte` object that encapsulates the given value.

parseByte

public static byte parseByte(String s) throws NumberFormatException

Parameters

`s`

The `String` to be converted to a `byte` value.

Returns

The numeric value of the byte represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte` or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

This method returns the numeric value of the `byte` represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static byte parseByte(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a `byte` value.

`radix`

The radix used in interpreting the characters in the `String` as digits. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If `radix` is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the byte represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte`, `radix` is not in the appropriate range, or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

This method returns the numeric value of the `byte` represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toString

public String toString(byte b)

Parameters

`b`

The `byte` value to be converted to a string.

Returns

The string representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

valueOf

public static Byte valueOf(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Byte` object.

Returns

The `Byte` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte` or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

Constructs a `Byte` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Byte valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Byte` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Byte` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte`, radix is not in the appropriate range, or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

Constructs a `Byte` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

Instance Methods

byteValue

public byte byteValue()

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`.

doubleValue

public double doubleValue()

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Byte` and it contains the same value as the object this method is associated with.

floatValue

public float floatValue()

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`.

hashCode

public int hashCode()

Returns

A hashcode based on the `byte` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object.

intValue

public int intValue()

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`.

longValue

public long longValue()

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

public short shortValue()

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`.

toString

public String toString()

Returns

The string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-` if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

JDK 1.0 or later

Description

The `Character` class provides an object wrapper for a `char` value. This is useful when you need to treat a char value as an object. For example, there are a number of utility methods that take a reference to an Object as one of their arguments. You cannot specify a char value for one of these arguments, but you can provide a reference to a Character object that encapsulates the char value. Furthermore, as of JDK 1.1, the Character class is necessary to support the Reflection API and class literals.

In Java, Character objects represent values defined by the Unicode standard. Unicode is defined by an organization called the Unicode Consortium. The defining document for Unicode is *The Unicode Standard, Version 2.0* (ISBN 0-201-48345-9). More recent information about Unicode is available at *http://unicode.org*. Appendix a, *The Unicode 2.0 Character Set*, contains a table that lists the characters defined by the Unicode 2.0 standard.

The Character class provides some utility methods, such as methods for determining the type (e.g., uppercase or lowercase, digit or letter) of a character and for converting from uppercase to lowercase. The logic for these utility methods is based on a Unicode attribute table that is part of the Unicode standard. That table is available at *ftp://unicode.org/pub/2.0-Update/UnicodeData-2.0.14.txt*.

Some of the methods in the Character class are concerned with characters that are digits; these characters are used by a number of other classes to convert strings that contain numbers into actual numeric values. The digit-related methods all use a radix value to interpret characters. The *radix* is the numeric base used to represent numbers as characters or strings. Octal is a radix 8 representation, while hexadecimal is a radix 16 representation. The methods that require a radix parameter use it to determine which characters should be treated as valid digits. In radix 2, only the characters `0' and `1' are valid digits. In radix 16, the characters `0' through `9', `a' through `z', and `A' through `Z' are considerd valid digits.

Class Summary

```
public final class java.lang.Character extends java.lang.Object
                                       implements java.io.Serializable {

Constants

COMBINING_SPACING_MARK

`public final static byte COMBINING_SPACING_MARK`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

CONNECTOR_PUNCTUATION

`public final static byte CONNECTOR_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

CONTROL

`public final static byte CONTROL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

CURRENCY_SYMBOL

`public final static byte CURRENCY_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

DASH_PUNCTUATION

`public final static byte DASH_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

DECIMAL_DIGIT_NUMBER

`public final static byte DECIMAL_DIGIT_NUMBER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

ENCLOSING_MARK

`public final static byte ENCLOSING_MARK`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

END_PUNCTUATION

`public final static byte END_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

FORMAT

`public final static byte FORMAT`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

LETTER_NUMBER

`public final static byte LETTER_NUMBER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

LINE_SEPARATOR

`public final static byte LINE_SEPARATOR`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

LOWERCASE_LETTER

`public final static byte LOWERCASE_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

MATH_SYMBOL

`public final static byte MATH_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

MAX_RADIX

`public static final int MAX_RADIX = 36`

Description

The maximum value that can be specified for a radix.

MAX_VALUE

`public final static char MAX_VALUE = '\ufff'f`

Description

The largest value that can be represented by a `char`.

MIN_RADIX

`public static final int MIN_RADIX = 2`

Description

The minimum value that can be specified for a radix.

MIN_VALUE

`public final static char MIN_VALUE = '\u0000'`

Description

The smallest value that can be represented by a `char`.

MODIFIER_LETTER

`public final static byte MODIFIER_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

MODIFIER_SYMBOL

`public final static byte MODIFIER_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

NON_SPACING_MARK

`public final static byte NON_SPACING_MARK`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_LETTER

`public final static byte OTHER_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_NUMBER

`public final static byte OTHER_NUMBER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_PUNCTUATION

`public final static byte OTHER_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_SYMBOL

`public final static byte OTHER_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

PARAGRAPH_SEPARATOR

`public final static byte PARAGRAPH_SEPARATOR`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

PRIVATE_USE

`public final static byte PRIVATE_USE`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

SPACE_SEPARATOR

`public final static byte SPACE_SEPARATOR`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

START_PUNCTUATION

`public final static byte START_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

SURROGATE

`public final static byte SURROGATE`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

TITLECASE_LETTER

`public final static byte TITLECASE_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `char`. It is always true that `Character.TYPE == char.class`.

UNASSIGNED

`public final static byte UNASSIGNED`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

UPPERCASE_LETTER

`public final static byte UPPERCASE_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

Constructors

Character

`public Character(char value)`

Parameters

`value`

The `char` value to be encapsulated by this object.

Description

Creates a `Character` object with the given `char` value.

Class Methods

digit

`public static int digit(char ch, int radix)`

Parameters

`ch`

A `char` value that is a legal digit in the given radix.

`radix`

The radix used in interpreting the specified character as a digit. If `radix` is in the range 2 through 10, only characters for which the `isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the digit. This method returns `-1` if the value of `ch` is not considered a valid digit, if `radix` is less than `MIN_RADIX`, or if `radix` is greater than `MAX_RADIX`.

Description

Returns the numeric value represented by a digit character. For example, `digit('7',10)` returns 7. If the value of `ch` is not a valid digit, the method returns `-1`. For example, `digit('7',2)` returns `-1` because `'7'` is not a valid digit in radix 2. A number of methods in other classes use this method to convert strings that contain numbers to actual numeric values. The `forDigit()` method is an approximate inverse of this method.

If `radix` is greater than 10, characters in the range `A' to `A'+`radix`-11 are treated as valid digits. Such a character has the numeric value `ch`-`A'+10. By the same token, if `radix` is greater than 10, characters in the range `a' to `a'+`radix`-11 are treated as valid digits. Such a character has the numeric value `ch`-`a'+10.

forDigit

`public static char forDigit(int digit, int radix)`

Parameters

`digit`

The numeric value represented as a digit character.

`radix`

The radix used to represent the specified value.

Returns

The character that represents the digit corresponding to the specified numeric value. The method returns `\ 0' if `digit` is less than 0, if `digit` is equal to or greater than `radix`, if `radix` is less than `MIN_RADIX`, or if `radix` is greater than `MAX_RADIX`.

Description

This method returns the character that represents the digit corresponding to the specified numeric value. If `digit` is in the range 0 through 9, the method returns `0'+`digit`. If `digit` is in the range 10 through `MAX_RADIX`-1, the method returns `a'+`digit`-10. The method returns `\ 0' if `digit` is less than 0, if `digit` is equal to or greater than `radix`, if `radix` is less than `MIN_RADIX`, or if `radix` is greater than `MAX_RADIX`.

getNumericValue

`public static int getNumericValue(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value.

Returns

The Unicode numeric value of the character as a nonnegative integer. This method returns `-1` if the character has no numeric value; it returns `-2` if the character has a numeric value that is not a nonnegative integer, such as `1/2`.

Description

This method returns the Unicode numeric value of the specified character as a nonnegative integer.

getType

`public static int getType(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value.

Returns

An `int` value that represents the Unicode general category type of the character.

Description

This method returns the Unicode general category type of the specified character. The value corresponds to one of the general category constants defined by `Character`.

isDefined

`public static boolean isDefined(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character has an assigned meaning in the Unicode character set; otherwise `false`.

Description

This method returns `true` if the specified character value has an assigned meaning in the Unicode character set.

isDigit

`public static boolean isDigit(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as a digit in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a digit, based on the definition of the character in Unicode.

isIdentifierIgnorable

`public static boolean isIdentifierIgnorable(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is ignorable in a Java or Unicode identifier; otherwise `false`.

Description

This method determines whether or not the specified character is ignorable in a Java or Unicode identifier. The following characters are ignorable in a Java or Unicode identifier:

`\u0000 - \u0008 \u000E - \u001B \u007F - \u009F`	ISO control characters that aren't whitespace
`\u200C - \u200F`	Join controls
`\u200A - \u200E`	Bidirectional controls
`\u206A - \u206F`	Format controls
`\uFEFF`	Zero-width no-break space

isISOControl

`public static boolean isISOControl(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is an ISO control character; otherwise `false`.

Description

This method determines whether or not the specified character is an ISO control character. A character is an ISO control character if it falls in the range `\u0000` through `\u001F` or `\u007F` through `\u009F`.

isJavaIdentifierPart

`public static boolean isJavaIdentifierPart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear after the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Java identifier after the first character. A character is considered part of a Java identifier if and only if it is a letter, a digit, a currency symbol (e.g., $), a connecting punctuation character (e.g., _), a numeric letter (e.g., a Roman numeral), a combining mark, a nonspacing mark, or an ignorable control character.

isJavaIdentifierStart

`public static boolean isJavaIdentifierStart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear as the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Java identifier as the first character. A character is considered a start of a Java identifier if and only if it is a letter, a currency symbol (e.g., $), or a connecting punctuation character (e.g., _).

isJavaLetter

`public static boolean isJavaLetter(char ch)`

Availability

Deprecated as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear as the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear as the first character in a Java identifier. A character is considered a Java letter if and only if it is a letter, the character $, or the character _ . This method returns `false` for digits because digits are not allowed as the first character of an identifier.

This method is deprecated as of JDK 1.1. You should use `isJavaIdentifierStart()` instead.

isJavaLetterOrDigit

`public static boolean isJavaLetterOrDigit(char ch)`

Availability

Deprecated as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear after the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Java identifier after the first character. A character is considered a Java letter or digit if and only if it is a letter, a digit, the character $, or the character _.

This method is deprecated as of JDK 1.1. You should use `isJavaIdentifierPart()` instead.

isLetter

`public static boolean isLetter(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as a letter in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a letter, based on the definition of the character in Unicode. This method does not consider character values in ranges that have not been assigned meanings by Unicode to be letters.

isLetterOrDigit

`public static boolean isLetterOrDigit(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as a letter in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a letter or a digit, based on the definition of the character in Unicode. There are some ranges that have not been assigned meanings by Unicode. If a character value is in one of these ranges, this method does not consider the character to be a letter.

isLowerCase

`public static boolean isLowerCase (char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as lowercase in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is lowercase. Unicode defines a number of characters that do not have case mappings; if the specified character is one of these characters, the method returns `false`.

isSpace

`public static boolean isSpace(char ch)`

Availability

Deprecated as of JDK 1.1

Parameters

`ch`

A char value to be tested.

Returns

true if the specified character is defined as whitespace in the ISO-Latin-1 character set; otherwise false.

Description

This method determines whether or not the specified character is whitespace. This method recognizes the whitespace characters shown in the following table.

\u0009	Horizontal tab
\u000A	Newline
\u000C	Formfeed
\u000D	Carriage return
\u0020 ` `	Space

This method is deprecated as of JDK 1.1. You should use isWhitespace() instead.

isSpaceChar

public static boolean isSpaceChar(char ch)

Availability

New as of JDK 1.1

Parameters

ch

A char value to be tested.

Returns

true if the specified character is a Unicode 2.0 space characters; otherwise false.

Description

This method determines if the specified character is a space character according to the Unicode 2.0 specification. A character is considered to be a Unicode space character if and only if it has the general category "Zs", "Zl", or "Zp" in the Unicode specification.

isTitleCase

`public static boolean isTitleCase(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as titlecase in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a titlecase character. Unicode defines a number of characters that do not have case mappings; if the specified character is one of these characters, the method returns `false`.

Many characters are defined by the Unicode standard as having upper- and lowercase forms. There are some characters defined by the Unicode standard that also have a titlecase form. The glyphs for these characters look like a combination of two Latin letters. The titlecase form of these characters has a glyph that looks like a combination of an uppercase Latin character and a lowercase Latin character; this case should be used when the character appears as the first character of a word in a title. For example, one of the Unicode characters that has a titlecase form looks like the letter `D' followed by the letter `Z'. Here is what the three forms of this letter look like:

Uppercase	`DZ'
Titlecase	`Dz'
Lowercase	`dz'

isUnicodeIdentifierPart

`public static boolean isUnicodeIdentifierPart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear after the first character in a Unicode identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Unicode identifier after the first character. A character is considered part of a Unicode identifier if and only if it is a letter, a digit, a connecting punctuation character (e.g., _), a numeric letter (e.g., a Roman numeral), a combining mark, a nonspacing mark, or an ignorable control character.

isUnicodeIdentifierStart

```
public static boolean isUnicodeIdentifierStart(char ch)
```

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear as the first character in a Unicode identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Unicode identifier as the first character. A character is considered a start of a Unicode identifier if and only if it is a letter.

isUpperCase

```
public static boolean isUpperCase(char ch)
```

Parameters

ch

A `char` value to be tested.

Returns

`true` if the specified character is defined as uppercase in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is uppercase. Unicode defines a number of characters that do not have case mappings; if the specified character is one of these characters, the method returns `false`.

isWhitespace

`public static boolean isWhitespace(char ch)`

Availability

New as of JDK 1.1

Parameters

ch

A `char` value to be tested.

Returns

`true` if the specified character is defined as whitespace according to Java; otherwise `false`.

Description

This method determines whether or not the specified character is whitespace. This method recognizes the following as whitespace:

Unicode category "Zs" except `\u00A0` and `\uFEFF`	Unicode space separators except no-break spaces
Unicode category "Zl"	Unicode line separators
Unicode category "Zp"	Unicode paragraph separators
`\u0009`	Horizontal tab

`\u000A`	Linefeed
`\u000B`	Vertical tab
`\u000C`	Formfeed
`\u000D`	Carriage return
`\u001C`	File separator
`\u001D`	Group separator
`\u001E`	Record separator
`\u001F`	Unit separator

toLowerCase

`public static char toLowerCase(char ch)`

Parameters

`ch`

A `char` value to be converted to lowercase.

Returns

The lowercase equivalent of the specified character, or the character itself if it cannot be converted to lowercase.

Description

This method returns the lowercase equivalent of the specified character value. If the specified character is not uppercase or if it has no lowercase equivalent, the character is returned unmodified. The Unicode attribute table determines if a character has a mapping to a lowercase equivalent.

Some Unicode characters in the range `\u2000` through `\u2FFF` have lowercase mappings. For example, `\u2160` (Roman numeral one) has a lowercase mapping to `\u2170` (small Roman numeral one). The `toLowerCase()` method maps such characters to their lowercase equivalents even though the method `isUpperCase()` does not return `true` for such characters.

toTitleCase

`public static char toTitleCase(char ch)`

Parameters

`ch`

A `char` value to be converted to titlecase.

Returns

The titlecase equivalent of the specified character, or the character itself if it cannot be converted to titlecase.

Description

This method returns the titlecase equivalent of the specified character value. If the specified character has no titlecase equivalent, the character is returned unmodified. The Unicode attribute table is used to determine the character's titlecase equivalent.

Many characters are defined by the Unicode standard as having upper- and lowercase forms. There are some characters defined by the Unicode standard that also have a titlecase form. The glyphs for these characters look like a combination of two Latin letters. The titlecase form of these characters has a glyph that looks like a combination of an uppercase Latin character and a lowercase Latin character; this case should be used when the character appears as the first character of a word in a title. For example, one of the Unicode characters that has a titlecase form looks like the letter `D' followed by the letter `Z'. Here is what the three forms of this letter look like:

Uppercase	`DZ'
Titlecase	`Dz'
Lowercase	`dz'

toUpperCase

`public static char toUpperCase(char ch)`

Parameters

`ch`

A `char` value to be converted to lowercase.

Returns

The uppercase equivalent of the specified character, or the character itself if it cannot be converted to uppercase.

Description

This method returns the uppercase equivalent of the specified character value. If the specified character is not lowercase or if it has no uppercase equivalent, the character is returned unmodified. The Unicode attribute table determines if a character has a mapping to an uppercase equivalent.

Some Unicode characters in the range `\u2000` through `\u2FFF` have uppercase mappings. For example, `\u2170` (small Roman numeral one) has a lowercase mapping to `\u2160` (Roman numeral one). The `toUpperCase()` method maps such characters to their uppercase equivalents even though the method `isLowerCase()` does not return `true` for such characters.

Instance Methods

charValue

```
public char charValue()
```

Returns

The `char` value contained by the object.

equals

```
public boolean equals(Object obj)
```

Parameters

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Character`, and it contains the same value as the object this method is associated with.

hashCode

```
public int hashCode()
```

Returns

> A hashcode based on the `char` value of the object.

Overrides

> `Object.hashCode()`

toString

```
public String toString()
```

Returns

> A `String` of length one that contains the character value of the object.

Overrides

> `Object.toString()`

Description

> This method returns a string representation of the `Character` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

4.12 Conditional Operator

The conditional operator (`? :`) is a ternary operator. The operator selects one of two expressions for evaluation, based on the value of its first operand. In this way, the conditional operator is similar to an `if` statement. A conditional operator may appear in a conditional expression:

[Graphic: Figure from the text]

The conditional operator produces a pure value. Conditional expressions group from right to left. Consider the following expression:

```
g?f:e?d:c?b:a
```

It is equivalent to

```
g?f:(e?d:(c?b:a))
```

The first operand of the conditional operator must be of type `boolean`, or a compile-time error occurs. If the first operand evaluates to `true`, the operator evaluates the second operand (i.e., the one following the `?`) and produces the pure value of that expression. Otherwise, if the first operand evaluates to `false`, the operator evaluates the third operand (i.e., the one following the `:`) and produces the pure value of that expression. Note that the conditional operator evaluates either its second operand or its third operand, but not both.

The second and third operands of the conditional operator may be of any type, but they must both be of the same kind of type or a compile-time error occurs. If one operand is of an arithmetic type, the other must also be of an arithmetic type. If one operand is of type `boolean`, the other must also be of type `boolean`. If one operand is a reference type, the other must also be a reference type. Note that neither the second nor the third operand can be an expression that invokes a `void` method.

The types of the second and third operands determine the type of pure value that the conditional operator produces. If the second and third operands are of different types, the operator may perform a type conversion on the operand that it evaluates. The operator does this to ensure that it always produces the same type of result for a given expression, regardless of the value of its first operand.

If the second and third operands are both of arithmetic types, the conditional operator determines the type of value it produces as follows:[6]

- If both operands are of the same type, the conditional operator produces a pure value of that type.

- If one operand is of type `short` and the other operand is of type `byte`, the conditional operator produces a `short` value.
- If one operand is of type `short`, `char`, or `byte` and the other operand is a constant expression that can be represented as a value of that type, the conditional operator produces a pure value of that type.
- Otherwise, if either operand is of type `double`, the operator produces a `double` value.
- Otherwise, if either operand is of type `float`, the operator produces a `float` value.
- Otherwise, if either operand is of type `long`, the operator produces a `long` value.
- Otherwise, if either operand is of type `int`, the operator produces an `int` value.

If the second and third operands are both of type `boolean`, the conditional operator produces a pure `boolean` value.

If the second and third operands are both reference types, the conditional operator determines the type of value it produces as follows:

- If both operands are `null`, the conditional operator produces the pure value `null`.
- Otherwise, if exactly one of the operands is `null`, the conditional operator produces a value of the type of the other operand.

[6] Some of these rules are different from the way it is done in C/C++. In those languages, integer data of types smaller than `int` are always converted to `int` when they appear in any expression.

- Otherwise, it must be possible to cast the value of one of the operands to the type of the other operand, or a compile-time error occurs. The conditional operator produces a value of the type that would be the target of the cast.

4.9 Equality Comparison Operators

The equality comparison operators in Java are used for equal-to (==) and not-equal-to (!=) comparison operations. The equality comparison operators may appear in an equality expression:

[Graphic: Figure from the text]

The equality comparison operators are equal in precedence and are evaluated from left to right. The == and != comparison operators can perform numerical comparisons, `boolean` comparisons, and reference type comparisons. Both of these operators produce `boolean` values.

References Relational Comparison Operators; Order of Operations

Equal-To Operator ==

The equal-to operator == performs a comparison between its operands and returns a `boolean` value. It returns the pure value `true` if the operands are equal to each other; otherwise it returns the pure value `false`. The == operator may appear as part of an equality expression. The equal-to operator never throws an exception.

The operands of == may be of any type, but they must both be of the same kind of type or a compile-time error occurs. If one operand is of an arithmetic type, the other must also be of an arithmetic type. If one operand is of type `boolean`, the other must also be of type `boolean`. If one operand is a reference type, the other must also be a reference type. Note that neither operand can be an expression that invokes a `void` method.

If both operands are of arithmetic types, then the operator performs an arithmetic equality comparison.

The operator may perform type conversions on the operands:

- If either operand is of type `double`, then the other operand is converted to `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float`.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long`.
- Otherwise, both operands are converted to `int`.

The equality comparison of any two arithmetic values produces `true` if and only if both operands are the same value; otherwise the comparison produces `false`. The comparison of floating-point data is governed by the following additional rules:

- If either operand is not-a-number (NaN), the comparison produces `false`.
- Positive infinity is a distinct value that is equal to itself, and not equal to any other value.
- Negative infinity is a distinct value that is equal to itself, and not equal to any other value.
- Positive and negative zero are treated as equal, so `-0.0==0.0` produces `true`.

If both operands are `boolean` values, the operator performs a Boolean equality comparison. The comparison produces `true` if both operands are `true` or both operands are `false`. Otherwise, the comparison produces `false`.

If both operands are reference types, the operator performs an object equality comparison. In order to perform this type of comparison, it must be possible to cast the value of one of the operands to the type of the other operand, or a compile-time error occurs. The comparison produces `true` if both of its operands refer to the same object or if both of its operands are `null`; otherwise the comparison produces `false`.

Because the == operator determines if two objects are the same object, it is not appropriate for comparisons that need to determine if two objects have the same contents. For example, if you need to know whether two `String` objects contain the same sequences of characters, the == operator is inappropriate. You should use the `equals()` method instead:[4]

> [4] This is similar to the difference in C between writing `string1==string2` and `strcmp(string1, string2)==0`.

```
string1.equals (string2)  // Compares contents of strings
```

```
string1 == string2        // Compares actual string objects
```

References Arithmetic Types; Boolean Type; Reference Types

Not-Equal-To-Operator !=

The not-equal-to operator `!=` performs a comparison between its operands and returns a `boolean` value. It returns the pure value `true` if the operands are not equal to each other; otherwise it returns the pure value `false`. The `!=` operator may appear as part of an equality expression. The not-equal-to operator never throws an exception.

The operands of `!=` may be of any type, but they must both be of the same kind of type or a compile-time error occurs. If one operand is of an arithmetic type, the other must also be of an arithmetic type. If one operand is of type `boolean`, the other must also be of type `boolean`. If one operand is a reference type, the other must also be a reference type. Note that neither operand can be an expression that invokes a `void` method.

If both operands are of arithmetic types, the operator performs an arithmetic inequality comparison. The operator may perform type conversions on the operands:

- If either operand is of type `double`, then the other operand is converted to `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float`.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long`.
- Otherwise, both operands are converted to `int`.

The inequality comparison of any two arithmetic values produces `true` if and only if both operands are not the same value; otherwise the comparison produces `false`. The comparison of floating-point data is governed by the following additional rules:

- If either operand is not-a-number (NaN), the comparison produces `true`. NaN is the only value that compares as not equal to itself.
- Positive infinity is a distinct value that is equal to itself, and not equal to any other value.
- Negative infinity is a distinct value that is equal to itself, and not equal to any other value.
- Positive and negative zero are treated as equal, so `-0.0!=0.0` produces `false`.

If both operands are `boolean` values, the operator performs a Boolean inequality comparison. The comparison produces `false` if both operands are `true` or both operands are `false`. Otherwise, the comparison produces `true`.

If both operands are reference types, the operator performs an object equality comparison. In order to perform this type of comparison, it must be possible to cast the value of one of the operands to the type of the other operand, or a compile-time error occurs. The comparison produces `true` if both of its operands refer to different objects and if both of its operands are not `null`; otherwise the comparison produces `false`.

Because the `!=` operator determines if two objects are different objects, it is not appropriate for comparisons that need to determine if two objects have different contents. For example, if you need to know whether two `String` objects contain different sequences of characters, the `!=` operator is inappropriate. You should use the `equals()` method instead:[5]

> [5] This is similar to the difference in C between writing `string1!=string2` and `strcmp(string1, string2)!=0`.

```
!string1.equals (string2) // Compares contents of strings
string1 != string2        // Compares actual string objects
```

References Arithmetic Types; Boolean Type; Reference Types

4.3 Increment/Decrement Operators

The ++ operator is used to increment the contents of a variable or an array element by one, while the -- operator is used to decrement such a value by one. The operand of ++ or -- must evaluate to a variable or an array element; it cannot be an expression that produces a pure value. For example, the following operations succeed because the operand of the ++ operator produces a variable:

```
int g = 0;
g++;
```

However, the following uses of ++ generate error messages:

```
final int h = 23;
h++;
5++;
```

The expression h++ produces an error because h is declared final, which means that its value cannot be changed. The expression 5++ generates an error message because 5 is a literal value, not a variable.

The increment and decrement operators can be used in both postfix expressions (e.g., i++ or i--) and in prefix expressions (e.g., ++i or --i). Although both types of expression have the same side effect of incrementing or decrementing a variable, they differ in the values that they produce. A postfix expression produces a pure value that is the value of the variable before it is incremented or decremented, while a prefix expression produces a pure value that is the value of the variable after it has been incremented or decremented. For example, consider the following code fragment:

```
int i = 3, j = 3;
System.out.println( "i++ produces " + i++);
System.out.println( "++j produces " + ++j);
```

The above code fragment produces the following output:

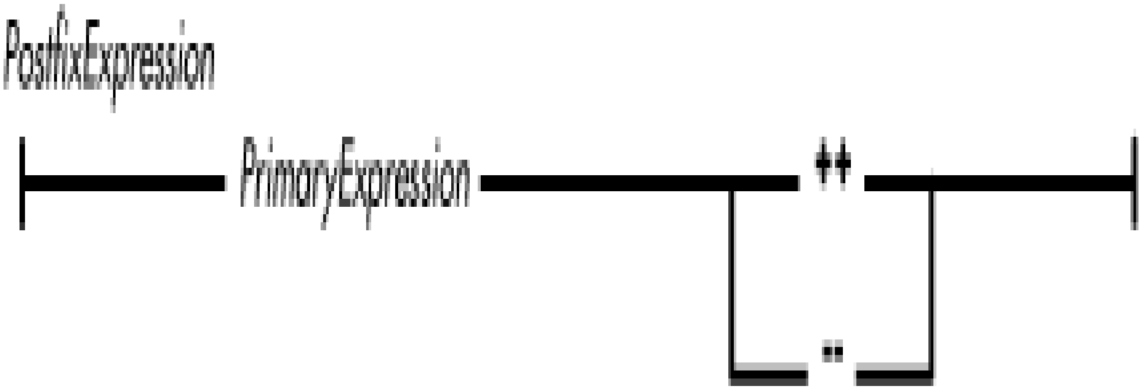
```
i++ produces 3
++j produces 4
```

After the code fragment has been evaluated, both `i` and `j` have the value 4.

In essence, what you need to remember is that a prefix expression performs its increment or decrement before producing a value, while a postfix expression performs its increment or decrement after producing a value.

Postfix Increment/Decrement Operators

A postfix increment/decrement expression is a primary expression that may be followed by either a `++` or a `- -`:



The postfix increment and decrement operators are equal in precedence and are effectively non-associative.

If a postfix expression includes a `++` or `- -`, the primary expression must produce a variable or an array element of an arithmetic type. The postfix increment operator (`++`) has the side effect of incrementing the contents of the variable or array element by one. The postfix decrement operator (`- -`) has the side effect of decrementing the contents of the variable or array element by one.

The data type of the value produced by a postfix increment/decrement operator is the same as the data type of the variable or array element produced by the primary expression. A postfix increment/decrement operator produces the original pure value stored in the variable or array element before it is incremented or decremented.

The following is an example of using a postfix decrement operator:

```
char j = '\u0100';
while (j-- > 0)        // call doit for char values
```

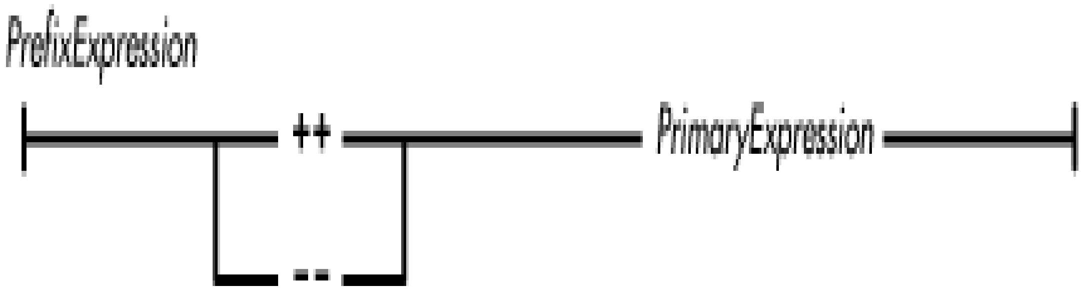
```
    doit(j);           // '\u00ff' through '\u0000'
```

This example works because Java treats `char` as an arithmetic data type.

References Arithmetic Types; Order of Operations; Primary Expressions

Prefix Increment/Decrement Operators

A prefix increment/decrement expression is a primary expression that may be preceded by either a `++` or a `- -`:



The prefix increment and decrement operators are equal in precedence and are effectively non-associative.

If a prefix expression includes a `++` or `- -`, the primary expression must produce a variable or an array element of an arithmetic type. The prefix increment operator (`++`) has the side effect of incrementing the contents of the variable or array element by one. The prefix decrement operator (`- -`) has the side effect of decrementing the contents of the variable or array element by one.

The data type of the value produced by a prefix increment/decrement operator is the same as the data type of the variable or array element produced by the primary expression. A prefix increment/decrement operator produces the pure value stored in the variable or array element after it has been incremented or decremented.

Here's an example of using a prefix increment operator:

```
void foo(int a[]) {
    int j = -1;
    while (++j < a.length)    // call doit for each element
        doit(a[j]);              // of a
    }
```

Integer

Name

Integer

Synopsis

Class Name:

`java.lang.Integer`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Integer` class provides an object wrapper for an `int` value. This is useful when you need to treat an `int` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify an `int` value for one of these arguments, but you can provide a reference to an `Integer` object that encapsulates the `int` value. Also, as of JDK 1.1, the `Integer` class is necessary to support the

Reflection API and class literals.

The `Integer` class also provides a number of utility methods for converting `int` values to other primitive types and for converting `int` values to strings and vice versa.

Class Summary

```
public final class java.lang.Integer extends java.lang.Number {
    // Constants
    public static final int MAX_VALUE;
    public static final int MIN_VALUE;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Integer(int value);
    public Integer(String s);
    // Class Methods
    public static Integer decode(String nm)            // New in 1.1
    public static Integer getInteger(String nm);
    public static Integer getInteger(String nm, int val);
    public static Integer getInteger(String nm, Integer val);
    public static int parseInt(String s);
    public static int parseInt(String s, int radix;
    public static String toBinaryString(long i);
    public static String toHexString(long i);
    public static String toOctalString(long i);
    public static String toString(int i);
    public static String toString(int i, int radix);
    public static Integer valueOf(String s);
    public static Integer valueOf(String s, int radix);
    // Instance Methods
    public byte byteValue();                           // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public long longValue();
    public short shortValue();                         // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final int MAX_VALUE = 0x7fffffff // 2147483647`

Description

The largest value that can be represented by an `int`.

MIN_VALUE

`public static final int MIN_VALUE = 0x80000000 // -2147483648`

Description

The smallest value that can be represented by an `int`.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `int`. It is always true that `Integer.TYPE` == `int.class`.

Constructors

Integer

`public Integer(int value)`

Parameters

`value`

The `int` value to be encapsulated by this object.

Description

Creates an `Integer` object with the specified `int` value.

`public Integer(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into an `Integer` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `int` literal.

Description

Constructs an `Integer` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `` `-' `` character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

decode

`public static Integer decode(String nm)`

Availability

New as of JDK 1.1

Parameters

`nm`

A `String` representation of the value to be encapsulated by an `Integer` object. If the string begins with # or `0x`, it is a radix 16 representation of the value. If the string begins with `0`, it is a radix 8 representation of the value. Otherwise, it is assumed to be a radix 10 representation of the value.

Returns

An `Integer` object that encapsulates the given value.

Throws

`NumberFormatException`

If the `String` contains any nondigit characters other than a leading minus sign or the value represented by the `String` is less than `Integer.MIN_VALUE` or greater than `Integer.MAX_VALUE`.

Description

This method returns an `Integer` object that encapsulates the given value.

getInteger

`public static Integer getInteger(String nm)`

Parameters

`nm`

The name of a system property.

Returns

The value of the system property as an `Integer` object, or an `Integer` object with the value 0 if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as an `Integer` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Integer getInteger(String nm, int val)`

Parameters

`nm`

The name of a system property.

`val`

A default `int` value for the property.

Returns

The value of the system property as an `Integer` object, or an `Integer` object with the value `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as an `Integer` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Integer getInteger(String nm, Integer val)`

Parameters

`nm`

The name of a system property.

`val`

A default `Integer` value for the property.

Returns

The value of the system property as an `Integer` object, or the `Integer` object `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as an `Integer` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's as a decimal integer.

parseInt

`public static int parseInt(String s) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to an `int` value.

Returns

The numeric value of the integer represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer.

Description

This method returns the numeric value of the integer represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static int parseInt(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to an `int` value.

`radix`

The radix used in interpreting the characters in the `String` as digits. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If `radix` is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the integer represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer, or `radix` is not in the appropriate range.

Description

This method returns the numeric value of the integer represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toBinaryString

`public static String toBinaryString(int value)`

Parameters

`value`

The `int` value to be converted to a string.

Returns

A string that contains the binary representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned binary number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^32 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more `0' and `1' characters. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method begins with `1'.

toHexString

`public static String toHexString(int value)`

Parameters

`value`

The `int` value to be converted to a string.

Returns

A string that contains the hexadecimal representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned hexadecimal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^32 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', `9', `a', `b', `c', `d', `e', and `f'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with `0'.

To produce a string that contains upper- instead of lowercase letters, use the `String.toUpperCase()` method.

toOctalString

`public static String toOctalString(int value)`

Parameters

`value`

The `int` value to be converted to a string.

Returns

A string that contains the octal representation of the given value.

Description

This method returns a `String` object that contains a representation of the given value as an unsigned octal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^32 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', and `7'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with `0'.

toString

`public static String toString(int i)`

Parameters

`i`

The `int` value to be converted to a string.

Returns

The string representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

public static String toString(int i, int radix)

Parameters

i

The int value to be converted to a string.

radix

The radix used in converting the value to a string. This value must be in the range Character.MIN_RADIX to Character.MAX_RADIX.

Returns

The string representation of the given value in the specified radix.

Description

This method returns a String object that contains the representation of the given value in the specified radix.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more characters that represent the magnitude of the given value. The characters that can appear in the sequence are determined by the value of radix. If *N* is the value of radix, the first *N* characters on the following line can appear in the sequence:

```
0123456789abcdefghijklmnopqrstuvwxyz
```

The method does not verify that radix is in the proper range. If radix is less than Character.MIN_RADIX or greater than Character.MAX_RADIX, the value 10 is used instead of the given value.

This method returns "0" if its argument is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

valueOf

public static Integer valueOf(String s) throws NumberFormatException

Parameters

s

The string to be made into an `Integer` object.

Returns

The `Integer` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer.

Description

Constructs an `Integer` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Integer valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into an `Integer` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Integer` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer or `radix` is not in the appropriate range.

Description

Constructs an `Integer` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

Instance Methods

byteValue

`public byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`. The high order bits of the value are discarded.

doubleValue

`public double doubleValue()`

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Integer` and it contains the same value as the object this method is associated with.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`. Rounding may occur.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `int` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object.

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`.

longValue

`public long longValue()`

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

`public short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a short.

Overrides

Number.shortValue()

Description

This method returns the value of this object as a short. The high order bits of the value are discarded.

toString

public String toString()

Returns

The string representation of the value of this object.

Overrides

Object.toString()

Description

This method returns a String object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-' if the value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if the value of the object is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	finalize()	Object
getClass()	Object	notify()	Object
notifyAll()	Object	wait()	Object

    public String toString();
}
```

Constants

MAX_VALUE

`public static final long MAX_VALUE = 0x7fffffffffffffffL`

Description

The largest value that can be represented by a `long`.

MIN_VALUE

`public static final long MIN_VALUE = 0x8000000000000000L`

Description

The smallest value that can be represented by a `long`.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `long`. It is always true that `Long.TYPE` == `long.class`.

Constructors

Long

`public Long(long value)`

Parameters

`value`

The `long` value to be encapsulated by this object.

Description

Creates a `Long` object with the specified `long` value.

`public Long(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Long` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `long` literal.

Description

Constructs a `Long` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

getLong

`public static Integer getLong(String nm)`

Parameters

`nm`

The name of a system property.

Returns

The value of the system property as a `Long` object or a `Long` object with the value 0 if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as a `Long` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Long getLong(String nm, long val)`

Parameters

`nm`

The name of a system property.

`val`

A default value for the property.

Returns

The value of the system property as a `Long` object or a `Long` object with the value `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as a `Long` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or # and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Long getLong(String nm, Long val)`

Parameters

`nm`

The name of a system property.

`val`

A default value for the property.

Returns

The value of the system property as a `Long` object, or the `Long` object `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as a `Long` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or # and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

parseLong

`public static long parseLong(String s) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a `long` value.

Returns

The numeric value of the `long` represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long` value.

Description

This method returns the numeric value of the `long` represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static long parseLong(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a `long` value.

`radix`

The radix used in interpreting the characters in the `String` as digits. It must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If `radix` is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the `long` represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long` or `radix` is not in the appropriate range.

Description

This method returns the numeric value of the `long` represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toBinaryString

`public static String toBinaryString(long value)`

Parameters

`value`

The `long` value to be converted to a string.

Returns

A string that contains the binary representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned binary number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^64 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more `0' and `1' characters. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method begins with `1'.

toHexString

`public static String toHexString(long value)`

Parameters

`value`

The `long` value to be converted to a string.

Returns

A string that contains the hexadecimal representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned hexadecimal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^64 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters \`0', \`1', \`2', \`3', \`4', \`5', \`6', \`7', \`8', \`9', \`a', \`b', \`c', \`d', \`e', and \`f'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with \`0'.

To produce a string that contains upper- instead of lowercase letters, use the `String.toUpperCase()` method.

toOctalString

`public static String toOctalString(long value)`

Parameters

`value`

The `long` value to be converted to a string.

Returns

A string that contains the octal representation of the given value.

Description

This method returns a `String` object that contains a representation of the given value as an unsigned octal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^64 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters \`0', \`1', \`2', \`3', \`4', \`5', \`6', and \`7'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with \`0'.

toString

`public static String toString(long i)`

Parameters

`i`

The `long` value to be converted to a string.

Returns

The string representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "`-0`".

`public static String toString(long i, int radix)`

Parameters

`i`

The `long` value to be converted to a string.

`radix`

The radix used in converting the value to a string. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The string representation of the given value in the specified radix.

Description

This method returns a `String` object that contains the representation of the given value in the specified radix.

This method returns a string that begins with`-' if the given value is negative. The rest of the string is a sequence of one or more characters that represent the magnitude of the given value. The characters that can appear in the sequence are determined by the value of `radix`. If *N* is the value of `radix`, the first *N* characters on the following line can appear in the sequence:

`0123456789abcdefghijklmnopqrstuvwxyz`

The method does not verify that `radix` is in the proper range. If `radix` is less than `Character.MIN_RADIX` or greater than `Character.MAX_RADIX`, the value 10 is used instead of the given value.

This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "`-`0".

valueOf

`public static Long valueOf(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Long` object.

Returns

The `Long` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long`.

Description

Constructs a `Long` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-` character. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Long valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Long` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Long` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long`.

Description

Constructs a `Long` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

The method does not verify that `radix` is in the proper range. If `radix` is less than `Character.MIN_RADIX` or greater than `Character.MAX_RADIX`, the value 10 is used instead of the given value.

Instance Methods

byteValue

`public byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`. The high order bits of the value are discarded.

doubleValue

`public double doubleValue()`

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`. Rounding may occur.

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Long` and it contains the same value as the object this method is associated with.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`. Rounding may occur.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `long` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object. More specifically, the result is the exclusive OR of the two halves of the `long` value represented by the object. If `value` is the value of the object, the method returns a result equivalent to the following expression:

```
(int)(value^(value>>>32))
```

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`. The high-order bits of the value are discarded.

longValue

`public long longValue()`

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

`public short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`. The high-order bits of the value are discarded.

toString

`public String toString()`

Returns

The string representation of the value of this object.

Overrides

```
Object.toString()
```

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-' if the value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if the value of the object is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

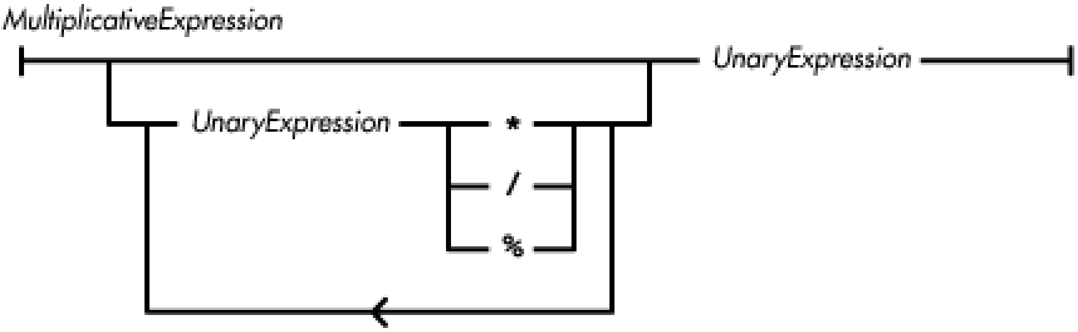
4.5 Multiplicative Operators

The multiplicative operators in Java are binary operators that are used for multiplication (*), division (/), and the remainder operation (%). The multiplicative operators appear in multiplicative expressions:



The multiplicative operators are equal in precedence and are evaluated from left to right.

References Unary Operators; Order of Operations

Multiplication Operator *

The binary multiplication operator * produces a pure value that is the product of its operands. The * operator may appear in a multiplicative expression. The multiplication operator never throws an exception.

Here is an example that uses the multiplication operator:

```
int doubleIt(int x) {
    return x*2;
}
```

The types of both operands of the multiplication operator must be arithmetic types, or a compile-time error occurs. The * operator may perform type conversions on its operands:

- If either operand is of type `double`, the other operand is converted to `double` and the operation produces a `double` value.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float` and the operation produces a `float` value.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.
- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

If the multiplication of integer data overflows, the low order bits of the product are returned; no exception is thrown. The most significant bit of the low order bits is treated as a sign bit. When overflow occurs, the sign of the number produced may not be the same as the sign of the mathematically correct product, due to the limitations of the two's complement representation used for integer data.

The multiplication of floating-point data is governed by the following rules:

- If either operand is not-a-number (NaN), the product is NaN.
- If neither operand is NaN and if both operands have the same sign, the product is positive.
- If neither operand is NaN and if the operands have different signs, the product is negative.
- If one of the operands is positive or negative infinity and the other operand is positive or negative zero, the product is NaN.
- If one of the operands is an infinity value and the other operand is neither zero nor NaN, the product is either positive or negative infinity, as determined by the rules governing the sign of products.
- If neither operand is a zero value, an infinity value, or NaN, the product is rounded to the nearest representable value. If the magnitude of the product is too large to be represented, the operation overflows and an infinity value of the appropriate sign is produced. If the magnitude of the product is too small to be represented, the operation underflows and a zero value of the appropriate sign is produced.

References Arithmetic Types

Division Operator /

The binary division operator `/` produces a pure value that is the quotient of its operands. The left operand is the dividend and the right operand is the divisor. The `/` operator may appear in a multiplicative expression.

Here is an example that uses the division operator:

```
int halfIt(int x) {
    return x/2;
}
```

The types of both operands of the division operator must be arithmetic types, or a compile-time error occurs. The `/` operator may perform type conversions on its operands:

- If either operand is of type `double`, the other operand is converted to `double` and the operation produces a `double` value.

- Otherwise, if either operand is of type `float`, the other operand is converted to `float` and the operation produces a `float` value.

- Otherwise, if either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.

- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

The division of integer data rounds toward zero. If the divisor of an integer division operator is zero, an `ArithmeticException` is thrown. If the dividend is `Integer.MIN_VALUE` or `Long.MIN_VALUE` and the divisor is -1, the quotient produced is `Integer.MIN_VALUE` or `Long.MIN_VALUE`, due to the limitations of the two's complement representation used for integer data.

The division of floating-point data is governed by the following rules:

- If either operand is not-a-number (NaN), the quotient is NaN.

- If neither operand is NaN and if both operands have the same sign, the quotient is positive.

- If neither operand is NaN and if the operands have different signs, the quotient is negative.

- If both of the operands are positive or negative infinity, the quotient is NaN.

- If the dividend is an infinity value and the divisor is a finite number, the quotient is either positive or negative infinity, as determined by the rules governing the sign of quotients.
- If the dividend is a finite number and the divisor is an infinity value, the quotient is either positive or negative zero, as determined by the rules governing the sign of quotients.
- If the divisor is positive or negative zero and the dividend is not zero or NaN, the quotient is either positive or negative infinity, as determined by the rules governing the sign of quotients.
- If both operands are zero values, the quotient is NaN.
- If the dividend is a zero value and the divisor is a non-zero finite number, the quotient is either positive or negative zero, as determined by the rules governing the sign of quotients.
- If the dividend is a non-zero finite number and the divisor is a zero value, the quotient is either positive or negative infinity, as determined by the rules governing the sign of quotients.
- If neither operand is a zero value, an infinity value, or NaN, the quotient is rounded to the nearest representable value. If the magnitude of the quotient is too large to be represented, the operation overflows and an infinity value of the appropriate sign is produced. If the magnitude of the quotient is too small to be represented, the operation underflows and a zero value of the appropriate sign is produced.

References Arithmetic Types; Integer; Long; Runtime exceptions

Remainder Operator %

The binary remainder operator % produces a pure value that is the remainder from an implied division of its operands. The left operand is the dividend and the right operand is the divisor. The % operator may appear in a multiplicative expression.

Here is an example that uses the remainder operator:

```
// format seconds into hours, minutes and seconds
String formatTime(int t) {
    int minutes, seconds;
    seconds = t%60;
    t /= 60;
    minutes = t%60;
    return t/60 + ":" + minutes + ":" + seconds;
}
```

The types of both operands of the remainder operator must be arithmetic types, or a compile-time error occurs. The % operator may perform type conversions on its operands:

- If either operand is of type `double`, the other operand is converted to `double` and the operation produces a `double` value.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float` and the operation produces a `float` value.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long` and the operation produces a `long` value.
- Otherwise, both operands are converted to `int` and the operation produces an `int` value.

When the remainder operation is performed on integer data, the following expression is guaranteed to produce the same value as `a%b`:

```
a-((a/b)*b)
```

The sign of the value produced by the remainder operator is always the sign of the dividend. The magnitude of the value produced by the remainder operator is always less than the absolute value of the divisor. If the divisor is zero, an `ArithmeticException` is thrown.

Unlike C/C++, Java provides a remainder operation for floating-point data. The remainder of floating-point data is computed in a manner similar to the remainder of integer data. The remainder operation uses a truncating division to compute its value. This is unlike the IEEE 754 remainder operation, which uses a rounding division. The IEEE remainder operation is provided by the `Math.IEEEremainder()` method.

The computation of the remainder of `double` and `float` data is governed by the following rules:

- If either operand is not-a-number (NaN), the remainder is NaN.
- If neither operand is NaN, the sign of the remainder is the same as the sign of the dividend.
- If the dividend is positive or negative infinity or the divisor is positive or negative zero, the remainder is NaN.
- If the dividend is a finite number and the divisor is an infinity value, the remainder is equal to the dividend.

- If the dividend is a zero value and the divisor is a finite number, the remainder is equal to the dividend.

- If neither operand is a zero value, an infinity value, or NaN, the remainder is computed according to the following mathematical formula:

  $$p - \left\lfloor \frac{p}{d} \right\rfloor \times d$$

  p is the dividend and d is the divisor. The notation $\lfloor x \rfloor$ means the greatest integer less than or equal to *x* ; this is called the floor operation.

4.8 Relational Comparison Operators

The relational comparison operators in Java are used for less than (<), less than or equal to (<=), greater than or equal to (>=), greater than (>), and `instanceof` comparison operations. They may appear in a relational expression:

[Graphic: Figure from the text]

The relational comparison operators are equal in precedence and are evaluated from left to right. The <, <=, >=, and > operators are numerical comparison operators, while `instanceof` is a type comparison operator. All of these operators produce `boolean` values.

References Shift Operators; Order of Operations; *Type* 3

Less-Than Operator <

The less-than operator < performs a comparison between its operands and returns a `boolean` value. It returns the pure value `true` if its left operand is less than its right operand; otherwise the operator returns the pure value `false`. The < operator may appear as part of a relational expression. The less-than operator never throws an exception.

The types of both operands of the less-than operator must be arithmetic types, or a compile-time error occurs. The < operator may perform type conversions on its operands:

- If either operand is of type `double`, then the other operand is converted to `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float`.

- Otherwise, if either operand is of type `long`, the other operand is converted to `long`.
- Otherwise, both operands are converted to `int`.

The comparison of any two arithmetic values produces `true` if the value of the left operand is less than the value of the right operand; otherwise the comparison produces `false`. The comparison of floating-point data is governed by the following additional rules:

- If either operand is not-a-number (NaN), the comparison produces `false`.
- Negative infinity is the most negative value. If the left operand is negative infinity, the comparison produces `true`, unless the right operand is also negative infinity, in which case the comparison produces `false`.
- Positive infinity is the most positive value. If the right operand is positive infinity, the comparison produces `true`, unless the left operand is also positive infinity, in which case the comparison produces `false`.
- Positive and negative zero are treated as equal, so `-0.0 < 0.0` produces `false`.

References Arithmetic Types

Less-Than-Or-Equal-To Operator <=

The less-than-or-equal-to operator <= performs a comparison between its operands and returns a `boolean` value. It returns the pure value `true` if its left operand is less than or equal to its right operand; otherwise the operator returns the pure value `false`. The <= operator may appear as part of a relational expression. The less-than-or-equal-to operator never throws an exception.

The types of both operands of the less-than-or-equal-to operator must be arithmetic types, or a compile-time error occurs. The <= operator may perform type conversions on its operands:

- If either operand is of type `double`, then the other operand is converted to `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float`.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long`.
- Otherwise, both operands are converted to `int`.

The comparison of any two arithmetic values produces `true` if the value of the left operand is less than or equal to the value of the right operand; otherwise the comparison produces `false`. The comparison of floating-point data is governed by the following additional rules:

- If either operand is not-a-number (NaN), the comparison produces `false`.
- Negative infinity is the most negative value. If the left operand is negative infinity, the comparison always produces `true`.
- Positive infinity is the most positive value. If the right operand is positive infinity, the comparison always produces `true`.
- Positive and negative zero are treated as equal, so `0.0 <= -0.0` produces `true`.

References Arithmetic Types

Greater-Than-Or-Equal-To Operator >=

The greater-than-or-equal-to operator `>=` performs a comparison between its operands and returns a `boolean` value. It returns the pure value `true` if its left operand is greater than or equal to its right operand; otherwise the operator returns the pure value `false`. The `>=` operator may appear as part of a relational expression. The greater-than-or-equal-to operator never throws an exception.

The types of both operands of the greater-than-or-equal-to operator must be arithmetic types, or a compile-time error occurs. The `>=` operator may perform type conversions on its operands:

- If either operand is of type `double`, then the other operand is converted to `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to `float`.
- Otherwise, if either operand is of type `long`, the other operand is converted to `long`.
- Otherwise, both operands are converted to `int`.

The comparison of any two arithmetic values produces `true` if the value of the left operand is greater than or equal to the value of the right operand; otherwise the comparison produces `false`. The comparison of floating-point data is governed by the following additional rules:

- If either operand is not-a-number (NaN), the comparison produces `false`.
- Negative infinity is the most negative value. If the right operand is negative infinity, the

comparison always produces `true`.

- Positive infinity is the most positive value. If the left operand is positive infinity, the comparison always produces `true`.

- Positive and negative zero are treated as equal, so `-0.0 >= 0.0` produces `true`.

References Arithmetic Types

Greater-Than Operator >

The greater-than operator `>` performs a comparison between its operands and returns a `boolean` value. It returns the pure value `true` if its left operand is greater than its right operand; otherwise the operator returns the pure value `false`. The `>` operator may appear as part of a relational expression. The greater-than operator never throws an exception.

The types of both operands of the greater-than operator must be arithmetic types, or a compile-time error occurs. The `>` operator may perform type conversions on its operands:

- If either operand is of type `double`, then the other operand is converted to `double`.

- Otherwise, if either operand is of type `float`, the other operand is converted to `float`.

- Otherwise, if either operand is of type `long`, the other operand is converted to `long`.

- Otherwise, both operands are converted to `int`.

The comparison of any two arithmetic values produces `true` if the value of the left operand is greater than the value of the right operand; otherwise the comparison produces `false`. The comparison of floating-point data is governed by the following additional rules:

- If either operand is not-a-number (NaN), the comparison produces `false`.

- Negative infinity is the most negative value. If the right operand is negative infinity, the comparison produces `true`, unless the left operand is also negative infinity, in which case the comparison produces `false`.

- Positive infinity is the most positive value. If the left operand is positive infinity, the comparison produces `true`, unless the right operand is also positive infinity, in which case the comparison produces `false`.

- Positive and negative zero are treated as equal, so `0.0 > -0.0` produces `false`.

References Arithmetic Types

The instanceof Operator

The `instanceof` operator performs a type comparison between its operands and returns a `boolean` value. It returns the pure value `true` if the object referred to by the left operand can be cast to the type specified as the right operand; otherwise the operator returns the pure value `false`. If the value of the left operand is `null`, the `instanceof` operator returns the pure value `false`. The `instanceof` operator may appear as part of a relational expression. The `instanceof` operator never throws an exception.

The type of the left operand of the `instanceof` operator must be a reference type, or a compile-time error occurs.

All objects inherit a method called `equals()` from the `Object` class. The `equals()` method defined in the `Object` class returns `true` if the two objects being compared are the same object. For some classes, it is more appropriate to override the `equals()` method so that it compares the contents of two objects. Before such a method can do the comparison, it should verify that the objects are instances of the same class by using `instanceof`. For example, let's suppose that you are defining a class to represent complex numbers. Since you want the `equals()` method to compare the contents of complex number objects, you define an `equals` method for the complex number class that looks like this:

```
boolean equals (Object o) {
   if (o instanceof complexNumber)
       return o.real == this.real
           && o.imaginary == this.imaginary;
}
```

The `instanceof` operator can also be used to find out if an object is an instance of a class that implements an interface. For example:

```
if (o instanceof Runnable)
    (new Thread((Runnable)o).start;
```

References Casts; Class Types; Interface Types

9.4 The Exception Hierarchy

The possible exceptions in a Java program are organized in a hierarchy of exception classes. The `Throwable` class, which is an immediate subclass of `Object`, is at the root of the exception hierarchy. `Throwable` has two immediate subclasses: `Exception` and `Error`. Figure 9.1 shows the standard exception classes defined in the `java.lang` package, while Figure 9.2 shows the standard error classes defined in `java.lang`.

Figure 9.1: Standard Java exception classes

[Graphic: Figure 9-1]

Figure 9.2: Standard Java error classes

[Graphic: Figure 9-2]

Exceptions

All of the subclasses of `Exception` represent exceptional conditions that a normal Java program may want to handle. Many of the standard exceptions are also subclasses of `RuntimeException`. Runtime exceptions represent runtime conditions that can generally occur in any Java method, so a method is not required to declare that it throws any of the runtime exceptions. However, if a method can throw any of the other standard exceptions, it must declare them in its `throws` clause.

A Java program should try to handle all of the standard exception classes, since they represent routine abnormal conditions that should be anticipated and caught to prevent program termination.

Runtime exceptions

The `java.lang` package defines the following standard runtime exception classes:

`ArithmeticException`

This exception is thrown to indicate an exceptional arithmetic condition, such as integer division by zero.

`ArrayIndexOutOfBoundsException`

This exception is thrown when an out-of-range index is detected by an array object. An out-of-range index occurs when the index is less than zero or greater than or equal to the size of the array.

`ArrayStoreException`

This exception is thrown when there is an attempt to store a value in an array element that is incompatible with the type of the array.

`ClassCastException`

This exception is thrown when there is an attempt to cast a reference to an object to an inappropriate type.

`IllegalArgumentException`

This exception is thrown to indicate that an illegal argument has been passed to a method.

`IllegalMonitorStateException`

This exception is thrown when an object's `wait()`, `notify()`, or `notifyAll()` method is called from a thread that does not own the object's monitor.

`IllegalStateException`

This exception is thrown to indicate that a method has been invoked when the run-time environment is in an inappropriate state for the requested operation. This exception is new in Java 1.1.

`IllegalThreadStateException`

This exception is thrown to indicate an attempt to perform an operation on a thread that is not legal for the thread's current state, such as attempting to resume a dead thread.

`IndexOutOfBoundsException`

The appropriate subclass of this exception (i.e., `ArrayIndexOutOfBoundsException` or

`StringIndexOutOfBoundsException`) is thrown when an array or string index is out of bounds.

`NegativeArraySizeException`

This exception is thrown in response to an attempt to create an array with a negative size.

`NullPointerException`

This exception is thrown when there is an attempt to access an object through a `null` object reference. This can occur when there is an attempt to access an instance variable or call a method through a `null` object or when there is an attempt to subscript an array with a `null` object.

`NumberFormatException`

This exception is thrown to indicate that an attempt to parse numeric information in a string has failed.

`RuntimeException`

The appropriate subclass of this exception is thrown in response to a runtime error detected at the virtual machine level. Because these exceptions are so common, methods that can throw objects that are instances of `RuntimeException` or one of its subclasses are not required to declare that fact in their `throws` clauses.

`SecurityException`

This exception is thrown in response to an attempt to perform an operation that violates the security policy implemented by the installed `SecurityManager` object.

`StringIndexOutOfBoundsException`

This exception is thrown when a `String` or `StringBuffer` object detects an out-of-range index. An out-of-range index occurs when the index is less than zero or greater than or equal to the length of the string.

Other exceptions

The `java.lang` package defines the following standard exception classes that are not runtime exceptions:

`ClassNotFoundException`

This exception is thrown to indicate that a class that is to be loaded cannot be found.

`CloneNotSupportedException`

This exception is thrown when the `clone()` method has been called for an object that does not implement the `Cloneable` interface and thus cannot be cloned.

`Exception`

The appropriate subclass of this exception is thrown in response to an error detected at the virtual machine level. If a program defines its own exception classes, they should be subclasses of the `Exception` class.

`IllegalAccessException`

This exception is thrown when a program tries to dynamically load a class (i.e., uses the `forName()` method of the `Class` class, or the `findSystemClass()` or the `loadClass()` method of the `ClassLoader` class) and the currently executing method does not have access to the specified class because it is in another package and not `public`. This exception is also thrown when a program tries to create an instance of a class (i.e., uses the `newInstance()` method of the `Class` class) that does not have a zero-argument constructor accessible to the caller.

`InstantiationException`

This exception is thrown in response to an attempt to instantiate an `abstract` class or an interface using the `newInstance()` method of the `Class` class.

`InterruptedException`

This exception is thrown to signal that a thread that is sleeping, waiting, or otherwise paused has been interrupted by another thread.

`NoSuchFieldException`

This exception is thrown when a specified variable cannot be found. This exception is new in Java 1.1.

`NoSuchMethodException`

This exception is thrown when a specified method cannot be found.

Errors

The subclasses of `Error` represent errors that are normally thrown by the class loader, the virtual machine, or other support code. Application-specific code should not normally throw any of these standard error classes. If a method does throw an `Error` class or any of its subclasses, the method is not required to declare that fact in its `throws` clause.

A Java program should not try to handle the standard error classes. Most of these error classes represent non-recoverable errors and as such, they cause the Java runtime system to print an error message and terminate program execution.

The `java.lang` package defines the following standard error classes:

`AbstractMethodError`

> This error is thrown in response to an attempt to invoke an `abstract` method.

`ClassCircularityError`

> This error is thrown when a circular reference among classes is detected during class initialization.

`ClassFormatError`

> This error is thrown when an error is detected in the format of a file that contains a class definition.

`Error`

> The appropriate subclass of this error is thrown when an unpredictable error, such as running out of memory, occurs. Because of the unpredictable nature of these errors, methods that can throw objects that are instances of `Error` or one of its subclasses are not required to declare that fact in their `throws` clauses.

`ExceptionInInitializerError`

> This error is thrown when an unexpected exception is thrown in a static initializer. This error is new in Java 1.1.

`IllegalAccessError`

This error is thrown when a class attempts to access a field or call a method it does not have access to. Usually this error is caught by the compiler; this error can occur at run-time if the definition of a class changes after the class that references it was last compiled.

`IncompatibleClassChangeError`

This error or one of its subclasses is thrown when a class refers to another class in an incompatible way. This situation occurs when the current definition of the referenced class is incompatible with the definition of the class that was found when the referring class was compiled. For example, say class `A` refers to a method in class `B`. Then, after class `A` is compiled, the method is removed from class `B`. When class `A` is loaded, the run-time system discovers that the method in class `B` no longer exists and throws an error.

`InstantiationError`

This error is thrown in response to an attempt to instantiate an `abstract` class or an interface. Usually this error is caught by the compiler; this error can occur at run-time if the definition of a class is changed after the class that references it was last compiled.

`InternalError`

This error is thrown to signal an internal error within the virtual machine.

`LinkageError`

The appropriate subclass of this error is thrown when there is a problem resolving a reference to a class. Reasons for this may include a difficulty in finding the definition of the class or an incompatibility between the current definition and the expected definition of the class.

`NoClassDefFoundError`

This error is thrown when the definition of a class cannot be found.

`NoSuchFieldError`

This error is thrown in response to an attempt to reference an instance or class variable that is not defined in the current definition of a class. Usually this error is caught by the compiler; this error can occur at run-time if the definition of a class is changed after the class that references it was last compiled.

`NoSuchMethodError`

> This error is thrown in response to an attempt to reference a method that is not defined in the current definition of a class. Usually this error is caught by the compiler; this error can occur at run-time if the definition of a class is changed after the class that references it was last compiled.

`OutOfMemoryError`

> This error is thrown when an attempt to allocate memory fails.

`StackOverflowError`

> This error is thrown when a stack overflow error occurs within the virtual machine.

`ThreadDeath`

> This error is thrown by the `stop()` method of a `Thread` object to kill the thread. Catching `ThreadDeath` objects is not recommended. If it is necessary to catch a `ThreadDeath` object, it is important to re-throw the object so that it is possible to cleanly stop the catching thread.

`UnknownError`

> This error is thrown when an error of unknown origins is detected in the run-time system.

`UnsatisfiedLinkError`

> This error is thrown when the implementation of a native method cannot be found.

`VerifyError`

> This error is thrown when the byte-code verifier detects that a class file, though well-formed, contains some sort of internal inconsistency or security problem.

`VirtualMachineError`

> The appropriate subclass of this error is thrown to indicate that the Java virtual machine has encountered an error.

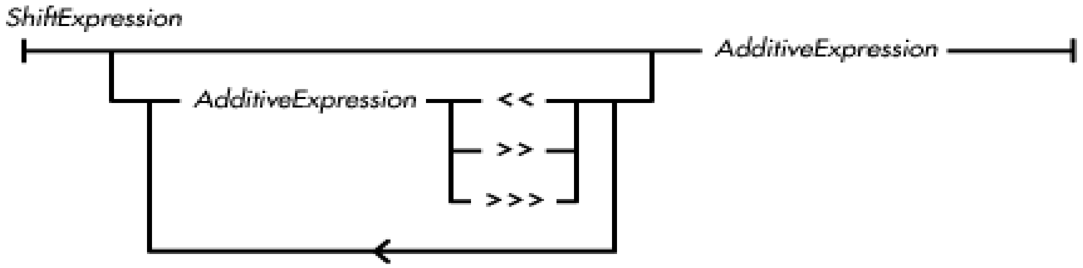
4.7 Shift Operators

The shift operators in Java are used for left shift (<<), right shift (>>), and unsigned right shift (>>>) operations. The shift operators may appear in a shift expression:



The shift operators are equal in precedence and are evaluated from left to right.

References Additive Operators; Order of Operations

Left Shift Operator <<

The left shift operator << produces a pure value that is its left operand left-shifted by the number of bits specified by its right operand. The << operator may appear in a shift expression. The left shift operator never throws an exception.

Here are some examples of the left shift operator:

```
(3<<2) == 12
(-3<<2) == -12
(0x01234567<<4) == 0x12345670
(0xF1234567<<4) == 0x12345670
```

The type of each operand of the left shift operator must be an integer data type, or a compile-time error occurs. The << operator may perform type conversions on its operands; unlike arithmetic binary operators, each operand is converted independently. If the type of an operand is `byte`, `short`, or `char`, that operand is converted to an `int` before the value of the operator is computed. The type of the value produced by the left shift operator is the type of its left operand.

If the converted type of the left operand is `int`, only the five least significant bits of the value of the right operand are used as the shift distance. Therefore, the shift distance is in the range 0 through 31. In this case, the value produced by `r << s` is mathematically equivalent to:

$$r \times 2^{s \bmod 32}$$

If the type of the left operand is `long`, only the six least significant bits of the value of the right operand are used as the shift distance. Therefore, the shift distance is in the range 0 through 63. In this case, the value produced by `r << s` is mathematically equivalent to:

$$r \times 2^{s \bmod 64}$$

References Integer types

Right Shift Operator >>

The right shift operator `>>` produces a pure value that is its left operand right-shifted with sign extension by the number of bits specified by its right operand. Right-shifting with sign extension means that shifting a value `n` places to the right causes the `n` high order bits to contain the same value as the sign bit of the unshifted value. The >> operator may appear as part of a shift expression. The right shift operator never throws an exception. Here are some examples of the right shift operator:

```
(0x01234567>>4) == 0x00123456
(0xF1234567>>4) == 0xFF123456
```

The type of each operand of the right shift operator must be an integer data type, or a compile-time error occurs. The `>>` operator may perform type conversions on its operands; unlike arithmetic binary operators, each operand is converted independently. If the type of an operand is `byte`, `short`, or `char`, that operand is converted to an `int` before the value of the operator is computed. The type of the value produced by the right shift operator is the type of its left operand.

If the converted type of the left operand is `int`, only the five least significant bits of the value of the right operand are used as the shift distance. Therefore, the shift distance is in the range 0 through 31.

In this case, the value produced by `r >> s` is mathematically equivalent to:

$$\left\lfloor \frac{r}{2^{s \bmod 32}} \right\rfloor$$

The notation $\lfloor x \rfloor$ means the greatest integer less than or equal to *x* ; this is called the floor operation.

If the type of the left operand is `long`, only the six least significant bits of the value of the right operand are used as the shift distance. Therefore, the shift distance is in the range 0 through 63. In this case, the value produced by `r >> s` is mathematically equivalent to:

$$\left\lfloor \frac{r}{2^{s \bmod 64}} \right\rfloor$$

References Integer types

Unsigned Right Shift Operator >>>

The unsigned right shift operator `>>>` produces a pure value that is its left operand right-shifted with zero extension by the number of bits specified by its right operand. Right-shifting with zero extension means that shifting a value `n` places to the right causes the `n` high order bits to contain zero. The `>>>` operator may appear as part of a shift expression. The unsigned right shift operator never throws an exception.

Here are some examples of the unsigned right shift operator:

```
(0x01234567>>>4) == 0x00123456
(0xF1234567>>>4) == 0x0F123456
```

The type of each operand of the unsigned right shift operator must be an integer data type, or a compile-time error occurs. The `>>>` operator may perform type conversions on its operands; unlike arithmetic binary operators, each operand is converted independently. If the type of an operand is `byte`, `short`, or `char`, that operand is converted to an `int` before the value of the operator is computed. The type of the value produced by the unsigned right shift operator is the type of its left operand. If the converted type of the left operand is `int`, only the five least significant bits of the value of the right operand are used as the shift distance. So, the shift distance is in the range 0 through 31. Here, the value produced by `r >>> s` is the same as:

```
s==0 ? r : (r >> s) & ~(-1<<(32-s))
```

If the type of the left operand is `long`, then only the six least significant bits of the value of the right operand are used as the shift distance. So, the shift distance is in the range 0 through 63. Here, the value produced by `r >>> s` is the same as the following:

```
s==0 ? r : (r >> s) & ~(-1<<(64-s))
```

Short

Name

Short

Synopsis

Class Name:

`java.lang.Short`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `Short` class provides an object wrapper for a `short` value. This is useful when you need to treat a `short` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `short` value for one of these arguments, but you can provide a reference to a `Short` object that encapsulates the `byte` value. Furthermore, the `Short` class is necessary as of JDK 1.1 to support the

Reflection API and class literals.

The `Short` class also provides a number of utility methods for converting `short` values to other primitive types and for converting `short` values to strings and vice-versa.

Class Summary

```
public final class java.lang.Short extends java.lang.Number {
  // Constants
  public static final short MAX_VALUE;
  public static final short MIN_VALUE;
  public static final Class TYPE;
  // Constructors
  public Short(short value);
  public Short(String s);
  // Class Methods
  public static Short decode(String nm);
  public static short parseShort(String s);
  public static short parseShort(String s, int radix);
  public static String toString(short s);
  public static Short valueOf(String s, int radix);
  public static Short valueOf(String s);
  // Instance Methods
  public byte byteValue();
  public double doubleValue();
  public boolean equals(Object obj);
  public float floatValue();
  public int hashCode();
  public int intValue();
  public long longValue();
  public short shortValue();
  public String toString();
}
```

Constants

MAX_VALUE

public static final short MAX_VALUE= 32767

The largest value that can be represented by a `short`.

MIN_VALUE

public static final byte MIN_VALUE= -32768

The smallest value that can be represented by a `short`.

TYPE

public static final Class TYPE

The `Class` object that represents the primitive type `short`. It is always true that `Short.TYPE` == `short.class`.

Constructors

Short

public Short(short value)

Parameters

`value`

The `short` value to be encapsulated by this object.

Description

Creates a `Short` object with the specified `short` value.

public Short(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Short` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `short` literal.

Description

Constructs a `Short` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `` `-' `` character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

decode

public static Short decode(String nm) throws NumberFormatException

Parameters

`nm`

A `String` representation of the value to be encapsulated by a `Short` object. If the string begins with # or `0x`, it is a radix 16 representation of the value. If the string begins with `0`, it is a radix 8 representation of the value. Otherwise, it is assumed to be a radix 10 representation of the value.

Returns

A `Short` object that encapsulates the given value.

Throws

`NumberFormatException`

If the `String` contains any non-digit characters other than a leading minus sign or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

This method returns a `Short` object that encapsulates the given value.

parseByte

```
public static short parseShort(String s) throws NumberFormatException
```

Parameters

`s`

The `String` to be converted to a `short` value.

Returns

The numeric value of the `short` represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short` or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

This method returns the numeric value of the `short` represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static short parseShort(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a short value.

`radix`

The radix used in interpreting the characters in the `String` as digits. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If radix is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' are considered valid digits.

Returns

The numeric value of the `short` represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short`, radix is not in the appropriate range, or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

This method returns the numeric value of the `short` represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toString

public String toString(short s)

Parameters

`s`

The `short` value to be converted to a string.

Returns

The `string` representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

valueOf

public static Short valueOf(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Short` object.

Returns

The `Short` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short` or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

Constructs a `Short` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-'. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Short valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Short` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Short` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short`, `radix` is not in the appropriate range, or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

Constructs a `Short` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

Instance Methods

byteValue

public byte byteValue()

Returns

The value of this object as a `byte`. The high order bits of the value are discarded.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`.

doubleValue

public double doubleValue()

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Short` and it contains the same value as the object this method is associated with.

floatValue

public float floatValue()

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`.

hashCode

public int hashCode()

Returns

A hashcode based on the `short` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hash code computed from the value of this object.

intValue

public int intValue()

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`.

longValue

public long longValue()

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

public short shortValue()

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`.

toString

public String toString()

Returns

The string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-' if the value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if the value of the object is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

4.4 Unary Operators

Unary operators are operators that take exactly one argument. Unary operators may appear in a unary expression:

[Graphic: Figure from the text]

The unary plus and minus operators, a Boolean negation operator (`!`), a bitwise negation operator (~), and the cast construct comprise the unary operators in Java. The unary operators are equal in precedence and are evaluated from right to left.

References Order of Operations; Postfix Increment/Decrement Operators; Prefix Increment/Decrement Operators; Primary Expressions; *Type* 3

Unary Plus Operator +

The unary plus operator (`+`) can appear as part of a unary expression. The operator does no explicit computation; it produces the same pure value that is produced by its operand. However, the unary + operator may perform a type conversion on its operand. The type of the operand must be an arithmetic data type, or a compile-time error occurs. If the type of the operand is `byte`, `short`, or `char,` the unary `+` operator produces an `int` value; otherwise the operator produces a value of the same type as its operand.

References Arithmetic Types

Unary Minus Operator -

The unary minus operator (-) can appear as part of a unary expression. The type of the operand of the unary - operator must be an arithmetic data type, or a compile-time error occurs. The operator produces a pure value that is the arithmetic negation (i.e., additive inverse) of the value of its operand.

The unary - operator may perform a type conversion. If the type of the operand is `byte`, `short`, or `char`, the operation converts the operand to an `int` before computing the value's arithmetic negation and producing an `int` value. Otherwise, unary - produces a value of the same type as its operand.

For integer data types, the unary - operator produces a value equivalent to subtracting its operand from zero. There are, however, negative values for which the unary - operator cannot produce a positive value; in these cases it produces the same negative value as its operand. This behavior results from the two's complement representation Java uses for integer values. The magnitude of the most negative number that can be represented using two's complement notation cannot be represented as a positive number. No exception is thrown when the unary - operator is given a value that cannot be negated. However, you can detect this situation by explicitly testing for these special values. The most negative `int` value is available as the predefined constant `Integer.MIN_VALUE` and the most negative `long` value is available as the predefined constant `Long.MIN_VALUE`.

For floating-point data types, the unary - operator changes the sign of its operand from + to - or from - to +, for both regular values, positive and negative zero, and positive and negative infinity. The only case where this is not true occurs when the operand is not-a-number (NaN). Given the value NaN, the unary - operator produces NaN.

References Arithmetic Types; Integer; Long

Boolean Negation Operator !

The Boolean negation operator (!) may appear as part of a unary expression. The type of the operand of the ! operator must be `boolean`, or a compile-time error occurs. If the value of its operand is `false`, the ! operator produces the pure `boolean` value `true`. If the value of its operand is `true`, the operator produces the pure `boolean` value `false`.

Here is an example that uses the Boolean negation operator:

```
public void paint(Graphics g) {
    if (!loaded) {
        //The next 2 lines are executed if loaded is false
        g.drawString("Loading data", 25, 25);
        return;
    }
    g.drawImage(img, 25, 25, this);
}
```

References Boolean Type

Bitwise Negation Operator ~

The bitwise negation operator (~) may appear as part of a unary expression. The type of the operand of the ~ operator must be an integer data type, or a compile-time error occurs. The ~ operator may perform a type conversion before it performs its computation. If the type of the operand is `byte`, `short`, or `char`, the operator converts its operand to `int` before producing a value. Otherwise the ~ operator produces a value of the same type as its operand.

After type conversion, the bitwise negation operator produces a pure value that is the bitwise complement of its operand. In other words, if a bit in the converted operand contains a one, the corresponding bit in the result contains a zero. If a bit in the converted operand contains a zero, the corresponding bit in the result contains a one.

Here's an example that shows the use of the bitwise negation operator:

```
// zero low order four bits
int getNibble(int x) {
    return x & ~0xf;
}
```

References Integer types

Casts

A *Type* enclosed in parentheses specifies a type cast operation. A cast may appear as part of a unary expression. A cast operation always produces a pure value of the specified type, by converting its operand to that type if necessary. This is different from a type cast in C/C++, which can produce garbage if it is given a pointer to a data type different than that implied by the pointer's declaration. If the actual data type of the operand of a cast cannot be guaranteed at compile-time, the Java compiler must produce code to check the type of the operand at runtime. In Java, any value that gets past all of the type-checking done on a cast is guaranteed to be compatible with the type specified by the cast.

A cast can convert between certain primitive types. A cast between object reference types never alters the type or content of the object, but may alter the type of the reference to the object.

Because it is not possible to convert between all types, some cast operations are permitted and others are not. Here are the rules governing casts:

- A value of any data type can be cast to its own type.
- A value of any arithmetic data type can be cast to any other arithmetic data type. Casting a floating-point value to an integer data type rounds toward zero.
- A value of the `boolean` data type cannot be cast to any other data type, nor can a value of any other data type be cast to `boolean`.
- A value of any primitive data type cannot be cast to a reference data type, nor can a reference be cast to any primitive data type.
- A reference to a class type can be cast to the type of the superclass of that class.
- A reference to a class type can be cast to the type of a subclass of that class if the reference actually refers to an object of the specified class or any of its subclasses. Unless the Java compiler can prove that the object actually referenced is of the specified class or any of its subclasses, the compiler must generate a runtime test to verify that the object is of an appropriate type. At runtime, if the object actually referenced is not of an appropriate type, a `ClassCastException` is thrown. Consider the following example:

  ```
  Object o = "ABC";
  String s = (String)o;   // This is okay
  Double d = (Double)o;   // Throws an exception
  ```

  The cast of `o` to `String` is fine because `o` is really a reference to a `String` object. The cast of `o` to `Double` throws an exception at runtime because the object that `o` references is not an instance of `Double`.

- A reference to a class type can be cast to an interface type if the reference actually refers to an object of a class that implements the specified interface. If the class of the reference being cast is a `final` class, the compiler can determine if the reference actually refers to an object of a class that implements the specified interface, because a `final` class cannot have any subclasses. Otherwise, the compiler must generate a runtime test to determine if the reference actually refers to an object of a class that implements the specified interface. At runtime, if the object actually referenced is not of a class that implements the interface, a `ClassCastException` is thrown. Here is an example that illustrates the rules governing casts to interface types:

  ```
  interface Weber { double flux(double x); }
  class B {}
  ```

```
final class C {}
class D implements Weber {
    public double flux(double x) {
        return Math.PI*x*x;
    }
}
class Intercast {
    public void main(String[] argv) {
        B b = new B();
        C c = new C();
        D d = new D();
        Weber w;
        w = (Weber)b;   // Throws an exception
        w = (Weber)c;   // Compiler complains
        w = (Weber)d;   // Okay, D implements Weber
    }
}
```

The cast of `b` to `Weber` is fine with the compiler because the class `B` might have a subclass that implements `Weber`. At runtime, however, this cast throws an exception because `B` does not implement `Weber`. The cast of `c` to `Weber` produces an error message from the compiler, as the `C` class does not implement `Weber`. Because `C` is `final`, it will not have any subclasses and therefore there is no possibility of `c` containing a reference to an object that implements the `Weber` interface. The cast of `d` to `Weber` is fine because the `D` class implements the `Weber` interface.

- A reference to the class `Object` can be cast to an array type if the reference actually refers to an array object of the specified type. The compiler generates a runtime test to determine if the reference actually refers to the specified type of array object. At runtime, if the object actually referenced is not the specified type of array, a `ClassCastException` is thrown.

- A reference to an interface type can be cast to a class type if the reference actually refers to an instance of the specified class or any of its subclasses. If the specified class is a `final` class that does not implement the referenced interface, the compiler can reject the cast because a `final` class cannot have any subclasses. Otherwise, the compiler generates a runtime test to determine if the reference actually refers to an object of the appropriate type. At runtime, if the object actually referenced is not of the appropriate type, a `ClassCastException` is thrown.

  Here is an example to illustrate these points:

```
interface Weber { double flux(double x); }
class B {}
```

```
final class C {}
class D implements Weber {
    public double flux(double x) {
        return Math.PI*x*x;
    }
}
class Intercast {
    public void doit(Weber w) {
        B b = (B)w;   // May throw an exception
        C c = (C)w;   // Compiler complains
        D d = (D)w;   // Okay
    }
}
```

The cast of `w` to class `B` is fine with the compiler even though `B` does not implement `Weber`. The compiler lets it pass because `B` might have a subclass that implements `Weber` and `w` could contain a reference to that class. However, at runtime, the cast will throw an exception if the object actually referenced is not an instance of `B` or a subclass of `B`. The cast of `w` to class `C` produces an error message from the compiler. `C` does not implement `Weber` and `C` cannot have any subclasses because it is `final`; any object that implements `Weber` cannot be an instance of `C`. The cast of `w` to class `D` is fine at compile-time because `D` implements `Weber`. At runtime, if `w` references an object that is not an instance of `D`, a `ClassCastException` is thrown.

- A reference to an interface type can be cast to another interface type if the reference actually refers to an object of a class that implements the specified interface. If the referenced interface extends the specified interface, the compiler knows that the cast is legal. Otherwise, the compiler generates a runtime test to determine if the reference actually refers to an object that implements the specified interface. At runtime, if the object actually referenced does not implement the specified interface, a `ClassCastException` is thrown.

  Here is an example to illustrate these points:

```
interface Weber { double flux(double x); }
interface Dyn { double squeeze(); }
interface Press extends Dyn {
    double squeeze(double theta);
}
class D implements Press {
    public double squeeze() { return Math.PI; }
    public double squeeze(double theta) {
        return Math.PI*Math.sin(theta);
    }
}
```

```
class Interinter {
    public static void doit(D d) {
        Dyn dyn = d;          // Okay
        Weber w = (Weber)d;   // May throw exception
    }
}
```

The assignment of `d` to `dyn` works because `d` is of class `D`, `D` implements `Press`, and `Press` extends `Dyn`. Therefore, `d` refers to an object that implements `Dyn` and we have assignment compatibility. The compiler lets the cast of `d` to `Weber` pass because there may be a subclass of `D` that implements `Weber`. At runtime, the cast will throw an exception if `D` does not implement `Weber`.

- A reference to an array object can be cast to the class type `Object`.
- A reference to an array object can be cast to another array type if either of the following is true:
    - The elements of the referenced array and the elements of the specified array type are of the same primitive type.
    - The elements of the referenced array are of a type that can be cast to the type of the elements of the specified array type.

Any cast operation not covered by the preceding rules is not allowed and the Java compiler issues an error message.

Double

Name

Double

Synopsis

Class Name:

`java.lang.Double`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Double` class provides an object wrapper for a `double` value. This is useful when you need to treat a `double` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `double` value for one of these arguments, but you can provide a reference to a `Double` object that encapsulates the `double` value. Furthermore, as of JDK 1.1, the `Double` class is necessary to support the Reflection API and class literals.

In Java, `double` values are represented using the IEEE 754 format. The `Double` class provides constants for the three special values that are mandated by this format: `POSITIVE_INFINITY`, `NEGATIVE_INFINITY`, and `NaN` (not-a-number).

The `Double` class also provides some utility methods, such as methods for determining whether a `double` value is an infinity value or NaN, for converting `double` values to other primitive types, and for converting a `double` to a `String` and vice versa.

Class Summary

```
public final class java.lang.Double extends java.lang.Number {
    // Constants
    public final static double MAX_VALUE;
    public final static double MIN_VALUE;
    public final static double NaN;
    public final static double NEGATIVE_INFINITY;
    public final static double POSITIVE_INFINITY;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Double(double value);
    public Double(String s);
    // Class Methods
    public static native long doubleToLongBits(double value);
    public static boolean isInfinite(double v);
    public static boolean isNaN(double v);
    public static native double longBitsToDouble(long bits);
    public static String toString(double d);
    public static Double valueOf(String s);
    // Instance Methods
    public byte byteValue();                           // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public boolean isInfinite();
    public boolean isNaN();
    public long longValue();
    public short shortValue();                          // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final double MAX_VALUE = 1.79769313486231570e+308`

Description

The largest value that can be represented by a `double`.

MIN_VALUE

`public static final double MIN_VALUE = 4.94065645841246544e-324`

Description

The smallest value that can be represented by a `double`.

NaN

`public static final double NaN = 0.0 / 0.0`

Description

This variable represents the value not-a-number (NaN), which is a special value produced by `double` operations such as division of zero by zero. When NaN is one of the operands, most arithmetic operations return NaN as the result.

Most comparison operators (<, <=, ==, >=, >) return `false` when one of their arguments is NaN. The exception is `!=`, which returns `true` when one of its arguments is NaN.

NEGATIVE_INFINITY

`public static final double NEGATIVE_INFINITY = -1.0 / 0.0`

Description

> This variable represents the value negative infinity, which is produced when a `double` operation underflows or a negative `double` value is divided by zero. Negative infinity is by definition less than any other `double` value.

POSITIVE_INFINITY

`public static final double POSITIVE_INFINITY = 1.0 / 0.0`

Description

> This variable represents the value positive infinity, which is produced when a `double` operation overflows or a positive `double` value is divided by zero. Positive infinity is by definition greater than any other `double` value.

TYPE

`public static final Class TYPE`

Availability

> New as of JDK 1.1

Description

> The `Class` object that represents the type `double`. It is always true that `Double.TYPE` == `double.class`.

Constructors

Double

`public Double(double value)`

Parameters

`value`

The `double` value to be encapsulated by this object.

Description

Creates a `Double` object with the specified `double` value.

public Double(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Double` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `double` literal.

Description

Constructs a `Double` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `double` literal.

Class Methods

doubleToLongBits

`public static native long doubleToLongBits(double value)`

Parameters

`value`

The `double` value to be converted.

Returns

The `long` value that contains the same sequence of bits as the representation of the given `double` value.

Description

This method returns the `long` value that contains the same sequence of bits as the representation of the given `double` value. The meaning of the bits in the result is defined by the IEEE 754 floating-point format: bit 63 is the sign bit, bits 62-52 are the exponent, and bits 51-0 are the mantissa.

An argument of `POSITIVE_INFINITY` produces the result `0x7ff0000000000000L`, an argument of `NEGATIVE_INFINITY` produces the result `0xfff0000000000000L`, and an argument of `NaN` produces the result `0x7ff8000000000000L`.

The value returned by this method can be converted back to the original `double` value by the `longBitsToDouble()` method.

isInfinite

`static public boolean isInfinite(double v)`

Parameters

`v`

The `double` value to be tested.

Returns

`true` if the specified value is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

This method determines whether or not the specified value is an infinity value.

isNaN

`public static boolean isNaN(double v)`

Parameters

`v`

The `double` value to be tested.

Returns

`true` if the specified value is equal to `NaN`; otherwise `false`.

Description

This method determines whether or not the specified value is NaN.

longBitsToDouble

`public static native double longBitsToDouble(long bits)`

Parameters

`bits`

The `long` value to be converted.

Returns

The `double` value whose representation is the same as the bits in the given `long` value.

Description

This method returns the `double` value whose representation is the same as the bits in the given `double` value. The meaning of the bits in the `long` value is defined by the IEEE 754 floating-point format: bit 63 is the sign bit, bits 62-52 are the exponent, and bits 51-0 are the mantissa. The argument `0x7f80000000000000L` produces the result `POSITIVE_INFINITY` and the argument `0xff80000000000000L` produces the result `NEGATIVE_INFINITY`. Arguments in the ranges `0x7ff0000000000001L` through `0x7fffffffffffffffL` and

`0xfff0000000000001L` through `0xffffffffffffffffL` all produce the result `NaN`.

Except for NaN values not normally used by Java, this method is the inverse of the `doubleToLongBits()` method.

toString

`public static String toString(double d)`

Parameters

`d`

The `double` value to be converted.

Returns

A string representation of the given value.

Description

This method returns a `String` object that contains a representation of the given `double` value.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of `d` is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

valueOf

`public static Double valueOf(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Double` object.

Returns

The `Double` object constructed from the string.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `double` literal.

Description

Constructs a `Double` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `double` literal. This method ignores leading and trailing white space in the string.

Instance Methods

byteValue

`public byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the truncated value of this object as a `byte`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `byte`, the method returns `Byte.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `byte`, the method returns `Byte.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

doubleValue

`public double doubleValue()`

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Double` and it contains the same value as the object this method is associated with. More specifically, the method returns `true` if the `doubleToLongBits()` method returns the same result for the values of both objects.

This method produces a different result than the `==` operator when both values are `NaN`. In this case, the `==` operator produces `false`, while this method returns `true`. By the same token, the method also produces a different result when the two values are `+0.0` and `-0.0`. In this case, the `==` operator produces `true`, while this method returns `false`.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns this object value as a `float`. Rounding may occur.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `double` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object. More specifically, if `d` is the value of the object, and `bitValue` is defined as:

```
long bitValue = Double.doubleToLongBits(d)
```

then the hashcode returned by this method is computed as follows:

```
(int)(bitValue ^ (bitValue>>>32))
```

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the truncated value of this object as an `int`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `int`, the method returns `Integer.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `int`, the method returns `Integer.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

isInfinite

`public boolean isInfinite()`

Returns

> `true` if the value of this object is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

> This method determines whether or not the value of this object is an infinity value.

isNaN

`public boolean isNaN()`

Returns

> `true` if the value of this object is equal to `NaN`; otherwise `false`.

Description

> This method determines whether or not the value of this object is NaN.

longValue

`public long longValue()`

Returns

> The value of this object as a `long`.

Overrides

> `Number.longValue()`

Description

> This method returns the truncated value of this object as a `long`. More specifically, if the value of

the object is NaN, the method returns 0. If the value is POSITIVE_INFINITY, or any other value too large to be represented by a long, the method returns Long.MAX_VALUE. If the value is NEGATIVE_INFINITY, or any other value too small to be represented by a long, the method returns Long.MIN_VALUE. Otherwise, the value is rounded toward zero and returned.

shortValue

public short shortValue()

Availability

New as of JDK 1.1

Returns

The value of this object as a short.

Overrides

Number.shortValue()

Description

This method returns the truncated value of this object as a short. More specifically, if the value of the object is NaN, the method returns 0. If the value is POSITIVE_INFINITY, or any other value that is too large to be represented by an short, the method returns Short.MAX_VALUE. If the value is NEGATIVE_INFINITY, or any other value that is too small to be represented by an short, the method returns Short.MIN_VALUE. Otherwise, the value is rounded toward zero and returned.

toString

public String toString()

Returns

A string representation of the value of this object.

Overrides

```
Object.toString()
```

Description

This method returns a `String` object that contains a representation of the value of this object.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of this object is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

Float

Name

Float

Synopsis

Class Name:

`java.lang.Float`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Float` class provides an object wrapper for a `float` value. This is useful when you need to treat a `float` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `float` value for one of these arguments, but you can provide a reference to a `Float` object that encapsulates the `float` value. Furthermore, as of JDK 1.1, the `Float` class is necessary to support the Reflection API and class literals.

In Java, `float` values are represented using the IEEE 754 format. The `Float` class provides constants for the three special values that are mandated by this format: `POSITIVE_INFINITY`, `NEGATIVE_INFINITY`, and `NaN` (not-a-number).

The `Float` class also provides some utility methods, such as methods for determining whether a `floatx` value is an infinity value or NaN, for converting `float` values to other primitive types, and for converting a `float` to a `String` and vice versa.

Class Summary

```
public final class java.lang.Float extends java.lang.Number {
    // Constants
    public static final float MIN_VALUE;
    public static final float MAX_VALUE;
    public static final float NaN;
    public static final float NEGATIVE_INFINITY;
    public static final float POSITIVE_INFINITY;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Float(double value);
    public Float(float value);
    public Float(String s);
    // Class Methods
    public static native int floatToIntBits(float value);
    public static native float intBitsToFloat(int bits);
    public static boolean isInfinite(float v);
    public static boolean isNaN(float v);
    public static String toString(float f);
    public static Float valueOf(String s);
    // Instance Methods
    public byte byteValue();                           // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public boolean isInfinite();
    public boolean isNaN();
    public long longValue();
    public short shortValue();                         // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final float MAX_VALUE = 3.40282346638528860e+38f`

Description

> The largest value that can be represented by a `float`.

MIN_VALUE

`public static final float MIN_VALUE = 1.40129846432481707e-45f`

Description

> The smallest value that can be represented by a `float`.

NaN

`public static final float NaN = 0.0f / 0.0f`

Description

> This variable represents the value NaN, a special value produced by `float` operations such as division of zero by zero. When NaN is one of the operands, most arithmetic operations return NaN as the result. Most comparison operators (`<`, `<=`, `==`, `>=`, `>`) return `false` when one of their arguments is NaN. The exception is `!=`, which returns `true` when one of its arguments is NaN.

NEGATIVE_INFINITY

`public static final float NEGATIVE_INFINITY = -1.0f / 0.0f`

Description

> This variable represents the value negative infinity, which is produced when a `float` operation underflows or a negative `float` value is divided by zero. Negative infinity is by definition less than any other `float` value.

POSITIVE_INFINITY

`public static final float POSITIVE_INFINITY = 1.0f / 0.0f`

Description

> This variable represents the value positive infinity, which is produced when a `float` operation overflows or a positive `float` value is divided by zero. Positive infinity is by definition greater than any other `float` value.

TYPE

`public static final Class TYPE`

Availability

> New as of JDK 1.1

Description

> The `Class` object that represents the type `float`. It is always true that `Float.TYPE` == `float.class`.

Constructors

Float

`public Float(double value)`

Parameters

`value`

The `double` value to be encapsulated by this object.

Description

Creates a `Float` object with the specified `double` value. The value is rounded to `float` precision.

public Float(float value)

Parameters

`value`

The `float` value to be encapsulated by this object.

Description

Creates a `Float` object with the specified `float` value.

public Float(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Float` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `float` literal.

Description

Constructs a `Float` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `float` literal.

Class Methods

floatToIntBits

`public static native int floatToIntBits(float value)`

Parameters

> `value`
>
> > The `float` value to be converted.

Returns

> The `int` value that contains the same sequence of bits as the representation of the given `float` value.

Description

> This method returns the `int` value that contains the same sequence of bits as the representation of the given `float` value. The meaning of the bits in the result is defined by the IEEE 754 floating-point format: bit 31 is the sign bit, bits 30-23 are the exponent, and bits 22-0 are the mantissa. An argument of `POSITIVE_INFINITY` produces the result `0x7f800000`, an argument of `NEGATIVE_INFINITY` produces the result `0xff800000`, and an argument of `NaN` produces the result `0x7fc00000`.
>
> The value returned by this method can be converted back to the original `float` value by the `intBitsToFloat()` method.

intBitsToFloat

`public static native float intBitsToFloat(int bits)`

Parameters

> `bits`
>
> > The `int` value to be converted.

Returns

The `float` value whose representation is the same as the bits in the given `int` value.

Description

This method returns the `float` value whose representation is the same as the bits in the given `int` value. The meaning of the bits in the `int` value is defined by the IEEE 754 floating-point format: bit 31 is the sign bit, bits 30-23 are the exponent, and bits 22-0 are the mantissa. The argument `0x7f800000` produces the result `POSITIVE_INFINITY`, and the argument `0xff800000` produces the result `NEGATIVE_INFINITY`. Arguments in the ranges `0x7f800001` through `0x7f8fffff` and `0xff800001` through `0xff8fffffL` all produce the result `NaN`.

Except for NaN values not normally used by Java, this method is the inverse of the `floatToIntBits()` method.

isInfinite

`public static boolean isInfinite(float v)`

Parameters

`v`

The `float` value to be tested.

Returns

`true` if the specified value is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

This method determines whether or not the specified value is an infinity value.

isNaN

`public static boolean isNaN(float v)`

Parameters

`v`

The `float` value to be tested.

Returns

`true` if the specified value is equal to `NaN`; otherwise `false`.

Description

This method determines whether or not the specified value is NaN.

toString

`public static String toString(float f)`

Parameters

`f`

The `float` value to be converted.

Returns

A string representation of the given value.

Description

This method returns a `String` object that contains a representation of the given `float` value.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of `f` is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

valueOf

```
public static Float valueOf(String s) throws NumberFormatException
```

Parameters

`s`

The string to be made into a `Float` object.

Returns

The `Float` object constructed from the string.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `float` literal.

Description

Constructs a `Float` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `float` literal. This method ignores leading and trailing whitespace in the string.

Instance Methods

byteValue

`public byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the truncated value of this object as a `byte`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `byte`, the method returns `Byte.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `byte`, the method returns `Byte.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

doubleValue

`public double doubleValue()`

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Float` and it contains the same value as the object this method is associated with. More specifically, the method returns `true` if the `floatToIntBits()` method returns the same result for the values of both objects.

This method produces a different result than the `==` operator when both values are `NaN`. In this case, the `==` operator produces `false`, while this method returns `true`. By the same token, the method also produces a different result when the two values are `+0.0` and `-0.0`. In this case, the `==` operator produces `true`, while this method returns `false`.

floatValue

public float floatValue()

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `float` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object. More specifically, if `f` is the value of the object, this method returns `Float.floatToIntBits(f)`.

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the truncated value of this object as an `int`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `int`, the method returns `Integer.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `int`, the method returns `Integer.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

isInfinite

`public boolean isInfinite(float v)`

Returns

`true` if the value of this object is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

This method determines whether or not the value of this object is an infinity value.

isNaN

`public boolean isNaN()`

Returns

`true` if the value of this object is equal to `NaN`; otherwise `false`.

Description

This method determines whether or not the value of this object is NaN.

longValue

`public long longValue()`

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the truncated value of this object as a `long`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by a `long`, the method returns `Long.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by a `long`, the method returns `Long.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

shortValue

`public short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the truncated value of this object as a `short`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `short`, the method returns `Short.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `short`, the method returns `Short.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

toString

`public String toString()`

Returns

A string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains a representation of the value of this object.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of this object is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

4.11 Boolean Operators

The Boolean operators in Java are used for conditional AND (&&) and conditional OR (||) operations. These operators have different precedence; the && operator has the higher precedence and || the lower precedence. Both of the operators are evaluated from left to right.

The unary operator ! provides a Boolean negation operation.

References Boolean Negation Operator !; Order of Operations

Boolean AND Operator &&

The conditional AND operator && produces a pure `boolean` value that is the conditional AND of its operands. The && operator may appear in a conditional AND expression:

[Graphic: Figure from the text]

The conditional AND operator is evaluated from left to right. The operator never throws an exception.

Here is a code example that shows the use of the conditional AND operator:

```
public final short readShort() throws IOException {
    int ch1, ch2;
    if ((ch1 = in.read()) >= 0 && (ch2 = in.read()) >= 0)
        return (short)((ch1 << 8) + ch2);
    throw new EOFException();
}
```

The operands of the conditional AND operator must both be of type `boolean`, or a compile-time error occurs.

The operands of the conditional AND operator are evaluated in a different way from the operands for most other operators in Java. Most other operators evaluate all of their operands before performing their operation; the conditional AND operator does not necessarily evaluate both of its operands.

As with all binary operators, the left operand of && is evaluated first. If the left operand evaluates to `true`, the conditional AND operator evaluates its right operand and produces a pure value that has the same value as its right operand. However, if the left operand evaluates to `false`, the right operand is not evaluated and the operator produces the pure value `false`.

In the above example, the expression `(ch2 = in.read())` is evaluated only if the expression `(ch1 = in.read())` produces a value that is greater than or equal to zero.

References Bitwise/Logical AND Operator &; Boolean Type; Bitwise/Logical Inclusive OR Operator |; Order of Operations

Boolean OR Operator ||

The conditional OR operator `||` produces a pure `boolean` value that is the conditional OR of its operands. The `||` operator may appear in a conditional OR expression:

[Graphic: Figure from the text]

The conditional OR operator is evaluated from left to right. The operator never throws an exception.

Here is a code example that shows the use of the conditional OR operator:

```
public final short readShort() throws IOException {
    int ch1, ch2;
    if ((ch1 = in.read()) < 0 || (ch2 = in.read()) < 0)
        throw new EOFException();
    return (short)((ch1 << 8) + ch2);
}
```

The operands of the conditional OR operator must both be of type `boolean`, or a compile-time error occurs.

The operands of the conditional OR operator are evaluated in a different way from the operands for most other operators in Java. Most other operators evaluate all of their operands before performing their operation; the conditional OR operator does not necessarily evaluate both of its operands.

As with all binary operators, the left operand of `||` is evaluated first. If the left operand evaluates to `false`, the conditional OR operator evaluates its right operand and produces a pure value that has the same value as its right operand. However, if the left operand evaluates to `true`, the right operand is not evaluated and the operator produces the pure value `true`.

References Bitwise/Logical Inclusive OR Operator |; Boolean Type; Boolean AND Operator &&; Order of Operations

6.7 Iteration Statements

Iteration statements are used to specify the logic of a loop. Java has three varieties of iteration statement: `while`, `do`, and `for`.

[Graphic: Figure from the text]

References The do Statement; The for Statement; The while Statement

The while Statement

A `while` statement evaluates a Boolean expression. If the expression is `true`, a given statement is repeatedly executed for as long as the expression continues to evaluate to `true`.

[Graphic: Figure from the text]

In Java, the expression in parentheses must produce a `boolean` value. This is different from C/C++, which allows any type of expression.

If the expression in parentheses evaluates to `true`, the statement contained in the `while` statement is executed and the expression in parentheses is evaluated again. This process continues until the expression evaluates to `false`.

If the expression in parentheses evaluates to `false`, the statement following the `while` statement is the next statement to be executed. The expression in parentheses is evaluated before the contained statement is executed, so it is possible for the contained statement not to be executed even once.

Here is an example of a `while` statement:

```
while ( (c = in.read()) >= 0) {
    out.write(c);
}
```

References Boolean Type; *Expression* 4; *Statement* 6

The do Statement

A `do` statement executes a given statement and then evaluates a Boolean expression. If the expression evaluates to `true`, the statement is executed repeatedly as long as the expression continues to evaluate to `true`:

[Graphic: Figure from the text]

In Java, the expression in parentheses must produce a `boolean` value. This is unlike C/C++, which allows any type of expression.

The statement contained in the `do` statement is executed and then the expression in parentheses is evaluated. If the expression evaluates to `true`, the process is repeated.

If the expression evaluates to false, the statement following the `do` statement is the next statement to be executed. Because the expression is evaluated after the contained statement is executed, the statement is always executed at least once.

Here's an example of a `do` statement:

```
do {
    c = in.read();
    out.write(c);
} while (c != ';');
```

References Boolean Type; *Expression* 4; *Statement* 6

The for Statement

A `for` statement is a more structured form of a `while` statement. A `for` statement performs an initialization step and then evaluates a Boolean expression. If the expression evaluates to `true`, a given statement is executed and an increment expression is evaluated repeatedly as long as the expression continues to evaluate to `true`:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

[Graphic: Figure from the text]

Here is an example of a `for` statement:

```
for (i = 0; i < a.length; i++) {
    a[i] = i;
}
```

The initialization part of the `for` statement is executed first. If the initialization part contains nothing, no initialization is performed. The expression that follows must produce a `boolean` value. Before the body of the `for` statement is executed, the expression is evaluated. If the expression portion of the `for` statement is omitted, the default expression `true` is used. If the expression evaluates to `true`, the body of the `for` statement is executed and then the increment portion of the `for` statement is evaluated. Finally, the expression is evaluated again to determine if there should be another iteration. This process continues until the expression evaluates to `false`, at which point the statement following the `for` statement is the next statement to be executed. The `for` statement in the above example can be rewritten as a `while` statement as follows:

```
i = 0;
while (i < a.length) {
    a[i] = i;
    i++;
}
```

One difference between comparable `for` and `while` loops is that a `continue` statement in the body of a `for` statement causes the increment portion of the statement to be evaluated. However, this may not be the case in a comparable `while` statement.

Here's a new version of our `for` example:

```
for (i = 0; i < a.length; i++) {
    a[i] = i;
    continue;
}
```

The added `continue` statement at the end of the `for` loop does not change the behavior of the loop. In particular, `i++` is still evaluated after each iteration through the body of the loop. Now let's add a `continue` statement at the equivalent place in our `while` example:

```
i = 0;
while (i < a.length) {
    a[i] = i;
    continue;
    i++;
}
```

The `continue` statement in this `while` loop prevents the statement `i++` from being executed. The `continue` statement would have to be moved after the increment operation to match the logic of the `for` statement.

If the expression portion of a `for` statement is omitted, the default expression `true` is supplied. Take, for example, the following `for` statement:

```
for ( FileInputStream in = new FileInputStream(fname);;) {
    c = in.read();
    if (c < 0)
        return;
    System.out.print((char)c);
}
```

This example uses a local variable declaration in the initialization portion of the `for` statement. Local variable declarations in a `for` statement are subject to the same restrictions as local variable declarations in a block. In particular, a `for` statement cannot declare a local variable with the same name as a local variable or formal parameter that is defined in an enclosing block.

The above `for` statement is equivalent to the following `while` statement:

```
{
    FileInputStream in = new FileInputStream(fname);
    while (true) {
        c = in.read();
        if (c < 0)
            return;
        System.out.print((char)c);
    }
}
```

The enclosing block in the above example is provided to limit the scope of the local variable `in` to just the `while` statement.

The initialization portion of a `for` statement can also be empty. The following statement is a legal way of specifying an infinite loop:

```
for (;;) {...}
```

This is equivalent to the following `while` statement:

```
while (true) {...}
```

Unlike C/C++, there is no comma operator in Java. However, commas are explicitly allowed in the initialization portion of a `for` statement. For example, a `for` initialization can consist of multiple expressions separated by commas:

```
i=2, j=5, k=44
```

When the initialization portion of a `for` statement contains local variable declarations, commas are also allowed because the syntax for declarations allows multiple variables, separated by commas, to be declared in one declaration. For example:

```
int i=2, j=5, k=44
```

6.5 The if Statement

An if statement determines which of two statements is executed, based on the value of a Boolean expression:

[Graphic: Figure from the text]

In Java, the expression in parentheses must produce a boolean value. This is different from C/C++, which allows any type of expression.

If the expression in parentheses evaluates to true, the statement after the parentheses is executed. After that statement has been executed, the statement following the entire if statement is executed. If the expression between the parentheses evaluates to false, the next statement to be executed depends on whether or not the if statement has an else clause. If there is an else clause, the statement after the else is executed. Otherwise, the statement after the entire if statement is executed.

When if statements are nested, each else clause is matched with the last preceding if statement in the same block that has not yet been matched with an if statement.

Here is an example of an if statement:

```
if (j == 4) {
    if (x > 0 ) {
        x *= 7;
    } else {
        x *= -7;
    }
}
return;
```

The outer `if` statement has no `else` clause. If `j` is not 4, the `return` statement is executed. Otherwise, the inner `if` statement is executed. This `if` statement does have an `else` clause. If `x` is greater than zero, the value of `x` is multiplied by 7. Otherwise, the value of `x` is multiplied by -7. Regardless of the value of `x`, the `return` statement is executed.

4.2 Allocation Expressions

An *allocation expression* is a primary expression that creates an object or an array. An allocation expression also produces a reference to the newly created object or array:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

When *AllocationExpression* contains parentheses, the allocation expression creates a non-array object. When *AllocationExpression* contains square brackets, the allocation expression creates an array.

An object created by an allocation expression continues to exist until the program terminates or it is freed by the garbage collector (see Object Destruction). Consider the following code:

```
class X {
    Double perm;
    void foo() {
        Double d = new Double(8.9473);
        int a[] = new int [2];
        d = new Double(3.1415926);
        a[0] = d.intValue();
        perm = d;
    }
}
```

The first line of `foo()` creates a `Double` object and uses it as the initial value of the variable `d`. The second line creates an array of integers and uses it as the initial value of the variable `a`. At this point, neither of the two objects that has been created is a candidate for garbage collection because there is a variable referencing each of them.

The third line of `foo` creates another `Double` object and assigns it to the variable `d`. Now there is nothing that refers to the first `Double` object that we created, so that object can now be garbage collected at any time.

When the block in this example finishes executing, the variables declared inside of the block, `a` and `d`, pass out of scope. Now there is nothing referring to the array object that we created; now that object can be garbage-collected at any time. However, because the variable `perm` now refers to the second `Double` object we created, that object is not a candidate for garbage collection.

References *ArgumentList* 4.1.8; *ClassBody* 5.4; Variable initializers; *Expression* 4; Identifiers; Object Creation; Object Destruction; Primary Expressions; *Type* 3

Object Allocation Expressions

An allocation expression that contains parentheses creates a non-array object; that is, an instance of a class. For example:

```
new Double(93.1872)
```

The *Type* in an object allocation expression must be a class or interface type. The argument list supplied between the parentheses provides the actual arguments to be passed to the object's constructor. However, if a *ClassBody* follows the parentheses, no arguments may appear between the parentheses, and different rules apply. (These rules are discussed in Allocating instances of anonymous classes.)

If `new` is preceded by a *PrimaryExpression* and a dot, the *PrimaryExpression* must produce a reference to an object. Furthermore, the object's class must be an inner or nested top-level class that is named by the identifier that follows `new`. If the specified class is a non-`static` inner class, the object created by the allocation expression has the object referenced by the *PrimaryExpression* as its enclosing instance. For example:

```
class Z {
    class Y {
    ...
    }
    public static void main(String[] argv) {
        Z myZ = new Z();
        Z.Y myY = myZ.new Y();
    }
}
```

In the preceding example, we must supply an explicit enclosing instance of `Z` to create a `Z.Y` object because `main()` is a `static` method. A non-`static` method of `Z` could create an instance of `Z.Y` without supplying an explicit enclosing instance of `Z` because the method itself is associated with an instance of `Z`. However, because a `static` method is not associated with an instance of its class, it must supply an explicit enclosing instance when creating an instance of an inner class.

The syntax that allows `new` to be preceded by a *PrimaryExpression* and a dot is not supported prior to Java 1.1.

The remainder of this section applies only to allocation expressions that contain parentheses but no *ClassBody*. Allocation expressions that contain a *ClassBody* are described in Allocating instances of anonymous classes.

An object allocation expression performs the following steps:

1. Creates a new object with all of its instance variables set to their default values. The default values for these variables are determined by their types.

2. Calls the constructor that matches the given argument list.

3. Produces a reference to the initialized object.

The process of selecting the appropriate constructor to call is similar to the process used to select the method invoked by a method call expression. The compiler determines which constructors have formal parameters compatible with the given arguments. If there is more than one suitable constructor, the compiler must select the constructor that most closely matches the given arguments. If the compiler cannot select one constructor as a better match than the others, the constructor selection process fails and an error message is issued.

Here are the details of the constructor selection process:

Step One

The constructor definitions are searched for constructors that, taken in isolation, could be called by the allocation expression. A constructor is a candidate if it meets the following criteria:

- The constructor is accessible to the allocation expression, based on any access modifiers specified in the constructor's declaration.

- The number of formal parameters declared for the constructor is the same as the number of actual arguments provided in the allocation expression.
- The data type of each actual parameter is assignment-compatible with the corresponding formal parameter.

Step Two

> If more than one constructor meets the criteria in Step One, the Java compiler tries to determine if one constructor is a more specific match than the others. If there is no constructor that matches more specifically, the constructor selection process fails and an error message is issued.
>
> Given two constructors that are both candidates to be invoked by the same object allocation expression, one constructor is more specific than another constructor if each parameter of the first constructor is assignment-compatible with the corresponding parameter of the second constructor.

When an object allocation expression is evaluated, the constructor selected in Step Two is invoked. This constructor returns a reference to the newly created object.

Here's an example that shows how the constructor selection process works:

```
class Consel {
    Consel() { }
    Consel(Object o, double d) {}
    Consel(String s, int i) {}
    Consel(int i, int j) {}
    public void main(String[] argv) {
        Consel c = new Consel("abc",4);
    }
}
```

The `main()` method in the `Consel` class creates a new `Consel` object. The process of selecting which constructor to call proceeds as follows:

1. The compiler finds all of the constructors that are accessible to the `new` operator. Since all of the constructors are accessible, the compiler then narrows its choices to those constructors that have the same number of formal parameters as the number of actual arguments in the allocation expression. This step eliminates the constructor with no formal parameters, so now there are three choices. The compiler again narrows its choices to those constructors with formal parameters that are assignment-compatible with the actual values. Because a `String` is not assignment-compatible with an `int` variable, the compiler eliminates the constructor that takes two `int`

parameters.

2. Now the compiler must choose which of the two remaining constructors is more specific than the other. Because a `String` object reference can be assigned to an `Object` variable and an `int` value can be assigned to a `double` variable, the constructor `Consel(String s, int i)` is the more specific of the two. This constructor is the one that is invoked to create the `Consel` object.

References Allocating instances of anonymous classes; Assignment Compatibility; *ClassBody* 5.4; Class Types; Constructors; Interface Types; Primary Expressions

Allocating instances of anonymous classes

An allocation expression that contains a *ClassBody* creates an instance of an *anonymous class*. It is called an anonymous class because it has no name of its own. The variables and methods of an anonymous class are defined in the *ClassBody*. If the type specified after `new` is a class, the anonymous class is a subclass of that class. If the type specified after `new` is an interface, the anonymous class implements that interface and is a subclass of `Object`. For example:

```
public class MainFrame extends Frame {
...
    public MainFrame(String title) {
        super(title);
        WindowAdapter listener;
        listener = new WindowAdapter() {
            public void windowClosing(WindowEvent evt) {
                exit();
            }
        };
        addWindowListener(listener);
    }
...
}
```

The example creates an instance of an anonymous subclass of the `WindowAdapter` class. If an allocation expression contains a *ClassBody*, it cannot contain any arguments between the parentheses because an anonymous class cannot declare any constructors. Instead, an anonymous class must use instance initializers to handle any complex initialization.

The body of an anonymous class cannot declare any `static` variables, `static` methods, `static` classes, or static initializers. Anonymous classes are not supported prior to Java 1.1.

References Anonymous classes; *ClassBody* 5.4; Constructors; Instance Initializers; Methods; Nested Top-Level and Member Classes; Static Initializers; Variables

Array Allocation Expressions

An allocation expression that contains square brackets creates an array, such as:

```
new int[10]
```

An array allocation expression performs the following steps:

1. Allocates storage for the array

2. Sets the `length` variable of the array and initializes the array elements to their default values

3. Produces a reference to the initialized array

Although Java does not support multi-dimensional arrays, it does support arrays of arrays. The most important distinction between a multi-dimensional array and an array of arrays is that in an array of arrays, each array need not be of the same length. Because arrays of arrays are most often used to represent multi-dimensional arrays, this book refers to them as multi-dimensional arrays, even though that is not precisely correct.

The type of the array created by an array allocation expression can be expressed by removing both the word `new` and the expressions from within the square brackets. For example, here is an allocation expression:

```
new int[3][4][5]
```

The type of the array produced by that expression is:

```
int[][][]
```

This means that the number of dimensions in the array produced by an allocation expression is the same as the number of pairs of square brackets in the allocation expression.

The expressions that appear in the square brackets must be of type `int`, `short`, `char`, or `byte`. Each of the expressions specifies the length of a single dimension of the array that is being created. For example, the allocation expression above creates an array of 3 arrays of 4 arrays of 5 `int` values. The length supplied for an array must not be negative. At runtime, if an expression in square brackets produces a negative array length, a `NegativeArraySizeException` is thrown.

The syntax of an array allocation expression specifies that the first pair of square brackets must contain an expression, while the trailing square brackets do not need to. This means that an array allocation expression can be written to build fewer dimensions of an array than there are dimensions in the array's type. For example, consider this allocation expression:

```
new char [10][]
```

The array produced by this allocation expression is an array of arrays of `char`. The allocation expression creates a single array of 10 elements, where each of those elements is a `char` array of unspecified length.

Array allocation expressions are often used to initialize array variables. Here are some examples:

```
int j[] = new int[10];           // array of 10 ints
ing k[][] = new float[3][4];     // array of 3 arrays
                                 // of 4 floats
```

Here's an example that builds an array of different length arrays, or in other words a non-rectangular array of arrays:

```
int a[][] = new int [3][];
a[0] = new int [5];
a[1] = new int [6];
a[2] = new int [7];
```

None of the array allocation expressions presented so far have used array initializers. When an array allocation expression does not include an array initializer, the array is created with all of its elements set to a default value. The default value is based on the type of the array. Table 4-1 shows the default values used for the various types in Java.

Table 4.1: Default Values for Array Elements

Array Type	**Default Value**
`byte`	`0`
`char`	`'\u0000'`
`short`	`0`
`int`	`0`

`long`	`0L`
`float`	`0.0F`
`double`	`0.0`
`Boolean`	`false`
Object reference	`null`

If you want to create an array that contains elements with different initial values, you can include an *ArrayInitializer* at the end of the allocation expression. For example:

```
new int [] { 4,7,9 }
```

Notice that there is no expression between the square brackets. If an allocation expression contains square brackets and no *ArrayInitializer*, at least the first pair of square brackets must contain an expression. However, if an allocation expression does contain an *ArrayInitializer*, there cannot be any expressions between any of the square brackets. An allocation expression that contains an *ArrayInitializer* can be used to create an anonymous array: one that is created and initialized without using a variable initializer.

The syntax that allows an *ArrayInitializer* in an allocation expression is not supported prior to Java 1.1.

4.14 Order of Operations

In an expression that contains multiple operators, Java uses a number of rules to decide the order in which the operators are evaluated. The first and most important rule is called *operator precedence*. Operators in an expression that have higher precedence are executed before operators with lower precedence. For example, multiplication has a higher precedence than addition. In the expression `2+3*4`, the multiplication is done before the addition, producing a result of 14.

If consecutive operators in an expression have the same precedence, a rule called *associativity* is used to decide the order in which those operators are evaluated. An operator can be left-associative, right-associative, or non-associative:

- Left-associative operators of the same precedence are evaluated in order from left to right. For example, addition and subtraction have the same precedence and they are left-associative. In the expression `10-4+2`, the subtraction is done first because it is to the left of the addition, producing a value of 8.
- Right-associative operators of the same precedence are evaluated in order from right to left. For example, assignment is right-associative. Consider the following code fragment:

  ```
  int a = 3;
  int b = 4;
  a = b = 5;
  ```

  After the code has been evaluated, both `a` and `b` contain 5 because the assignments are evaluated from right to left.
- A non-associative operator cannot be combined with other operators of the same precedence.

Table 4-2 shows the precedence and associativity of all the operators in Java.[7]

[7] Although the precedence of operators in Java is similar to that in C++, there are some differences. For example, new has a higher precedence in Java than it does in C++. Another difference is that the ++ and - - operators are effectively non-associative in Java.

Table 4.2: Precedence and Associativity of Operators in Java

Precedence	Operator	Associativity
1	(), []	non-associative
2	new	non-associative
3	.	left-associative
4	++, - -	non-associative
5	- (unary), + (unary), !, ~, ++, - -, (*type*)	right-associative
6	*, /, %	left-associative
7	+, -	left-associative
8	<<, >>, >>>	left-associative
9	<, >, <=, >=, instanceof	non-associative
10	==, !=	left-associative
11	&	left-associative
12	^	left-associative
13	|	left-associative
14	&&	left-associative
15	||	left-associative
16	?:	right-associative
17	=, *=, /=, %=, -=, <<=, >>=, >>>=, &=, ^=, |=	right-associative

As in C/C++, the order in which operators are evaluated can be modified by the use of parentheses.

The rest of the rules that concern order of operations have to do with the evaluation of operands or arguments in a single expression.

- The left operand of a binary operator is evaluated before its right operand.

- The operands of an operator are evaluated before the operator is evaluated. Consider the following expression:

```
((x=4) * x)
```

First, the left operand of * is evaluated; it produces the value 4. Then the right operand of * is evaluated. Since evaluation of the left operand set x to 4, evaluation of the right operand produces 4. Finally, the * operator itself is evaluated, producing the value 16.

- In an index expression, the expression to the left of the square brackets is evaluated before the expression inside the square brackets.
- In an expression that calls a method through an object reference, the object reference is evaluated before the argument expressions.
- In any expression that calls a method or constructor, the expressions supplied as the actual arguments are evaluated from left to right.
- In an array allocation expression, the expressions that appear in square brackets and provide the dimensions of the array are evaluated from left to right.

The intent of all of these rules is to guarantee that every implementation of Java evaluates any given expression in the same way.[8] In order to produce optimized code, a Java compiler is allowed to deviate from the rules governing the order in which operations are performed, provided that the result is the same as if it had followed the rules.

[8] This is different than C/C++, which leaves a number of details of expression evaluation up to an implementation, such as the order in which the actual parameters of a function call are evaluated.

4.16 Constant Expressions

A constant expression is an expression that always produces the same result. More precisely, a constant expression is an expression that produces a pure value of a primitive data type and is only composed of the following:

- Literals of primitive data types
- String literals
- Variables that are declared `final` and are initialized by constant expressions
- Type casts to primitive data types or the type `String`
- The unary operators `+ -`, `~`, and `!`
- The binary operators `*`, `/`, `%`, `+`, `-`, `<<`, `>>`, `>>>`, `<`, `<=`, `>=`, `>`, `==`, `!=`, `&`, `^`, `|`, `&&`, and `||`
- The ternary operator `?:`

Note that expressions that use `++`, `- -`, and `instanceof` are not constant expressions. Also note that expressions that produce or contain references to objects that are not `String` objects are never constant expressions.

The compiler generally evaluates a constant expression and substitutes the result for the expression during the compilation process.

5.3 Object-Orientation Java Style

Before considering class and interface declarations in Java, it is essential that you understand the object-oriented model used by the language. No useful programs can be written in Java without using objects. Java deliberately omits certain C++ features that promote a less object-oriented style of programming. Thus, all executable code in a Java program must be part of an object (or a class to be more precise).

The two main characteristics of objects in Java are:

- Objects are always dynamically allocated. The lifetime of the storage occupied by an object is determined by the program's logic, not by the lifetime of a procedure call or the boundaries of a block. The lifetime of the storage occupied by an object refers to the span of time that begins when the object is created and ends at the earliest time it can be freed by the garbage collector.

- Objects are not contained by variables. Instead, a variable contains a reference to an object. A reference is similar to what is called a pointer in some other languages. If there are two variables of the same reference type and one of the variables is assigned to the other, both variables refer to the same object. If the information in that object is changed, the change is visible through both variables.

Classes

An object is a collection of variables, associated methods, and other associated classes. Objects in Java are described by *classes*; a particular object is an *instance* of a particular class. A class describes the data an object can contain by defining variables to contain the data in each instance of the class. A class describes the behavior of an object by defining methods for the class and possibly other auxiliary classes. Methods are named pieces of executable code; they are similar to what other programming languages call functions or procedures. Collectively, the variables, methods, and auxiliary classes of a class are called its members.

A class can define multiple methods with the same name if the number or type of parameters for each method is different. Multiple methods with the same name are called *overloaded methods*. Like C++, Java supports overloaded methods, but unlike C++, Java does not support overloaded operators. Overloaded methods are useful when you want to describe similar operations on different types of data. For example, Java provides a class called `java.io.OutputStream` that is used to write data. The `OutputStream` class defines three different `write()` methods: one to write a single byte of data, another to write some of the bytes in an array, and another to write all of the bytes in an array.

References Class Declarations

Encapsulation

Encapsulation is the technique of hiding the details of the implementation of an object, while making its functionality available to other objects. When encapsulation is used properly, you can change an object's implementation without worrying that any other object can see, and therefore depend on, the implementation details.

The portion of an object that is accessible to other types of objects is called the object's *interface*.[1] For example, consider a class called `Square`. The interface for this class might consist of:

> [1] The notion of an object's interface is a commonly accepted concept in the object-oriented community. Later in this chapter, a Java construct called an interface is described. A Java interface is not the same thing as the interface of an object, so there is some potential for confusion. Outside of this section, the term "interface" is only used to mean the Java interface construct.

- Methods to get and set the size of a square.

- A method to tell a square to draw itself at a particular location on the screen.

The implementation of this `Square` class would include executable code that implements the various methods, as well as an internal variable that an object would use to remember its size. Variables that an object uses to remember things about itself are called *state variables*.

The point of the distinction between the interface and the implementation of a class is that it makes programs easier to maintain. The implementation of a class may change, but as long as the interface remains the same, these changes do not require changes to any other classes that may use the class.

In Java, encapsulation is implemented using the `public`, `protected`, and `private` access modifiers. If a field of a class is part of the interface for the class, the field should be declared with the `public` modifier or with no access modifier. The `private` and `protected` modifiers limit the accessibility of a field, so these modifiers should be used for state variables and other implementation-specific functionality.

Here's a partial definition of a `Square` class that has the interface just described:

```
class Square {
    private int sideLength;
    public void setSideLength(int len) {
        sideLength = len;
    }
    public int getSideLength() {
        return sideLength;
    }
    public void draw(int x, int y) {
        // code to draw the square
        ...
    }
}
```

References Method modifiers; Inner class modifiers; Variable modifiers

Object Creation

An object is typically created using an allocation expression. The `newInstance()` methods of the `Class` or `java.lang.reflect.Contructor` class can also be used to create an instance of a class. In either case, the storage needed for the object is allocated by the system.

When a class is instantiated, a special kind of method called a *constructor* is invoked. A constructor for a class does not have its own name; instead it has the same name as the class of which it is a part. Constructors can have parameters, just like regular methods, and they can be overloaded, so a class can have multiple constructors. A constructor does not have a return type. The main purpose of a constructor is to do any initialization that is necessary for an object.

If a class declaration does not define any constructors, Java supplies a default `public` constructor that takes no parameters. You can prevent a class from being instantiated by methods in other classes by defining at least one `private` constructor for the class without defining any `public` constructors.

References Class; Constructors; Object Allocation Expressions

Object Destruction

Java does not provide any way to explicitly destroy an object. Instead, an object is automatically destroyed when the garbage collector detects that it is safe to do so. The idea behind *garbage collection* is that if it is possible to prove that a piece of storage will never be accessed again, that piece of storage can be freed for reuse. This is a more reliable way of managing storage than having a program explicitly deallocate its own storage. Explicit memory allocation and deallocation is the single largest source of programming errors in C/C++. Java eliminates this source of errors by handling the deallocation of memory for you.

Java's garbage collector runs continuously in a low priority thread. You can cause the garbage collector to take a single pass through allocated storage by calling `System.gc()`.

Garbage collection will never free storage before it is safe to do so. However, garbage collection usually does not free storage as soon as it would be freed using explicit deallocation. The logic of a program can sometimes help the garbage collector recognize that it is safe to free some storage sooner rather than later. Consider the following code:

```
class G {
    byte[] buf;
    String readIt(FileInputStream f) throws IOException {
        buf = new byte[20000];
        int length = f.read(buf);
        return new String(buf, 0, 0, length);
    }
}
```

The first time `readIt()` is called, it allocates an array that is referenced by the instance variable `buf`. The variable `buf` continues to refer to the array until the next time that `readIt()` is called, when `buf` is set to a new array. Since there is no longer any reference to the old array, the garbage collector will free the storage on its next pass. This situation is less than optimal. It would be better if the garbage collector could recognize that the array is no longer needed once a call to `readIt()` returns. Defining the variable `buf` as a local variable in `readIt()` solves this problem:

```
class G {
    String readIt(FileInputStream f) throws IOException {
        byte[] buf;
        buf = new byte[20000];
        int length = f.read(buf);
        return new String(buf, 0, 0, length);
    }
}
```

Now the reference to the array is in a local variable that disappears when `readIt()` returns. After `readIt()` returns, there is no longer any reference to the array, so the garbage collector will free the storage on its next pass.

Just as a constructor is called when an object is created, there is a special method that is called before an object is destroyed by the garbage collector. This method is called a *finalizer* ; it has the name `finalize()`. A `finalize()` method is similar to a destructor in C++. The `finalize()` method for a class must be declared with no parameters, the `void` return type, and no modifiers. A finalizer can be used to clean up after a class, by doing such things as closing files and terminating network connections.

If an object has a `finalize()` method, it is normally called by the garbage collector before the object is destroyed. A program can also explicitly call an object's `finalize()` method, but in this case, the garbage collector does not call the method during the object destruction process. If the garbage collector does call an object's `finalize()` method, the garbage collector does not immediately destroy the object because the `finalize()` method might do something that causes a variable to refer to the object again.[2] Thus the garbage collector waits to destroy the object until it can again prove it is safe to do so. The next time the garbage collector decides it is safe to destroy the object, it does so without calling the finalizer again. In any case, a `finalize()` method is never called more than once for a particular object.

> [2] A `finalize()` method should not normally do something that results in a reference to the object being destroyed, but Java does not do anything to prevent this situation from happening.

The garbage collector guarantees that the thread it uses to call a `finalize()` method will not be holding any programmer-visible synchronization locks when the method is called. This means that a `finalize()` method never has to wait for the garbage collector to release a lock. If the garbage collector calls a `finalize()` method and the `finalize()` method throws any kind of exception, the garbage collector catches and ignores the exception.

References System; The finalize method

Inheritance

One of the most important benefits of object-oriented programming is that it promotes the reuse of code, particularly by means of inheritance. *Inheritance* is a way of organizing related classes so that they can share common code and state information. Given an existing class declaration, you can create a similar class by having it inherit all of the fields in the existing definition. Then you can add any fields that are needed in the new class. In addition, you can replace any methods that need to behave differently in the new class.

To illustrate the way that inheritance works, let's start with the following class definition:

```
class RegularPolygon {
    private int numberOfSides;
    private int sideLength;
    RegularPolygon(int n, int len) {
        numberOfSides = n;
        sideLength = len;
    }
    public void setSideLength(int len) {
        sideLength = len;
    }
    public int getSideLength() {
        return sideLength;
    }
    public void draw(int x, int y) {
        // code to draw the regular polygon
        ...
    }
}
```

The `RegularPolygon` class defines a constructor, methods to set and get the side length of the regular polygon, and a method to draw the regular polygon. Suppose that after writing this class you realize that you have been using it to draw a lot of squares. You can use inheritance to build a more specific `Square` class from the existing `RegularPolygon` class as follows:

```
class Square extends   RegularPolygon {
    Square(int len) {
        super(4,len);
    }
}
```

The `extends` clause indicates that the `Square` class is a *subclass* of the `RegularPolygon` class, or looked at another way, `RegularPolygon` is a *superclass* of `Square`. When one class is a subclass of another class, the subclass inherits all of the fields of its superclass that are not `private`. Thus `Square` inherits `setSideLength()`, `getSideLength()`, and `draw()` methods from `RegularPolygon`. These methods work fine without any modification, which is why the definition of `Square` is so short. All the `Square` class needs to do is define a constructor, since constructors are not inherited.

There is no limit to the depth to which you can carry subclassing. For example, you could choose to write a class called `ColoredSquare` that is a subclass of the `Square` class. The `ColoredSquare` class would inherit the public methods from both `Square` and `RegularPolygon`. However, `ColoredSquare` would need to override the `draw()` method with an implementation that handles drawing in color.

Having defined the three classes `RegularPolygon`, `Square`, and `ColoredSquare`, it is correct to say that `RegularPolygon` and `Square` are superclasses of `ColoredSquare` and `ColoredSquare` and `Square` are subclasses of `RegularPolygon`. To describe a relationship between classes that extends through exactly one level of inheritance, you can use the terms *immediate superclass* and *immediate subclass*. For example, `Square` is an immediate subclass of `RegularPolygon`, while `ColoredSquare` is an immediate subclass of `Square`. By the same token, `RegularPolygon` is the immediate superclass of `Square`, while `Square` is the immediate superclass of `ColoredSquare`.

A class can have any number of subclasses or superclasses. However, a class can only have one immediate superclass. This constraint is enforced by the syntax of the `extends` clause; it can only specify the name of one superclass. This style of inheritance is called *single inheritance* ; it is different from the multiple inheritance scheme that is used in C++.

Every class in Java (except `Object`) has the class `Object` as its ultimate superclass. The class `Object` has no superclass. The subclass relationships between all of the Java classes can be drawn as a tree that has the `Object` class as its root. Another important difference between Java and C++ is that C++ does not have a class that is the ultimate superclass of all of its classes.

References Class Inheritance; Interfaces; Object

Abstract classes

If a class is declared with the `abstract` modifier, the class cannot be instantiated. This is different than C++, which has no way of explicitly specifying that a class cannot be instantiated. An `abstract` class is typically used to declare a common set of methods for a group of classes when there are no reasonable or useful implementations of the methods at that level of abstraction.

For example, the `java.lang` package includes classes called `Byte`, `Short`, `Integer`, `Long`, `Float`, and `Double`. These classes are subclasses of the `abstract` class `Number`, which declares the following methods: `byteValue()`, `shortValue()`, `intValue()`, `longValue()`, `floatValue()`, and `doubleValue()`. The purpose of these methods is to return the value of an object converted to the type implied by the method's name. Every subclass of `Number` implements all of these methods. The advantage of the abstraction is that it allows you to write code to extract whatever type of value you need from a `Number` object, without knowing the actual type of the underlying object.

Methods defined in an `abstract` class can be declared `abstract`. An `abstract` method is declared without any implementation; it must be overridden in a subclass to provide an implementation.

References Class Modifiers; Inner class modifiers; Local class modifiers; Method modifiers; Number

Final classes

If a class is declared with the `final` modifier, the class cannot be subclassed. Declaring a class `final` is useful if you need to ensure the exact properties and behavior of that class. Many of the classes in the `java.lang` package are declared `final` for that reason.

Methods defined in a non-`abstract` class can be declared `final`. A `final` method cannot be overridden by any subclasses of the class in which it appears.

References Class Modifiers; Inner class modifiers; Local class modifiers; Method modifiers

Interfaces

Java provides a construct called an interface to support certain multiple inheritance features that are desirable in an object-oriented language. An interface is similar to a class, in that an interface declaration can define both variables and methods. But unlike a class, an interface cannot provide implementations for its methods.

A class declaration can include an `implements` clause that specifies the name of an interface. When a class declaration specifies that it implements an interface, the class inherits all of the variables and methods declared in that interface. The class declaration must then provide implementations for all of the methods declared in the interface, unless the class is declared as an `abstract` class. Unlike the `extends` clause, which can only specify one class, the `implements` clause can specify any number of interfaces. Thus a class can implement an unlimited number of interfaces.

Interfaces are most useful for declaring that an otherwise unrelated set of classes have a common set of methods, without needing to provide a common implementation. For example, if you want to store a variety of objects in a database, you might want all of the those objects to have a common set of methods for storing and fetching. Since the fetch and store methods for each object need to be different, it is appropriate to declare these methods in an interface. Then any class that needs fetch and store methods can implement the interface.

Here is a simplistic example that illustrates such an interface:

```
public interface Db {
    void dbStore(Database d, Object key);
    Object dbFetch(Database d, Object key);
}
```

The `Db` interface declaration contains two methods, `dbStore()` and `dbFetch()`. Here is a partial class definition for a class that implements the `Db` interface:

```
class DbSquare extends Square implements Db {
    public void dbStore(Database d, Object key) {
        // Perform database operation to store Square
        ...
    }
    public Square dbFetch(Database d, Object key) {
        // Perform database operation to fetch Square
        ...
    }
    ...
}
```

The `DbSquare` class defines implementations for both of the methods declared in the `Db` interface. The point of this interface is that it provides a uniform way for unrelated objects to arrange to be stored in a database. The following code shows part of a class that encapsulates database operations:

```
class Database {
    ...
    public void store(Object o, Object key) {
        if (o instanceof Db)
          ((Db)o).dbStore(this, key);
    }
    ...
}
```

When the database is asked to store an object, it does so only if the object implements the `Db` interface, in which case it can call the `dbStore()` of the object.

References Interface Declarations

Inner Classes

Java 1.1 provides a new feature that allows programmers to encapsulate even more functionality within objects. With the addition of inner classes to the Java language, classes can be defined as members of other classes, just like variables and methods. Classes can also be defined within blocks of Java code, just like local variables. The ability to declare a class inside of another class allows you to encapsulate auxiliary classes inside of a class, thereby limiting access to the auxiliary classes. A class that is declared inside of another class may have access to the instance variables of the enclosing class; a class declared within a block may have access to the local variable and/or formal parameters of that block.

Nested top-level classes and interfaces

A *nested top-level class* or *interface* is declared as a `static` member of an enclosing top-level class or interface. The declaration of a nested top-level class uses the `static` modifier, so you may also see these classes called *static classes*. A nested interface is implicitly `static`, but you can declare it to be `static` to make it explicit. Nested top-level classes and interfaces are typically used to group related classes in a convenient way.

A nested top-level class or interface functions like a normal top-level class or interface, except that the name of the nested entity includes the name of the class in which it is defined. For example, consider the following declaration:

```
public class Queue {
    ...
    public static class EmptyQueueException extends Exception {
    }
    ...
}
```

Code that calls a method in `Queue` that throws an `EmptyQueueException` can catch that exception with a `try` statement like this:

```
try {
    ...
} catch (Queue.EmptyQueueException e) {
    ...
}
```

A nested top-level class cannot access the instance variables of its enclosing class. It also cannot call any non-`static` methods of the enclosing class without an explicit reference to an instance of that class. However, a nested top-level class can use any of the `static` variables and methods of its enclosing class without qualification.

Only top-level classes in Java can contain nested top-level classes. In other words, a `static` class can only be declared as a direct member of a class that is declared at the top level, directly as a member of a package. In addition, a nested top-level class cannot declare any `static` variables, `static` methods, or static initializers.

References Class Declarations; Methods; Nested Top-Level and Member Classes; Variables

Member classes

A *member class* is an inner class that is declared within an enclosing class without the `static` modifier.

Member classes are analogous to the other members of a class, namely the instance variables and methods. The code within a member class can refer to any of the variables and methods of its enclosing class, including `private` variables and methods.

Here is a partial definition of a `Queue` class that uses a member class:

```
public class Queue {
    private QueueNode queue;
    ...
    public Enumeration elements() {
        return new QueueEnumerator();
    }
    ...
    private class QueueEnumerator implements Enumeration {
        private QueueNode start, end;
        QueueEnumerator() {
            synchronized (Queue.this) {
                if (queue != null) {
                    start = queue.next;
                    end = queue;
                }
            }
        }
        public boolean hasMoreElements() {
            return start != null;
        }
        public synchronized Object nextElement() {
            ...
        }
    }
    private static class QueueNode {
        private Object obj;
        QueueNode next;
        QueueNode(Object obj) {
            this.obj = obj;
        }
        Object getObject() {
            return obj;
        }
    }
}
```

The `QueueEnumerator` class is a `private` member class that implements the `java.util.Enumeration` interface. The advantage of this approach is that the `QueueEnumerator` class can access the `private` instance variable `queue` of the enclosing `Queue` class. If `QueueEnumerator` were declared outside of the `Queue` class, this `queue` variable would need to be `public`, which would compromise the encapsulation of the `Queue` class. Using a member class that implements the `Enumeration` interface provides a means to offer controlled access to the data in a `Queue` without exposing the internal data structure of the class.

An instance of a member class has access to the instance variables of exactly one instance of its enclosing class. That instance of the enclosing class is called the *enclosing instance*. Thus, every `QueueEnumerator` object has exactly one `Queue` object that is its enclosing instance. To access an enclosing instance, you use the construct *ClassName*`.this`. The `QueueEnumerator` class uses this construct in the `synchronized` statement in its constructor to synchronize on its enclosing instance. This synchronization is necessary to ensure that the newly created `QueueEnumerator` object has exclusive access to the internal data of the `Queue` object.

The `Queue` class also contains a nested top-level, or `static`, class, `QueueNode`. However, this class is also declared `private`, so it is not accessible outside of `Queue`. The main difference between `QueueEnumerator` and `QueueNode` is that `QueueNode` does not need access to any instance data of `Queue`.

A member class cannot declare any `static` variables, `static` methods, `static` classes, or static initializers.

Although member classes are often declared `private`, they can also be `public` or `protected` or have the default accessibility. To refer to a class declared inside of another class from outside of that class, you prefix the class name with the names of the enclosing classes, separated by dots. For example, consider the following declaration:

```
public class A {
    public class B {
        public class C {
            ...
        }
        ...
    }
    ...
}
```

Outside of the class named `A`, you can refer to the class named `C` as `A.B.C`.

Local classes

A *local class* is an inner class that is declared inside of a block of Java code. A local class is only visible within the block in which it is declared, so it is analogous to a local variable. However, a local class can access the variables and methods of any enclosing classes. In addition, a local class can access any `final` local variables or method parameters that are in the scope of the block that declares the class.

Local classes are most often used for *adapter classes*. An adapter class is a class that implements a particular interface, so that another class can call a particular method in the adapter class when a certain event occurs. In other words, an adapter class is Java's way of implementing a "callback" mechanism. Adapter classes are commonly used with the new event-handling model required by the Java 1.1 AWT and by the JavaBeans API.

Here is an example of a local class functioning as an adapter class:

```
public class Z extends Applet {
    public void init() {
        final Button b = new Button("Press Me");
        add(b);
        class ButtonNotifier implements ActionListener {
            public void actionPerformed(ActionEvent e) {
                b.setLabel("Press Me Again");
                doIt();
            }
        }
        b.addActionListener(new ButtonNotifier());
    }
    ...
}
```

The above example is from an applet that has a `Button` in its user interface. To tell a `Button` object that you want to be notified when it is pressed, you pass an instance of an adapter class that implements the `ActionListener` interface to its `addActionListener()` method. A class that implements the `ActionListener` interface is required to implement the `actionPerformed()` method. When the `Button` is pressed, it calls the adapter object's `actionPerformed()` method. The main advantage of declaring the `ButtonNotifier` class in the method that creates the `Button` is that it puts all of the code related to creating and setting up the `Button` in one place.

As the preceding example shows, a local class can access local variables of the block in which it is declared. However, any local variables that are accessed by a local class must be declared `final`. A local class can also access method parameters and the exception parameter of a `catch` statement that are accessible within the scope of its block, as long as the parameter is declared `final`. The Java compiler complains if a local class uses a non-`final` local variable or parameter. The lifetime of a parameter or local variable is extended indefinitely, as long as there is an instance of a local class that refers to it.

Anonymous classes

An *anonymous class* is a kind of local class that does not have a name and is declared inside of an allocation expression. As such, an anonymous class is a more concise declaration of a local class that combines the declaration of the class with its instantiation.

Here is how you can rewrite the previous adapter class example to use an anonymous class instead of a local class:

```
public class Z extends Applet {
    public void init() {
        final Button b = new Button("Press Me");
        add(b);
        b.addActionListener(new ActionListener () {
            public void actionPerformed(ActionEvent e) {
                b.setLabel("Press Me Again");
            }
        } );
    }
    ...
}
```

As you can see, an anonymous class is declared as part of an allocation expression. If the name after `new` is the name of an interface, as is the case in the preceding example, the anonymous class is an immediate subclass of `Object` that implements the given interface. If the name after `new` is the name of a class, the anonymous class is an immediate subclass of the named class.

Obviously, an anonymous class doesn't have a name. The other restriction on an anonymous class is it can't have any constructors other than the default constructor. Any constructor-like initialization must be done using an instance initializer. Other than these differences, anonymous classes function just like local classes.

References Allocation Expressions; Class Declarations; Instance Initializers; Object

Implementation of inner classes

It is possible to use inner classes without knowing anything about how they are implemented. However, a high-level understanding can help you comprehend the filenames that the compiler produces, and also some of the restrictions associated with inner classes. The implementation of inner classes is less than transparent in a number of ways, primarily because the Java virtual machine does not know about inner classes. Instead, the Java compiler implements inner classes by rewriting them in a form that does not use inner classes. The advantage of this approach is that the Java virtual machine does not require any new features to be able to run programs that use inner classes.

Since a class declared inside another class is rewritten by the compiler as an external class, the compiler must give it a name unique outside of the class in which it is declared. The unique name is formed by prefixing the name of the inner class with the name of the class in which it is declared and a dollar sign (`$`). Thus, when the `Queue` class is compiled, the Java compiler produces four *.class* files:

- *Queue.class*
- *Queue$EmptyQueueException.class*
- *Queue$QueueEnumerator.class*
- *Queue$QueueNode.class*

Because anonymous classes do not have names, the Java compiler gives each anonymous class a number for a name; the numbers start at 1. When the version of the `Z` applet that uses an anonymous class is compiled, the Java compiler produces two *.class* files:

- *Z.class*
- *Z$1.class*

In order to give an inner class access to the variables of its enclosing instance, the compiler adds a `private` variable to the inner class that references the enclosing instance. The compiler also inserts a formal parameter into each constructor of the inner class and passes the reference to the enclosing instance using this parameter. Therefore, the `QueueEnumerator` class is rewritten as follows:

```
class Queue$QueueEnumerator implements Enumeration {
    private Queue this$0;
    private QueueNode start, end;
    QueueEnumerator(Queue this$0) {
        this.this$0 = this$0;
        synchronized (this$0) {
            if (queue != null) {
                start = queue.next;
                end = queue;
            }
        }
    }
    ...
}
```

As you can see, the compiler rewrites all references to the enclosing instance as `this$0`. One implication of this implementation is that you cannot pass the enclosing instance as an argument to its superclass's constructor because `this$0` is not available until after the superclass's constructor returns.

7.2 Packages

A package is a group of classes. If a class is not declared as `public`, it can only be referenced by other classes in the same package. A class is specified as being part of a particular package by a `package` directive at the beginning of its compilation unit:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

A `package` directive can only occur at the beginning of a compilation unit (ignoring comments and white space). If there is no `package` directive in a compilation unit, the compilation unit is part of the default package. A package is identified by its name. However, the default package has no name. Here are some examples of package directives:

```
package tools.text;
package COM.geomaker;
```

A class or interface definition can refer to class and interface definitions in a different package by qualifying the class or interface name with the package name and a period. For example, you can refer to the `Socket` class as follows:

```
java.net.Socket
```

However, if you attempt to use a non-`public` class or interface defined in another package, the Java compiler issues an error message.

An `import` directive, described in the next section, makes the class and interface definitions in another package available by their simple names. In other words, if you use an `import` directive, you do not have to qualify the names of the classes and interfaces in the package with the package name.

In Sun's implementation of Java, the name of the package for a given compilation unit is used to determine the directories that the Java interpreter searches to find the compiled Java code (i.e., the *.class* file) for the compilation unit. The Java interpreter uses a two-step process to find the compiled code for a class in a named package:

- The name of the package is converted into a relative path. Each identifier in the package name becomes the name of a directory in this relative path. (This scheme assumes that the Java interpreter is operating in an environment that supports a hierarchical file system.)

- The relative path is appended to the directories specified in the `CLASSPATH` environment variable and the resulting paths are searched for the *.class* file.

If the Java interpreter is searching for the compiled code for a class that is in the default package, it simply searches the directories specified in the `CLASSPATH` environment variable.

For example, say that the value of the `CLASSPATH` environment variable is as follows:[1]

```
\java\classes;.\;
```

In this case, the Java interpreter searches for the *.class* files for classes in the package named `COM.geomaker` in the following directories:

```
\java\classes\COM\geomaker
.\COM\geomaker
```

If a package name contains a Unicode character that cannot directly appear in a directory name, the character is represented in the directory name by an "at" sign (`@`) followed by one to four hexadecimal digits. For example, the package name:

```
COM.geomaker.hg\u00f8
```

becomes the relative path:

```
\COM\geomaker\hg@f8
```

[1] This example uses Windows syntax for directory names. The syntax for directory names is different in other environments. In particular, the character used to separate directory names varies in other environments.

Java classes can also be retrieved out of a *.zip* file if the file is specified as part of the CLASSPATH. For instance, the value of CLASSPATH could be set as follows:

```
\java\classes;\java\classes.zip;.\;
```

When the Java interpreter finds a *.zip* file in the CLASSPATH, it searches the *.zip* file for the appropriate *.class* file. The core classes in the Java API are supplied in a file that is typically named something like *jdk1.1/lib/classes.zip*. As of Java 1.1, you do not normally need to put that *.zip* file in CLASSPATH because the Java interpreter automatically puts *startDir/../classes.zip* on the end of CLASSPATH (where *startDir* is the directory that contains the interpreter's executable file).

The Java language specification defines a scheme for creating package names that should be globally unique. Since Internet domain names are globally unique, the idea is to incorporate them into package names. This is done by reversing the order of the components of the domain name, capitalizing the top-level component of the domain name, and using the result as a prefix for the descriptive portion of a package name. For example, if different organizations were to create packages that they all wanted to call opinion_poll, they could use this scheme to ensure global uniqueness. The resulting package names might be:

```
COM.cnn.opinion_poll
GOV.whitehouse.opinion_poll
EDU.syracuse.newhouse.opinion_poll
```

Package names that begin with an identifier that does not contain all uppercase letters are reserved for use as local package names. The one exception is package names that begin with the identifier java, which are reserved for packages that are part of the standard Java distribution.

Class

Name

Class

Synopsis

Class Name:

`java.lang.Class`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Seriablizable`

Availability:

JDK 1.0 or later

Description

As of Java 1.1, instances of the `Class` class are used as run-time descriptions of all Java data types, both reference types and primitive types. The `Class` class has also been greatly expanded in 1.1 to provide support for the Reflection API. Prior to 1.1, `Class` just provided run-time descriptions of reference types.

A `Class` object provides considerable information about the data type. You can use the `isPrimitive()` method to find out if a `Class` object describes a primitive type, while `isArray()` indicates if the object describes an array type. If a `Class` object describes a class or interface type, there are numerous methods that return information about the fields, methods, and constructors of the type. This information is returned as `java.lang.reflect.Field`, `java.lang.reflect.Method`, and `java.lang.reflect.Constructor` objects.

There are a number of ways that you can get a `Class` object for a particular data type:

- If you have an object, you can get the `Class` object that describes the class of that object by calling the object's `getClass()`method. Every class inherits this method from the `Object` class.

- As of Java 1.1, you can get the `Class` object that describes any Java type using the new class literal syntax. A class literal is simply the name of a type (a class name or a primitive type name) followed by a period and the `class` keyword. For example:

  ```
  Class s = String.class;
  Class i = int.class;
  Class v = java.util.Vector.class;
  ```

- In Java 1.0, you can get the `Class` object from the name of a data type using the `forName()` class method of `Class`. For example:

  ```
  Class v = Class.forName("java.util.Vector");
  ```

  This technique still works in Java 1.1, but it is more cumbersome (and less efficient) than using a class literal.

You can create an instance of a class using the `newInstance()` method of a `Class` object, if the class has a constructor that takes no arguments.

The `Class` class has no `public` constructors; it cannot be explicitly instantiated. `Class` objects are normally created by the `ClassLoader` class or a `ClassLoader` object.

Class Summary

```
public final class java.lang.Class extends java.lang.Object
                                   implements java.io.Serializable {
    // Class Methods
    public static native Class forName(String className);
    // Instance Methods
    public Class[] getClasses();                              // New in 1.1
    public native ClassLoader getClassLoader();
    public native Class getComponentType();                   // New in 1.1
    public Constructor
           getConstructor(Class[] parameterTypes);            // New in 1.1
    public Constructor[] getConstructors();                   // New in 1.1
    public Class[] getDeclaredClasses();                      // New in 1.1
    public Constructor
           getDeclaredConstructor(Class[] parameterTypes); // New in 1.1
    public Constructor[] getDeclaredConstructors();           // New in 1.1
```

```
    public Field getDeclaredField(String name);             // New in 1.1
    public Field[] getDeclaredFields();                     // New in 1.1
    public Method getDeclaredMethod(String name,
                  Class[] parameterTypes)                   // New in 1.1
    public Method[] getDeclaredMethods()                    // New in 1.1
    public Class getDeclaringClass();                       // New in 1.1
    public Field getField(String name);                     // New in 1.1
    public Field[] getFields();                             // New in 1.1
    public native Class[] getInterfaces();
    public Method getMethod(String name,
                  Class[] parameterTypes);                  // New in 1.1
    public Method[] getMethods();                           // New in 1.1
    public native int getModifiers();                       // New in 1.1
    public native String getName();
    public URL getResource(String name);                    // New in 1.1
    public InputStream getResourceAsStream(String name);   // New in 1.1
    public native Object[] getSigners();                    // New in 1.1
    public native Class getSuperclass();
    public native boolean isArray();                        // New in 1.1
    public native boolean isAssignableFrom(Class cls);     // New in 1.1
    public native boolean isInstance(Object obj);          // New in 1.1
    public native boolean isInterface();
    public native boolean isPrimitive();                    // New in 1.1
    public native Object newInstance();
    public String toString();
}
```

Class Methods

forName

`public static Class forName(String className) throws ClassNotFoundException`

Parameters

`className`

Name of a class qualified by the name of its package. If the class is defined inside of another class, all dots (`.`) that separate the top-level class name from the class to load must be changed to dollar signs ($) for the name to be recognized.

Returns

A `Class` object that describes the named class.

Throws

`ClassNotFoundException`

If the class cannot be loaded because it cannot be found.

Description

This method dynamically loads a class if it has not already been loaded. The method returns a `Class` object that describes the named class.

The most common use of `forName()` is for loading classes on the fly when an application wants to use classes it wasn't built with. For example, a web browser uses this technique. When a browser needs to load an applet, the browser calls `Class.forName()` for the applet. The method loads the class if it has not already been loaded and returns the `Class` object that encapsulates the class. The browser then creates an instance of the applet by calling the `Class` object's `newInstance()` method.

When a class is loaded using a `ClassLoader` object, any classes loaded at the instigation of that class are also loaded using the same `ClassLoader` object. This method implements that security policy by trying to find a `ClassLoader` object to load the named class. The method searches the stack for the most recently invoked method associated with a class that was loaded using a `ClassLoader` object. If such a class is found, the `ClassLoader` object associated with that class is used.

Instance Methods

getClasses

`public Class[] getClasses()`

Availability

New as of JDK 1.1

Returns

An array of `Class` objects that contains the `public` classes and interfaces that are members of this class.

Description

If this `Class` object represents a reference type, this method returns an array of `Class` objects that lists all of the `public` classes and interfaces that are members of this class or interface. The list includes `public` classes and interfaces that are inherited from superclasses and that are defined by this class or interface. If there are no `public` member classes or interfaces, or if this `Class` represents a primitive type, the method returns an array of length `0`.

As of Java 1.1.1, this method always returns an array of length `0`, no matter how many `public` member classes this class or interface actually declares.

getClassLoader

`public native ClassLoader getClassLoader()`

Returns

The `ClassLoader` object used to load this class or `null` if this class was not loaded with a `ClassLoader`.

Description

This method returns the `ClassLoader` object that was used to load this class. If this class was not loaded with a `ClassLoader`, `null` is returned.

This method is useful for making sure that a class gets loaded with the same class loader as was used for loading this `Class` object.

getComponentType

`public native Class getComponentType()`

Availability

New as of JDK 1.1

Returns

A `Class` object that describes the component type of this class if it is an array type.

Description

If this `Class` object represents an array type, this method returns a `Class` object that describes the component type of the array. If this `Class` does not represent an array type, the method returns `null`.

getConstructor

`public Constructor getConstructor(Class[] parameterTypes) throws NoSuchMethodException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the constructor.

Returns

A `Constructor` object that reflects the specified `public` constructor of this class.

Throws

`NoSuchMethodException`

If the specified constructor does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns a `Constructor` object that reflects the specified `public` constructor of this class. The constructor is located by searching all of the constructors of the class for a `public` constructor that has exactly the same formal parameters as specified. If this `Class` does not represent a class, the method returns `null`.

getConstructors

```
public Constructor[] getConstructors() throws SecurityException
```

Availability

New as of JDK 1.1

Returns

An array of `Constructor` objects that reflect the `public` constructors of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns an array of `Constructor` objects that reflect the `public` constructors of this class. If there are no `public` constructors, or if this `Class` does not represent a class, the method returns an array of length `0`.

getDeclaredClasses

```
public Class[] getDeclaredClasses() throws SecurityException
```

Availability

New as of JDK 1.1

Returns

An array of `Class` objects that contains all of the declared classes and interfaces that are members of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a reference type, this method returns an array of `Class` objects that lists all of the classes and interfaces that are members of this class or interface. The list includes `public`, `protected`, default access, and `private` classes and interfaces that are defined by this class or interface, but it excludes classes and interfaces inherited from superclasses. If there are no such member classes or interfaces, or if this `Class` represents a primitive type, the method returns an array of length `0`.

As of Java 1.1.1, this method always returns an array of length `0`, no matter how many member classes this class or interface declares.

getDeclaredConstructor

```
 public Constructor getDeclaredConstructor(Class[] parameterTypes) throws
NoSuchMethodException, SecurityException
```

Availability

New as of JDK 1.1

Parameters

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the constructor.

Returns

A `Constructor` object that reflects the specified declared constructor of this class.

Throws

`NoSuchMethodException`

If the specified constructor does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns a `Constructor` object that reflects the specified declared constructor of this class. The constructor is located by searching all of the constructors of the class for a `public`, `protected`, default access, or `private` constructor that has exactly the same formal parameters as specified. If this `Class` does not represent a class, the method returns `null`.

getDeclaredConstructors

`public Constructor[] getDeclaredConstructors() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Constructor` objects that reflect the declared constructors of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns an array of `Constructor` objects that reflect the `public`, `protected`, default access, and `private` constructors of this class. If there are no declared constructors, or if this `Class` does not represent a class, the method returns an array of length `0`.

getDeclaredField

`public Field getDeclaredField(String name) throws NoSuchFieldException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the field.

Returns

A `Field` object that reflects the specified declared field of this class.

Throws

`NoSuchFieldException`

If the specified field does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Field` object that reflects the specified declared field of this class. The field is located by searching all of the fields of the class (but not inherited fields) for a `public`, `protected`, default access, or `private` field that has the specified simple name. If this `Class` does not represent a class or interface, the method returns `null`.

getDeclaredFields

public Field[] getDeclaredFields() throws SecurityException

Availability

New as of JDK 1.1

Returns

An array of `Field` objects that reflect the declared fields of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Field` objects that reflect the `public`, `protected`, default access, and `private` fields declared by this class, but excludes inherited fields. If there are no declared fields, or if this `Class` does not represent a class or interface, the method returns an array of length `0`.

This method does not reflect the implicit `length` field for array types. The methods of the class `Array` should be used to manipulate array types.

getDeclaredMethod

`public Method getDeclaredMethod(String name, Class[] parameterTypes) throws NoSuchMethodException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the method.

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the method.

Returns

A `Method` object that reflects the specified declared method of this class.

Throws

`NoSuchMethodException`

If the specified method does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Method` object that reflects the specified declared method of this class. The method is located by searching all of the methods of the class (but not inherited methods) for a `public`, `protected`, default access, or `private` method that has the specified simple name and exactly the same formal parameters as specified. If this `Class` does not represent a class or interface, the method returns `null`.

getDeclaredMethods

public Method[] getDeclaredMethods() throws SecurityException

Availability

New as of JDK 1.1

Returns

An array of `Method` objects that reflect the declared methods of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Method` objects that reflect the `public`, `protected`, default access, and `private` methods declared by this class, but excludes inherited methods. If there are no declared methods, or if this `Class` does not represent a class or interface, the method returns an array of length `0`.

getDeclaringClass

`public Class getDeclaringClass()`

Availability

New as of JDK 1.1

Returns

A `Class` object that represents the declaring class if this class is a member of another class.

Description

If this `Class` object represents a class or interface that is a member of another class or interface, this method returns a `Class` object that describes the declaring class or interface. If this class or interface is not a member of another class or interface, or if it represents a primitive type, the method returns `null`.

getField

`public Field getField(String name) throws NoSuchFieldException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the field.

Returns

A `Field` object that reflects the specified `public` field of this class.

Throws

`NoSuchFieldException`

If the specified field does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Field` object that reflects the specified `public` field of this class. The field is located by searching all of the fields of the class, including any inherited fields, for a `public` field that has the specified simple name. If this `Class` does not represent a class or interface, the method returns `null`.

getFields

`public Field[] getFields() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Field` objects that reflect the `public` fields of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Field` objects that reflect the `public` fields declared by this class and any inherited `public` fields. If there are no `public` fields, or if this `Class` does not represent a class or interface, the method returns an array of length `0`.

This method does not reflect the implicit `length` field for array types. The methods of the class `Array` should be used to manipulate array types.

getInterfaces

public native Class[] getInterfaces()

Returns

An array of the interfaces implemented by this class or extended by this interface.

Description

If the `Class` object represents a class, this method returns an array that refers to all of the interfaces that the class implements. The order of the interfaces referred to in the array is the same as the order in the class declaration's `implements` clause. If the class does not implement any interfaces, the length of the returned array is 0.

If the object represents an interface, this method returns an array that refers to all of the interfaces that this interface extends. The interfaces occur in the order they appear in the interface declaration's `extends` clause. If the interface does not extend any interfaces, the length of the returned array is 0.

If the object represents a primitive or array type, the method returns an array of length 0.

getMethod

public Method getMethod(String name, Class[] parameterTypes) throws NoSuchMethodException, SecurityException

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the method.

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the method.

Returns

A `Method` object that reflects the specified `public` method of this class.

Throws

`NoSuchMethodException`

If the specified method does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Method` object that reflects the specified `public` method of this class. The method is located by searching all of the methods of the class, including any inherited methods, for a `public` method that has the specified simple name and exactly the same formal parameters as specified. If this `Class` does not represent a class or interface, the method returns `null`.

getMethods

`public Method[] getMethods() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Method` objects that reflect the `public` methods of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Method` objects that reflect the `public` methods declared by this class and any inherited `public` methods. If there are no `public` methods or if this `Class` doesn't represent a class or interface, the method returns an array of length `0`.

getModifiers

`public native int getModifiers()`

Availability

New as of JDK 1.1

Returns

An integer that represents the modifier keywords used to declare this class.

Description

If this `Class` object represents a class or interface, this method returns an integer value that represents the modifiers used to declare the class or interface. The `Modifier` class should be used to decode the returned value.

getName

`public native String getName()`

Returns

The fully qualified name of this class or interface.

Description

This method returns the fully qualified name of the type represented by this `Class` object.

If the object represents the class of an array, the method returns a `String` that contains as many left square brackets as there are dimensions in the array, followed by a code that indicates the type of element contained in the base array. Consider the following:

```
(new int [3][4][5]).getClass().getName()
```

This code returns "`[[[I`". The codes used to indicate the element type are as follows:

Code	**Type**
`[`	array
`B`	`byte`
`C`	`char`
`d`	`double`
`F`	`float`
`I`	`int`
`J`	`long`

`L` *fully_qualified_class_name*	class or interface
`S`	`short`
`Z`	`boolean`

getResource

`public URL getResource(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

A `URL` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name for this `Class` object and returns a `URL` object that is connected to the resource. The rules for searching for a resource associated with a class are implemented by the `ClassLoader` for the class; this method simply calls the `getResource()` method of the `ClassLoader`. If this class does not have a `ClassLoader` (i.e., it is a system class), the method calls the `ClassLoader.getSystemResource()` method.

getResourceAsStream

`public InputStream getResourceAsStream(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

An `InputStream` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name for this `Class` object and returns an `InputStream` object that is connected to the resource. The rules for searching for a resource associated with a class are implemented by the `ClassLoader` for the class; this method simply calls the `getResourceAsStream()` method of the `ClassLoader`. If this class does not have a `ClassLoader` (i.e., it is a system class), the method calls the `ClassLoader.getSystemResourceAsStream()` method.

getSigners

`public native Object[] getSigners()`

Availability

New as of JDK 1.1

Returns

An array of `Object`s that represents the signers of this class.

Description

This method returns an array of objects that represents the digital signatures for this class.

getSuperclass

`public native Class getSuperclass()`

Returns

The superclass of this class or `null` if there is no superclass.

Description

If the `Class` object represents a class other than `Object`, this method returns the `Class` object that represents its superclass. If the object represents an interface, the `Object` class, or a primitive type, the method returns `null`.

isArray

`public native boolean isArray()`

Availability

New as of JDK 1.1

Returns

`true` if this object describes an array type; otherwise `false`.

isAssignableFrom

`public native boolean isAssignableFrom(Class cls)`

Availability

New as of JDK 1.1

Parameters

`cls`

A `Class` object to be tested.

Returns

`true` if the type represented by `cls` is assignable to the type of this class: otherwise `false`.

Throws

`NullPointerException`

If `cls` is `null`.

Description

This method determines whether or not the type represented by `cls` is assignable to the type of this class. If this class represents a class, this class must be the same as `cls` or a superclass of `cls`. If this class represents an interface, this class must be the same as `cls` or a superinterface of `cls`. If this class represents a primitive type, this class must be the same as `cls`.

isInstance

`public native boolean isInstance(Object obj)`

Availability

New as of JDK 1.1

Parameters

`obj`

An `Object` to be tested.

Returns

true if obj can be cast to the reference type specified by this class; otherwise false.

Throws

NullPointerException

If obj is null.

Description

This method determines whether or not the object represented by obj can be cast to the type of this class object without causing a ClassCastException. This method is the dynamic equivalent of the instanceof operator.

isInterface

```
public native boolean isInterface()
```

Returns

true if this object describes an interface; otherwise false.

isPrimitive

```
public native boolean isPrimitive()
```

Availability

New as of JDK 1.1

Returns

true if this object describes a primitive type; otherwise false.

newInstance

```
 public native Object newInstance () throws InstantiationException,
IllegalAccessException
```

Returns

A reference to a new instance of this class.

Throws

`InstantiationException`

If the `Class` object represents an interface or an `abstract` class.

`IllegalAccessException`

If the class or an initializer is not accessible.

Description

This method creates a new instance of this class by performing these steps:

1. It creates a new object of the class represented by the `Class` object.
2. It calls the constructor for the class that takes no arguments.
3. It returns a reference to the initialized object.

The `newInstance()` method is useful for creating an instance of a class that has been dynamically loaded using the `forName()` method.

The reference returned by this method is usually cast to the type of object that is instantiated.

The `newInstance()` method can throw objects that are not instances of the classes it is declared to throw. If the constructor invoked by `newInstance()` throws an exception, the exception is thrown by `newInstance()` regardless of the class of the object.

toString

`public String toString()`

Returns

A `String` that contains the name of the class with either `'class'` or `'interface'` prepended as appropriate.

Overrides

`Object.toString()`

Description

This method returns a string representation of the `Class` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals()`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Void

Name

Void

Synopsis

Class Name:

```
    java.lang.Void
```

Superclass:

```
    java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability

New as of JDK 1.1

Description

The `Void` class is an uninstantiable wrapper for the primitive type `void`. The class contains simply a reference to the `Class` object that represents the primitive type `void`. The `Void` class is necessary as of JDK 1.1 to support the Reflection API and class literals.

Class Summary

```
public final class java.lang.Void extends java.lang.Object {
  // Constants
  public static final Class TYPE;
}
```

Constants

TYPE

public static final Class TYPE

The `Class` object that represents the primitive type `void`. It is always true that `Void.TYPE` == `void.class`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

5.2 Lexical Scope of Declarations

The lexical scope of a declaration determines where the named entity is a valid identifier. Every declaration is associated with a lexical level that corresponds to one of the following Java constructs:

Package

> The names at this level include all of the non-nested, outer-level class and interface declarations in files that belong to the same package as the file that is being compiled. This level also includes non-nested, outer-level class and interface declarations that are declared `public` in other packages.

.java file

> The names at this level include all of the class and interface declarations in the file, as well as all of the classes and interfaces that are imported by the file. The names declared directly in a file are defined from the beginning to the end of the file. An `import` statement defines simple identifiers as synonyms for names that are only fully qualified with the name of a package. These synonyms for fully qualified names are defined from the `import` statement that defines them to the end of the file.

Class or interface declaration

> The names at this level include the names of methods, variables, and classes or interfaces that are declared directly in the class or interface declaration, as well as names inherited from superclasses or super interfaces. The names declared in a class or interface are defined throughout the class or interface.

Method declaration

> The names at this level include the formal parameters of the method. The formal parameters are defined throughout the method.

Block

> The names at this level include the local variables, local classes, and statement labels declared in the block. Statement labels are defined throughout a block, while local variables and classes are defined from their declaration to the end of the block.

A nested block or a `for` statement

> The names at this level include local variables declared in the initialization of the `for` statement or the local variables, classes, and statement labels declared in a nested block. Local variables declared in the initialization of a `for` statement are defined from their declaration to the end of the `for` statement. Statement labels are defined throughout a nested block, while local variables and classes are defined from their declaration to the end of the nested block.

These lexical levels correspond to nested constructs. When the Java compiler encounters a name in a program, it finds the declaration for that name by first looking in the lexical level where the name is encountered. If the compiler does not find the name in that lexical level, it searches progressively higher lexical levels until it finds the declaration. If all of the lexical levels are exhausted, the compiler issues an error message.

If, however, an identifier is qualified by a class or package name, the compiler only searches that lexical level for a declaration.

6.2 Labeled Statements

Zero or more labels can appear before a statement:

[Graphic: Figure from the text]

A label is defined throughout the block in which it occurs. The names of labels are independent of all other kinds of names. In other words, if a label has the same name as a local variable, formal parameter, class, interface, field variable, or method, there is never any confusion or interaction between those names.[1] For example, the following code works even though it contains a label and formal parameter with the same name:

> [1] Prior to version 1.0.2, Java required labels to have names that did not conflict with the names of local variables or formal parameters.

```
public static void main (String[] argv) {
  argv:
    while (true) {
        System.out.println(argv[0]);
        if ( Math.random() >.4)
            break argv;
        System.out.println("Again");
    }
}
```

Labels are used to mark statements, but a labeled statement does not affect the order of execution when it is defined. The statement following the label is executed as if the label were not present. However, a label can be used in a `break` or `continue` statement to transfer control to a labeled statement. Unlike C/C++, Java does not have a `goto` statement.

6.6 The switch Statement

A `switch` statement selects a specially labeled statement in its block as the next statement to be executed, based on the value of an expression:

[Graphic: Figure from the text]

In Java, the type of the expression in parentheses must be `byte`, `char`, `short`, or `int`. This is unlike C/C++, which allows the type of a `switch` statement to be any integer type, including `long`.

The body of a `switch` statement must be a block. The top-level statements inside a `switch` may contain `case` labels. The expression following a `case` label must be a constant expression that is assignable to the type of the `switch` expression. No two `case` labels in a `switch` can contain the same value. At most one of the top-level statements in a `switch` can contain a `default` label.

A `switch` statement does the following:

- Evaluates the expression in parentheses. If the type of the expression is not `int`, the value produced by the expression is converted to `int`.
- Compares the value produced by the expression to the values in the `case` labels. Prior to comparison, the value in the `case` label is converted to `int` if it is not already `int`.
- If a `case` label is found that has the same value as the expression, that label's statement is the next statement to be executed.

- If no `case` label is found with the same value as the expression, and a statement in the block has a `default` label, that statement is the next one to be executed.

- If there is no statement in the block that has a `default` label, the statement after the `switch` statement is the next statement to be executed.

Here's an example of a `switch` statement:

```
switch (rc) {
  case 1:
    msg = "Syntax error";
    break;
  case 2:
    msg = "Undefined variable";
    break;
  default:
    msg = "Unknown error";
    break;
}
```

After the `switch` statement has transferred control to a `case`-labeled statement, statements are executed sequentially in the normal manner. Any `case` labels and the `default` label have no further effect on the flow of control. If no statement inside the block alters the flow of control, each statement is executed in sequence with control flowing past each `case` label and out the bottom of the block. The following example illustrates this behavior:

```
void doInNTimes(int n){
    switch (n > 5 ? 5 : n) {
      case 5:
        doIt();
      case 4:
        doIt();
      case 3:
        doIt();
      case 2:
        doIt();
      case 1:
        doIt();
    }
}
```

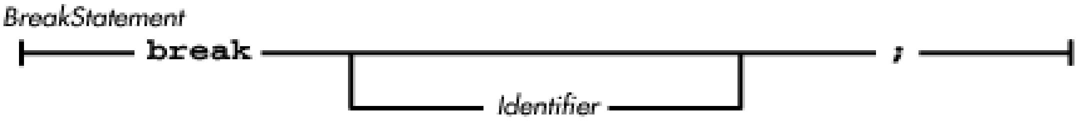
The above method calls the `doIt()` method up to 5 times.

To prevent control from flowing through `case` labels, it is common to end each `case` with a flow-altering statement such as a `break` statement. Other statements used for this purpose include the `continue` statement and the `return` statement.

References Constant Expressions; *Expression* 4; Identifiers; Integer types; Local Classes; Local Variables; *Statement* 6; The break Statement; The continue Statement; The return Statement

6.8 The break Statement

A break statement transfers control out of an enclosing statement:



If a break statement does not contain an identifier, the statement attempts to transfer control to the statement that follows the innermost enclosing while, for, do, or switch statement. The Java compiler issues an error message if a break statement without an identifier occurs without an enclosing while, for, do, or switch statement. Here is an example of a break statement that contains no identifier:

```
while (true) {
    c = in.read();
    if (Character.isSpace(c)
        break;
    s += (char)c;
}
```

In this example, the break statement is used to exit from the while loop.

The innermost while, for, do, or switch statement that encloses the break statement must be in the immediately enclosing method or initializer block. In other words, a break statement cannot be used to leave a method or initializer block. The break statement in the following example is used incorrectly and generates an error:

```
while (true) {
    class X {
        void doIt() {
            break;
        }
    }
    new X().doIt();
}
```

If a break statement contains an identifier, the identifier must be defined as the label of an enclosing statement. A break statement that contains an identifier attempts to transfer control to the statement that immediately follows the statement labeled with that identifier. Here's an example of a break statement that contains an identifier:

```
foo:{
    doIt();
    if (n > 4) break foo;
    doIt();
}
```

In this example, the break statement transfers control to the statement following the block labeled foo.

The label used in a break statement must be in the immediately enclosing method or initializer block. The break statement in the following example is used incorrectly and generates an error:

```
foo: {
    class X {
        void doIt() {
            break foo;
        }
    }
    new X().doIt();
}
```

The statement to which a break statement attempts to transfer control is called the *target statement*. If a break statement occurs inside a try statement, control may not immediately transfer to the target statement. If a try statement has a finally clause, the finally block is executed before control leaves the try statement for any reason. This means that if a break statement occurs inside a try statement (but not in its finally block) and the target statement is outside of the try statement, the finally block is executed first, before the control transfer can take place.

If the finally block contains a break, continue, return, or throw statement, the pending control transfer for the previously executed break statement is forgotten. Instead, control is transferred to the target of the break, continue, return, or throw statement in the finally block.

If the `finally` block does not contain a `break`, `continue`, `return`, or `throw` statement, the pending control transfer happens after the `finally` block is done executing, unless the target statement is enclosed by another `try` statement. If there is another enclosing `try` statement and it has a `finally` clause, that `finally` block is also executed before the control transfer can take place. Execution proceeds in this manner until the target statement of the `break` is executed.

Here is an example that illustrates a simple scenario:

```
ll:{
    try {
        f = new FileInputStream(fname);
        i = f.read();
        if (i != ' ')
            break ll;
        i = f.read();
    } catch (IOException e) {
        System.out.println("Got an IO Exception!");
        break ll;
    } finally {
        f.close();           // Always executed
    }
    // Only reached if we don't break out of the try
    System.out.println("No breaks");
}
```

In this example, a `break` statement is executed if one of two things happens. First, if an `IOException` is thrown, the `catch` clause prints a message and then executes a `break` statement. Otherwise, if the first call to `read()` does not return a space, a `break` statement is executed. In either case, the `finally` clause is executed before control is transferred to the statement following the statement labeled with `ll`.

References Identifiers; Labeled Statements; The continue Statement; The do Statement; The for Statement; The return Statement; The throw Statement; The try Statement; The while Statement

6.9 The continue Statement

A continue statement stops the current iteration of an iteration statement and transfers control to the start of the next iteration:

[Graphic: Figure from the text]

A continue statement must occur within a while, for, or do statement or the compiler issues an error message.

If a continue statement does not contain an identifier, the statement stops the current iteration in the innermost enclosing while, for, or do statement and attempts to transfer control to the start of the next iteration. This means that in a while or do statement, the continue statement transfers control to just after the contained statement of the while or do statement. In a for statement, the continue statement transfers control to the increment portion of the for statement. Here is an example of a continue statement that contains no identifier:

```
public static void main (String[] argv) {
    for (int i=0; i<=15; i++) {
        System.out.println(i);
        if ( (i&1) == 0 )
            continue;
        System.out.println("That's odd");
    }
}
```

The above example outputs the numbers 0 through 15, printing "That's odd" after each odd number.

The innermost `while`, `for`, `do`, or `switch` statement that encloses the `continue` statement must be in the immediately enclosing method or initializer block. The `continue` statement in the following example is used incorrectly and generates an error:

```
while (true) {
    class X {
        void doIt() {
            continue;
        }
    }
    new X().doIt();
}
```

If a `continue` statement contains an identifier, the identifier must be defined as the label of an enclosing `while`, `for`, or `do` statement. A `continue` statement that contains an identifier stops the current iteration of the labeled iteration statement and attempts to transfer control to the start of the next iteration of that loop. Here is an example of a `continue` statement that contains an identifier:

```
public boolean search(int x, int a[][]) {
    int count = 0;
  top:
    for (int i=0; i<a.length; i++) {
        int b[] = a[i];
        for (int j=0; j < b.length; j++) {
            if (x == b[j])
                return true;
            if ( x < b[j])
                continue top;
        } // for j
        count++;
        if (count > 100)
            return false;
    } // for i
    return false;
} // search()
```

The above method searches an array of arrays of integers for a specified value. The method assumes that the values in the sub-arrays are in descending order. The method gives up after checking 100 values.

The label used in a `continue` statement must be in the immediately enclosing method or initializer block.

The statement to which a `continue` statement attempts to transfer control is called the target statement. If a `continue` statement occurs inside a `try` statement, control may not immediately transfer to the target statement. If a `try` statement has a `finally` clause, the `finally` block is executed before control leaves the `try` statement for any reason. This means that if a `continue` statement occurs inside a `try` statement (but not in its `finally` block) and the target statement is outside of the `try` statement, the `finally` block is executed first, before the control transfer can take place.

If the `finally` block contains a `break`, `continue`, `return`, or `throw` statement, the pending control transfer for the previously executed `continue` statement is forgotten. Instead, control is transferred to the target of the `break`, `continue`, `return`, or `throw` statement in the `finally` block.

If the `finally` block does not contain a `break`, `continue`, `return`, or `throw` statement, the pending control transfer happens after the `finally` block is done executing, unless the target statement is enclosed by another `try` statement. If there is another enclosing `try` statement and it has a `finally` clause, that `finally` block is also executed before the control transfer can take place. Execution proceeds in this manner until the target statement of the `continue` is executed.

References Identifiers; Labeled Statements; The break Statement; The do Statement; The for Statement; The return Statement; The throw Statement; The try Statement; The while Statement

6.10 The return Statement

A `return` statement returns control of the current method or constructor to the caller:

[Graphic: Figure from the text]

If a `return` statement does not contain an expression, the statement must be in a method declared with the `void` return type or in a constructor. Otherwise, the compiler issues an error message. When a `return` statement does not contain an expression, the statement simply attempts to transfer control back to the method or constructor that invoked the current method or constructor.

If a `return` statement contains an expression, it must be in a method that returns a value or the compiler issues an error message. The type of the expression must be assignment-compatible with the declared return type of the method. The `return` statement attempts to transfer control back to the method or constructor that invoked the current method. The value produced by the expression is the return value of the current method.

Here's an example of a `return` statement:

```
int doubleIt (int k) {
    return k*2;
}
```

If a `return` statement occurs inside a `try` statement, control may not immediately transfer to the invoking method or constructor. If a `try` statement has a `finally` clause, the `finally` block is executed before control leaves the `try` statement for any reason. This means that if a `return` statement occurs inside a `try` statement (but not in its `finally` block), the `finally` block is executed first, before the control transfer can take place.

If the `finally` block contains a `break`, `continue`, `return`, or `throw` statement, the pending control transfer for the previously executed `return` statement is forgotten. Instead, control is transferred to the target of the `break`, `continue`, `return`, or `throw` statement in the `finally` block.

If the `finally` block does not contain a `break`, `continue`, `return`, or `throw` statement, the pending control transfer happens after the `finally` block is done executing, unless there is another enclosing `try` statement. If there is such a `try` statement and it has a `finally` clause, that `finally` block is also executed before the control transfer can take place. Execution proceeds in this manner until control is transferred to the invoking method or constructor.

References Constructors; *Expression* 4; Identifiers; Methods; The break Statement; The continue Statement; The throw Statement; The try Statement

6.11 The throw Statement

A `throw` statement is used to cause an exception to be thrown:

[Graphic: Figure from the text]

The expression in a `throw` statement must produce a reference to an object that is an instance of the `Throwable` class or one of its subclasses. Otherwise, the compiler issues an error message. You typically want the expression in a `throw` statement to produce an object that is an instance of a subclass of the `Exception` class.

Here is an example of a `throw` statement:

```
throw new ProtocolException();
```

A `throw` statement causes normal program execution to stop. Control is immediately transferred to the innermost enclosing `try` statement in the search for a `catch` clause that can handle the exception. If the innermost `try` statement cannot handle the exception, the exception propagates up through enclosing statements in the current method. If the current method does not contain a `try` statement that can handle the exception, the exception propagates up to the invoking method. If this method does not contain an appropriate `try` statement, the exception propagates up again, and so on. Finally, if no `try` statement is found to handle the exception, the currently running thread terminates. The termination of a thread is described in Stopping a thread.

As an exception propagates through enclosing `try` statements, any `finally` blocks associated with those `try` statements are executed until the exception is caught. If a `finally` block contains a `break`, continue, return, or throw statement, the pending control transfer initiated by the throw statement is forgotten. Instead, control is transferred to the target of the break, continue, return, or throw statement in the finally block.

6.12 The try Statement

A `try` statement provides a way to catch exceptions and execute clean-up code for a block:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

A `try` statement contains a block of code to be executed. A `try` statement can have any number of optional `catch` clauses; these clauses act as exception handlers for the `try` block. A `try` statement can also have a `finally` clause. If present, the `finally` block is always executed before control leaves the `try` statement, so it is a good place to supply clean-up code for the `try` block. Note that a `try` statement must have either a `catch` clause or a `finally` clause.

Here is an example of a `try` statement that includes a `catch` clause and a `finally` clause:

```
try {
    out.write(b);
} catch (IOException e) {
    System.out.println("Output Error");
} finally {
    out.close();
}
```

If `out.write()` throws an `IOException`, the exception is caught by the `catch` clause. Regardless of whether `out.write()` returns normally or throws an exception, the `finally` block is executed, which ensures that `out.close()` is always called.

A `try` statement begins by executing the block that follows the keyword `try`. If an exception is thrown from within the `try` block and the `try` statement has any `catch` clauses, those clauses are searched in order for one that can handle the exception. A `catch` clause can handle an exception if the *ClassOrInterfaceName* specified in the clause is the same class as or a superclass of the object specified in the `throw` statement that caused the exception. The *ClassOrInterfaceName* specified in a catch clause must be `Throwable` or be one of its subclasses. If a `catch` clause handles an exception, that `catch` block is executed.

If an exception is thrown from within the `try` block and the `try` statement does not have any `catch` clauses that can handle the exception, the exception propagates up to the next enclosing `try` statement. An exception also propagates up if it is thrown from within a `catch`block in a `try` statement.

The identifier specified in parentheses for the `catch` clause is defined as a local variable within the `catch` block. The local variable is initialized to refer to the thrown object, in a manner that is similar to the way it which formal parameters for a method are handled. This means that an identifier in a `catch` clause cannot have the same name as a local variable or formal parameter that is defined in an enclosing block. If the `catch` parameter is declared as `final`, any assignment to that parameter in the `catch` block generates an error. The syntax for specifying `final catch` parameters is not supported prior to Java 1.1.

Any `catch` clauses in a `try` statement are checked in sequence to see if they can handle a given exception. Thus, the order in which `catch` clauses appear is important. In essence, more specific `catch` clauses should appear before more general `catch` clauses. Figure 6.1 shows the inheritance hierarchy for a few of the classes of objects that can be thrown in Java.

Figure 6.1: Some exception classes in Java

[Graphic: Figure 6-1]

Based on the classes shown in Figure 6.1, consider the following example:

```
try {
    System.out.write(b);
} catch (InterruptedIOException e) { ...
} catch (IOException e) { ...
} catch (Exception e) { ...
}
```

The `catch` clauses in this example appear in order from most specific to least specific. That means that if an `InterruptedIOException` were thrown, it would be caught by the first `catch` clause. Similarly, an `IOException` would be caught by the second `catch` clause and an `Exception` would be caught by the third clause. If, however, the `catch` clause for `Exception` appeared first, neither of the other `catch` clauses would ever be executed because the `catch` clause for `Exception` would catch all of the exceptions.

If a `try` statement includes a `finally` clause, the `finally` block is always executed before control leaves the `try` statement. There are two different ways that control can leave a `try` statement:

- The `try` statement completes normally. Normal completion occurs when all of the statements in the `try` block have been executed, so that control falls out of the bottom of the `try` block. Normal completion can also occur when an exception is thrown in the `try` block, as long as the exception is handled by a `catch` clause in the `try` statement.

- The `try` statement completes abruptly, due to an attempted control transfer out of the `try` block. A `break`, `continue`, or `return` statement in the `try` block causes an abrupt completion. In addition, abrupt completion can occur when an exception occurs and is not handled by a `catch` clause in the `try` statement, since the exception propagates out of the `try` block.

If a `try` statement completes normally and it does not have a `finally` clause, the statement following the `try` statement is the next statement to be executed. However, if the `try` statement does have a `finally` clause, the `finally` block is executed first, before control can be transferred to the statement following the `try` statement. If the `finally` block contains a `break`, `continue`, `return`, or `throw` statement, the pending control transfer is forgotten and control is instead transferred to the target of the `break`, `continue`, `return`, or `throw` statement in the `finally` block.

If a `try` statement completes abruptly and it does not have a `finally` clause, the control transfer out of the `try` block takes place immediately. However, if the `try` statement does have a `finally` clause, the `finally` block is executed first, before the control transfer can take place. If the `finally` block contains a `break`, `continue`, `return`, or `throw` statement, the pending control transfer is forgotten and control is instead transferred to the target of the `break`, `continue`, `return`, or `throw` statement in the `finally` block.

7.3 The import Directive

You can refer to classes and interfaces defined in a particular package by qualifying their names with the package name and a period. For example, you can refer to the `Socket` class as `java.net.Socket`. Using this notation, you could write a declaration like the following:

```
java.net.Socket s = new java.net.Socket();
```

This declaration is rather verbose. As you can imagine, it would quickly become cumbersome to refer to classes this way in all of your programs.

The `import` directive provides an alternative to prefixing the names of classes and interfaces defined in particular packages with their package names. An `import` directive makes definitions from another package available by their simple names:

[Graphic: Figure from the text]

An `import` directive can only occur after the `package` directive in a compilation unit (if there is one) and before any class or interface declarations.

An `import` directive with an identifier after the package name defines that identifier to have the same meaning as the fully qualified class or interface name. When an identifier is defined using an `import` directive, the definition exists only from the `import` directive that defines it to the end of the compilation unit.

For example, you could use the following `import` directive:

```
import java.net.Socket;
```

Now the identifier `Socket` is defined to mean `java.net.Socket`. With the above `import` directive at the beginning of a compilation unit, you can rewrite the previous declaration as follows:

```
Socket s = new Socket();
```

If more than one `import` directive provides a definition for the same identifier, the compiler issues an error message.

An `import` directive can also be used to define an identifier as a synonym for the fully qualified name of a class that is declared inside of another class. For example, consider the following class declaration:

```
package COM.geomaker;
...
public class z {
    ...
    class zz {
        ...
    }
}
```

A class in another file can refer to the class `COM.geomaker.z.zz` as just `zz` if the file contains the following `import` directive:

```
import COM.geomaker.z.zz;
```

An `import` directive with an asterisk (`*`) after the package name tells the compiler to search the specified package when it cannot find a definition for an identifier. In other words, this type of `import` directive makes all of the classes and interfaces in the package available by their simple names. Here's an example of such an `import` directive:

```
import java.awt.*;
```

When the compiler is searching packages specified by this type of `import` directive, it issues an error message if it finds the same name defined in two different packages.

Every package in Java is considered separate and distinct, even if the name of a package begins with the name of another package. For example, the package `java.awt` is separate and distinct from the package `java.awt.image`. Even though the names imply a parent-child relationship, Java recognizes no such relationship between packages. Consider the following directive:

```
import java.awt.*;
```

This tells the Java compiler to search the `java.awt` package for class and interface names; it does not, however, tell the compiler to search `java.awt.image` for such names. For that to happen, a compilation unit must also include the following directive:

```
import Java.awt.image.*;
```

It is important to understand that an `import` directive does not cause the Java compiler to read any class or interface definitions. An `import` directive simply defines an identifier as a synonym for a fully qualified class or interface name or directs the compiler to search a package when it needs to find a definition. The compiler only reads a class or interface definition when its finds an actual reference to the class or interface.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.4 Documentation Comments

Documentation comments are used to create stand-alone documentation for classes. Documentation comments are processed into Web pages by the *javadoc* program that is part of Sun's Java Development Kit (JDK). The *javadoc* program and the way that it processes *.java* files into Web pages is fully described in the documentation for *javadoc* provided by Sun. The remainder of this section describes the special formatting information that can be embedded in documentation comments.

Documentation comments are comments that begin with `/**`. If a documentation comment immediately precedes the declaration of a class, interface, method, or field variable, it is assumed to describe that class, interface, method, or field variable.

HTML tags can be included in a documentation comment; they are passed directly to the generated Web page. In addition to passing HTML tags, *javadoc* recognizes special tags that start with an "at" sign (@). These tags must appear as the first word on a line in order to be recognized. Here is an example of a documentation comment that includes these special *javadoc* tags:

```
/**
 * RomanNumeral is a class similar to Integer, except that
 * it uses roman numerals for its string based
 * representation.  It only represents positive numbers.
 *
 * @see        Integer
 * @see        Number
 * @see        Float
 * @see        Double
 * @version    1.1, 9/27/96
 * @author     Mark Grand
 */
```

Here are the special documentation comment tags recognized by *javadoc* :

`@author author-name`

Formats the given author name. This tag can only be used in a class or interface documentation comment.

`@exception name description`

Formats the given exception name and its description in the throws section of a method description. The name should be the fully qualified class name of the exception. This tag can only be used in a method documentation comment.

`@param name description`

Formats the given parameter name and its description in the parameters section of a method description. This tag can only be used in a method documentation comment.

`@return description`

Formats the given description in the returns section of a method description. This tag can only be used in a method documentation comment.

`@see classname`

Generates a hypertext link to the specified class. The class name may be qualified by its package name.

`@see classname#method-name`

Generates a hypertext link to the specified method in the specified class. The class name may be qualified by its package name.

`@version text`

Formats the given text as version information. This tag can only be used in a class or interface documentation comment.

`@deprecated`

Indicates that a class, method, or variable is deprecated, which means that it has been superceded by a newer, preferred class, method, or variable. Deprecated features should not be used in new Java programs. In addition, you should try to update existing code so that it does not rely on deprecated features. While the deprecated features in Java 1.1 are still supported, there is no guarantee that they will be supported in future releases. The `@deprecated` tag is new as of Java 1.1.

The documentation comment that immediately precedes a declaration is associated with the declaration. If two comments precede a declaration, only the one immediately preceding the declaration is processed by *javadoc*. The first comment is not considered to be associated with a declaration, so it is ignored. If there is anything but white space between a documentation comment and a declaration, the documentation comment is not considered to be associated with the declaration.

The import Directive BOOK INDEX Applications

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.5 Applications

For a Java program to run as an application, it must have at least one `public` class that contains a `public static` method called `main()` that takes exactly one parameter, an array of `String` objects.

Here is a very simple sample application that outputs "Hello World!" and then exits:

```
class DoIt {
    public static void main  (String argv[]){
         System.out.println ("Hello World!");
    }
}
```

The `main()` method must be `public` so that the Java virtual machine can find it. If the method is not `public`, its name is not included in the compiler's output. The system does not create any objects prior to the start of the application's `main()` method, so the `main()` method must be `static` because it cannot be associated with an object.

If an application has a graphical user interface, then it typically creates a `java.awt.Frame` object in `main()`. The `Frame` object acts as the top-level window for the application.

In Sun's implementation of Java, you run a Java application by running the Java interpreter with a command-line argument that specifies the name of the class that contains the `main()`. The name of the Java interpreter is *java*. Here's the command-line for our sample application:

```
C:\> java DoIt
```

The capitalization of the class name on the command line must match the capitalization of the class name within the program. If the class is part of a named package, the name of the class must be qualified with the package name. For example, if you have a package called `COM.geomaker` and it contains the class called DoIt, you would use the following command to run the application:

```
C:\> java COM.geomaker.DoIt
```

Any additional information that you provide on the command line is passed to the application as command line arguments. These arguments are passed to the application using the String array passed to main(). The number of elements in the array is equal to the number of arguments passed to the application. If there are no arguments to the application, the length of the array passed to main() is zero.

7.6 Applets

A Java applet must be run from within another program, called a host application. At this point, most host applications are Web browsers. The interaction between an applet and its host application is rather involved.

From the viewpoint of an applet, the interaction involves defining a subclass of the `java.applet.Applet` class. The `Applet` class defines a number of methods that control the applet. A subclass of `Applet` overrides one or more of the methods:

`init()`

> The `init()` method is called to initialize the applet. Most initialization of an applet is done here instead of in a constructor because the constructor may be called before the hosting program is ready to provide all of the services needed for initialization.

`start()`

> The `start()` method is called in a separate thread to tell the applet to start doing whatever it is supposed to do.

`paint()`

> The `paint()` method is called at unpredictable times to draw the applet onto the screen.

`stop()`

> The `stop()` method is called to tell the applet to stop doing whatever it does.

`destroy()`

The `destroy()` method is called to tell the applet to release any resources that it holds.

From the viewpoint of the host application, the interaction typically follows a standard sequence of events. The host application usually does the following:

1. Installs a `SecurityManager` object to implement a security policy.
2. Creates a `ClassLoader` object to load the applet.
3. Loads the applet and calls its default constructor.
4. Passes an `AppletStub` object to the applet's `setStub()` method.
5. Calls the applet's `init()` method in a separate thread.
6. Marks the applet as active.
7. Starts a new thread to run the applet's `start()` method.
8. Calls the applet's `show()` method, which makes the applet visible and causes the applet's `paint()` method to be called for the first time.
9. Calls the applet's `paint()` method whenever the applet needs to be refreshed.
10. Calls the applet's `start()` and `stop()` methods when the host wants the applet to start or stop. These methods are typically called when the applet is exposed or hidden.
11. Calls the applet's `hide()` method followed by its `destroy()` method when the host wants to shut down the applet.

Embedding an Applet in a Web Page

Web pages are written in a language called HTML. This explanation of how to embed an applet in a Web page assumes that you have some knowledge of basic HTML. An applet is embedded in a Web page using an `<applet>` tag. A minimal `<applet>` tag looks as follows:

```
<applet code=Clock height=300 width=350>
</applet>
```

The `code` attribute of this sample `<applet>` tag specifies that the applet to be run is a class named `Clock`. The `width` and `height` attributes specify that the applet should be given a screen area that is

300 pixels high and 350 pixels wide.

The following list shows all of the attributes that can be specified in an `<applet>` tag. The attributes should be specified in the order in which they are listed. The `code`, `height`, and `width` attributes are required in an `<applet>` tag; the other attributes are optional:

`codebase`

> The `codebase` attribute should specify a URL that identifies the directory used to find the *.class* files needed for the applet. Files for classes that belong to the default package should be in this directory. Files for classes that belong to named packages should be in subdirectories of this directory, where the relative path is specified by individual identifiers in the package name. If `codebase` is not specified, the `<applet>` tag uses the directory that contains the HTML file as a default.

`code`

> The `code` attribute specifies the name of the class that implements the applet. If the applet is part of a named package, you must specify the fully qualified class name. So, if the name of the class is `DataPlot` and it is part of a package called `COM.geomaker.graph`, the value of the `code` attribute should be:

```
code=COM.geomaker.graph.DataPlot.class
```

> The browser locates the compiled code for the class by appending *.class* to the filename and searching the directory specified by the base URL for the document.

`object`

> The `object` attribute specifies the name of a file that contains a serialized representation of an applet. If this attribute is specified, the applet is created by deserialization, rather than by calling its default constructor. The serialization is assumed to have occurred after the applet's `init()` method has been invoked, so the `start()` method is called instead of the `init()` method. Any attributes specified when the applet was serialized are not restored; the applet sees the attributes specified for this invocation.

> The `object` attribute is new as of Java 1.1. An `<applet>` tag must include either the `code` attribute or the `object` attribute, but it cannot include both.

`archive`

> The `archive` attribute specifies a list of one or more archives that contain classes or other resources for an applet. Archives can be JAR or ZIP files. If this attribute is specified, the

resources in the archives are loaded before the applet is run. If multiple archives are listed, they should be separated by commas. The `archive` attribute is new for Java 1.1.

`alt`

The `alt` attribute specifies the text that should be displayed by Web browsers that understand the `<applet>` tag but cannot run Java applets. If the text contains space characters, it should be enclosed in quotation marks.

`name`

The `name` attribute specifies a name for a particular instance of an applet. An applet can get a reference to another applet on the same Web page using the `getApplet()` method.

`width`

The `width` attribute specifies the width of the applet in pixels.

`height`

The `height` attribute specifies the height of the applet in pixels.

`align`

The `align` attribute specifies the positioning of the applet. The possible values are: `left`, `right`, `top`, `texttop`, `middle`, `absmiddle`, `baseline`, `bottom`, or `absbottom`.

`vspace`

The `vspace` attribute specifies the amount of vertical space above and below the applet in pixels.

`hspace`

The `hspace` attribute specifies the amount of horizontal space to the left and right of the applet in pixels.

Applet-specific parameters can be provided to an applet using `<param>` tags inside the `<applet>` tag. A `<param>` tag must specify `name` and `value` attributes. For example:

```
<param name=speed value=65>
```

If a Web browser does not support the `<applet>` tag, it ignores the tag and simply displays any HTML content provided inside the tag. However, if the browser understands the `<applet>` tag, this HTML content is ignored. This means that you can provide HTML content inside an `<applet>` tag to inform users of non-Java-enabled browsers about what they are missing.

Here is an example that combines all of these elements:

```
<applet code=Compass height=400 width=300>
<param name=direction value=north>
<param name=speed value=65>
<p>
<i>If you can see this message, your Web browser is not Java enabled.
There is a Java applet on this Web page that you are not seeing.</i>
<p>
</applet>
```

If a non-Java-enabled browser is used to view this HTML file, the following text is displayed:

> If you can see this message, your Web browser is not Java-enabled. There is a Java applet on this Web page that you are not seeing.

8.2 Synchronizing Multiple Threads

The correct behavior of a multithreaded program generally depends on multiple threads cooperating with each other. This often involves threads not doing certain things at the same time or waiting for each other to perform certain tasks. This type of cooperation is called *synchronization*. This section discusses some common strategies for synchronization and how they can be implemented in Java.

The simplest strategy for ensuring that threads are correctly synchronized is to write code that works correctly when executed concurrently by any number of threads. However, this is more easily said than done. Most useful computations involve doing some activity, such as updating an instance variable or updating a display, that must be synchronized in order to happen correctly.

If a method only updates its local variables and calls other methods that only modify their local variables, the method can be invoked by multiple threads without any need for synchronization. `Math.sqrt()` and the `length()` method of the `String` class are examples of such methods.

A method that creates objects and meets the above criterion may not require synchronization. If the constructors invoked by the method do not modify anything but their own local variables and instance variables of the object they are constructing, and they only call methods that do not need to be synchronized, the method itself does not need to be synchronized. An example of such a method is the `substring()` in the `String` class.

Beyond these two simple cases, it is impossible to give an exhaustive list of rules that can tell you whether or not a method needs to be synchronized. You need to consider what the method is doing and think about any ill effects of concurrent execution in order to decide if synchronization is necessary.

Single-Threaded Execution

When more than one thread is trying to update the same data at the same time, the result may be wrong or inconsistent. Consider the following example:

```
class CountIt {
    int i = 0;
    void count() {
        i = i + 1;
    }
}
```

The method `count()` is supposed to increment the variable `i` by one. However, suppose that there are two threads, `A` and `B`, that call `count()` at the same time. In this case, it is possible that `i` could be incremented only once, instead of twice. Say the value of `i` is 7. Thread `A` calls the `count()` method and computes `i+1` as 8. Then thread `B` calls the `count()` method and computes `i+1` as 8 because thread `A` has not yet assigned the new value to `i`. Next, thread `A` assigns the value 8 to the variable `i`. Finally, thread `B` assigns the value 8 to the variable `i`. Thus, even though the `count()` method is called twice, the variable has only been incremented once when the sequence is finished.

Clearly, this code can fail to produce its intended result when it is executed concurrently by more than one thread. A piece of code that can fail to produce its intended result when executed concurrently is called a *critical section*. However, a critical section does behave correctly when it is executed by only one thread at a time. The strategy of single-threaded execution is to allow only one thread to execute a critical section of code at a time. If a thread wants to execute a critical section that another thread is already executing, the thread has to wait until the first thread is done and no other thread is executing that code before it can proceed.

Java provides the `synchronized` statement and the `synchronized` method modifier for implementing single-threaded execution. Before executing the block in a `synchronized` statement, the current thread must obtain a lock for the object referenced by the expression. If a method is declared with the `synchronized` modifer, the current thread must obtain a lock before it can invoke the method. If the method is not declared `static`, the thread must obtain a lock associated with the object used to access the method. If the method is declared `static`, the thread must obtain a lock associated with the class in which the method is declared. Because a thread must obtain a lock before executing a `synchronized` method, Java guarantees that `synchronized` methods are executed by only one thread at a time.

Modifying the `count()` method to make it a `synchronized` method ensures that it works as intended.

```
class CountIt {
    int i = 0;
    synchronized void count() {
        i = i + 1;
    }
}
```

The strategy of single-threaded execution can also be used when multiple methods update the same data. Consider the following example:

```
class CountIt2 {
    int i = 0;
    void count() {
        i = i + 1;
    }
    void count2() {
        i = i + 2;
    }
}
```

By the same logic used above, if the `count()` and `count2()` methods are executed concurrently, the result could be to increment `i` by 1, 2, or 3. Both the `count()` and `count2()` methods can be declared as `synchronized` to ensure that they are not executed concurrently with themselves or each other:

```
class CountIt2 {
    int i = 0;
    synchronized void count() {
        i = i + 1;
    }
    synchronized void count2() {
        i = i + 2;
    }
}
```

Sometimes it's necessary for a thread to make multiple method calls to manipulate an object without another thread calling that object's methods at the same time. Consider the following example:

```
System.out.print(new Date());
System.out.print(" : ");
System.out.println(foo());
```

If the code in the example is executed concurrently by multiple threads, the output from the two threads will be interleaved. The `synchronized` keyword provides a way to ensure that only one thread at a time can execute a block of code. Before executing the block in a `synchronized` statement, the current thread must obtain a lock for the object referenced by the expression. The above code can be modified to give a thread exclusive access to the `OutputStream` object referenced by `System.out`:

```
synchronized (System.out) {
    System.out.print(new Date());
    System.out.print(" : ");
    System.out.println(foo());
}
```

Note that this approach only works if other code that wants to call methods in the same object also uses similar `synchronized` statements, or if the methods in question are all `synchronized` methods. In this case, the `print()` and `println()` methods are `synchronized`, so other pieces of code that need to use these methods do not need to use a `synchronized` statement.

When an inner class is updating fields in its enclosing instance, simply making a method `synchronized` does not provide the needed single-threaded execution. Consider the following code:

```
public class Z extends Frame {
    int pressCount = 0;
    ...
    private class CountButton extends Button
                              implements ActionListener {
        public void actionPerformed(ActionEvent evt) {
            pressCount ++;
        }
    }
    ...
}
```

If a `Z` object instantiates more than one instance of `CountButton`, you need to use single-threaded execution to ensure that updates to `pressCount` are done correctly. Unfortunately, declaring the `actionPerformed()` method of `CountButton` to be `synchronized` does not accomplish that goal because it only forces the method to acquire a lock on the instance of `CountButton` it is associated with before it executes. The object you need to acquire a lock for is the enclosing instance of `Z`.

One way to have a `CountButton` object capture a lock on its enclosing instance of `Z` is to update `pressCount` inside of a `synchronized` statement. For example:

```
synchronized (Z.this) {
    pressCount ++;
}
```

The drawback to this approach is that every piece of code that accesses `pressCount` in any inner class of `Z` must be in a similar `synchronized` statement. Otherwise, it is possible for `pressCount` to be updated incorrectly. The more pieces of code that need to be inside of `synchronized` statements, the more places there are to introduce bugs in your program.

A more robust approach is to have the inner class update a field in its enclosing instance by calling a `synchronized` method in the enclosing instance. For example:

```
public class Z extends Frame {
    int pressCount = 0;
    synchronized incrementPressCount() {
        pressCount++;
    }
    ...
    private class CountButton extends Button
                              implements ActionListener {
        public void actionPerformed(ActionEvent evt) {
            incrementPressCount();
        }
    }
    ...
}
```

References Inner Classes; Method modifiers; The synchronized Statement

Optimistic Single-Threaded Execution

When multiple threads are updating a data structure, single-threaded execution is the obvious strategy to use to ensure correctness of the operations on the data structure. However, single-threaded execution can cause some problems of its own. Consider the following example:

```
public class Queue extends java.util.Vector {
    synchronized public void put(Object obj) {
        addElement(obj);
    }
    synchronized public Object get() throws EmptyQueueException {
        if (size() == 0)
            throw new EmptyQueueException();
        Object obj = elementAt(0);
        removeElementAt(0);
        return obj;
    }
}
```

This example implements a first-in, first-out (FIFO) queue. If the `get()` method of a `Queue` object is called when the queue is empty, the method throws an exception. Now suppose that you want to write the `get()` method so that when the queue is empty, the method waits for an item to be put in the queue, rather than throwing an exception. In order for an item to be put in the queue, the `put()` method of the queue must be invoked. But using the single-threaded execution strategy, the `put()` method will never be able to run while the `get()` method is waiting for the queue to receive an item. A good way to solve this dilemma is to use a strategy called *optimistic single-threaded execution*.

The optimistic single-threaded execution strategy is similar to the single-threaded execution strategy. They both begin by getting a lock on an object to ensure that the currently executing thread is the only thread that can execute a piece of code, and they both end by releasing that lock. The difference is what happens in between. Using the optimistic single-threaded execution strategy, if a piece of code discovers that conditions are not right to proceed, the code releases the lock it has on the object that enforces single-threaded execution and waits. When another piece of code changes things in such a way that might allow the first piece of code to proceed, it notifies the first piece of code that it should try to regain the lock and proceed.

To implement this strategy, the `Object` class provides methods called `wait()`, `notify()`, and `notifyAll()`. These methods are inherited by every other class in Java. The following example shows how to implement a queue that uses the optimistic single-threaded execution strategy, so that when the queue is empty, its `get()` method waits for the queue to have an item put in it:

```
public class Queue extends java.util.Vector {
    synchronized public void put(Object obj) {
        addElement(obj);
        notify();
    }
    synchronized public Object get() throws EmptyQueueException {
        while (size() == 0)
            wait();
        Object obj = elementAt(0);
        removeElementAt(0);
        return obj;
    }
}
```

In the above implementation of the `Queue` class, the `get()` method calls `wait()` when the queue is empty. The `wait()` method releases the lock that excludes other threads from executing methods in the `Queue` object, and then waits until another thread calls the `put()` method. When `put()` is called, it adds an item to the queue and calls `notify()`. The `notify()` method tells a thread that is waiting to return from a `wait()` method that it should attempt to regain its lock and proceed. If there is more than one thread waiting to regain the lock on the object, `notify()` chooses one of the threads arbitrarily. The `notifyAll()` method is similar to `notify()`, but instead of choosing one thread to notify, it notifies all of the threads that are waiting to regain the lock on the object.

Notice that the `get()` method calls `wait()` inside a `while` loop. Between the time that `wait()` is notified that it should try to regain its lock and the time it actually does regain the lock, another thread may have called the `get()` method and emptied the queue. The `while` loop guards against this situation.

References Method modifiers; Object; The synchronized Statement

Rendezvous

Sometimes it is necessary to have a thread wait to continue until another thread has completed its work and died. This type of synchronization uses the rendezvous strategy. The `Thread` class provides the `join()` method for implementing this strategy. When the `join()` method is called on a `Thread` object, the method returns immediately if the thread is dead. Otherwise, the method waits until the thread dies and then returns.

References Thread

Balking

Some methods should not be executed concurrently, and have a time-sensitive nature that makes postponing calls to them a bad idea. This is a common situation when software is controlling real-world devices. Suppose you have a Java program that is embedded in an electronic control for a toilet. There is a method called `flush()` that is responsible for flushing a toilet, and `flush()` can be called from more than one thread. If a thread calls `flush()` while another thread is already executing `flush()`, the second call should do nothing. A toilet is capable of only one flush at a time, and having a concurrent call to the `flush()` method result in a second flush would only waste water.

This scenario suggests the use of the balking strategy. The balking strategy allows no more than one thread to execute a method at a time. If another thread attempts to execute the method, the method simply returns without doing anything. Here is an example that shows what such a `flush()` method might look like:

```
boolean busy;
void flush() {
    synchronized (this) {
        if (busy)
            return;
        busy = true;
    }
    // code to make flush happen goes here
    busy = false;
}
```

Explicit Synchronization

When the synchronization needs of a thread are not known in advance, you can use a strategy called explicit synchronization. The explicit synchronization strategy allows you to explicitly tell a thread when it can and cannot run. For example, you may want an animation to start and stop in response to external events that happen at unpredictable times, so you need to be able to tell the animation when it can run.

To implement this strategy, the `Thread` class provides methods called `suspend()` and `resume()`. You can suspend the execution of a thread by calling the `suspend()` method of the `Thread` object that controls the thread. You can later resume execution of the thread by calling the `resume()` method on the `Thread` object.

Thread

Name

Thread

Synopsis

Class Name:

`java.lang.Thread`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Runnable`

Availability:

JDK 1.0 or later

Description

The Thread class encapsulates all of the information about a single thread of control running in a Java environment. Thread objects are used to control threads in a multithreaded program.

The execution of Java code is always under the control of a Thread object. The Thread class provides a static method called currentThread() that can be used to get a reference to the Thread object that controls the current thread of execution.

In order for a Thread object to be useful, it must be associated with a method that it is supposed to run. Java provides two ways of associating a Thread object with a method:

- Declare a subclass of Thread that defines a run() method. When such a class is instantiated and the object's start() method is called, the thread invokes this run() method.

- Pass a reference to an object that implements the Runnable interface to a Thread constructor. When the start() method of such a Thread object is called, the thread invokes the run() method of the Runnable object.

After a thread is started, it dies when one of the following things happens:

- The run() method called by the Thread returns.

- An exception is thrown that causes the run() method to be exited.

- The stop() method of the Thread is called.

Class Summary

```
public class java.lang.Thread extends java.lang.Object
                              implements java.lang.Runnable {
    // Constants
    public final static int MAX_PRIORITY;
    public final static int MIN_PRIORITY;
    public final static int NORM_PRIORITY;
    // Constructors
    public Thread();
    public Thread(Runnable target);
    public Thread(Runnable target, String name);
    public Thread(String name);
    public Thread(ThreadGroup group, Runnable target);
    public Thread(ThreadGroup group, Runnable target, String name);
    public Thread(ThreadGroup group, String name);
    // Class Methods
    public static int activeCount();
    public static native Thread currentThread();
    public static void dumpStack();
    public static int enumerate(Thread tarray[]);
    public static boolean interrupted();
    public static native void sleep(long millis);
    public static void sleep(long millis, int nanos);
    public static native void yield();
    // Instance Methods
    public void checkAccess();
    public native int countStackFrames();
    public void destroy();
    public final String getName();
    public final int getPriority();
    public final ThreadGroup getThreadGroup();
    public void interrupt();
    public final native boolean isAlive();
    public final boolean isDaemon();
    public boolean isInterrupted();
    public final void join();
    public final synchronized void join(long millis);
    public final synchronized void join(long millis, int nanos);
    public final void resume();
    public void run();
    public final void setDaemon(boolean on);
    public final void setName(String name);
    public final void setPriority(int newPriority);
    public synchronized native void start();
    public final void stop();
    public final synchronized void stop(Throwable o);
    public final void suspend();
    public String toString();
}
```

Constants

MAX_PRIORITY

`public final static int MAX_PRIORITY = 10`

Description

The highest priority a thread can have.

MIN_PRIORITY

`public final static int MIN_PRIORITY = 1`

Description

The lowest priority a thread can have.

NORM_PRIORITY

`public final static int NORM_PRIORITY = 5`

Description

The default priority assigned to a thread.

Constructors

Thread

`public Thread()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the same `ThreadGroup` object as the current thread, has the same daemon attribute as the current thread, has the same priority as the current thread, and has a default name.

A `Thread` object created with this constructor invokes its own `run()` method when the `Thread` object's `start()` method is called. This is not useful unless the object belongs to a subclass of the `Thread` class that overrides the `run()` method.

Calling this constructor is equivalent to:

```
Thread(null, null, genName)
```

`genName` is an automatically generated name of the form `"Thread-"+n`, where `n` is an integer incremented each time a `Thread` object is created.

public Thread(String name)

Parameters

`name`

The name of this `Thread` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the same `ThreadGroup` object as the current thread, has the same daemon attribute as the current thread, has the same priority as the current thread, and has the specified name.

A `Thread` object created with this constructor invokes its own `run()` method when the `Thread` object's `start()` method is called. This is not useful unless the object belongs to a subclass of the `Thread` class that overrides the `run()` method.

Calling this constructor is equivalent to:

```
Thread(null, null, name)
```

The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their name.

`public Thread(ThreadGroup group, Runnable target)`

Parameters

`group`

The `ThreadGroup` object that this `Thread` object is to be added to.

`target`

A reference to an object that implements the `Runnable` interface.

Throws

SecurityException

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the specified `ThreadGroup` object, has the same daemon attribute as the current thread, has the same priority as the current thread, and has a default name.

A `Thread` object created with this constructor invokes the `run()` method of the specified `Runnable` object when the `Thread` object's `start()` method is called.

Calling this constructor is equivalent to:

```
Thread(group, target, genName)
```

`genName` is an automatically generated name of the form `"Thread-"+n`, where `n` is an integer that is incremented each time a `Thread` object is created.

`public Thread(ThreadGroup group, Runnable target, String name)`

Parameters

`group`

The `ThreadGroup` object that this `Thread` object is to be added to.

`target`

A reference to an object that implements the `Runnable` interface.

`name`

The name of this `Thread` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the specified `ThreadGroup` object, has the same daemon attribute as the current thread, has the same priority as the current thread, and has the specified name.

A `Thread` object created with this constructor invokes the `run()` method of the specified `Runnable` object when the `Thread` object's `start()` method is called.

The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their names.

`public Thread(ThreadGroup group, String name)`

Parameters

`group`

The `ThreadGroup` object that this `Thread` object is to be added to.

`name`

The name of this `Thread` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the specified `ThreadGroup` object, has the same daemon attribute as the current thread, has the same priority as the current thread, and has the specified name.

A `Thread` object created with this constructor invokes its own `run()` method when the `Thread` object's `start()` method is called. This is not useful unless the object belongs to a subclass of the `Thread` class that overrides the `run()` method. Calling this constructor is equivalent to:

```
Thread(group, null, name)
```

The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their name.

Class Methods

activeCount

`public static int activeCount()`

Returns

The current number of threads in the `ThreadGroup` of the currently running thread.

Description

This method returns the number of threads in the `ThreadGroup` of the currently running thread for which the `isAlive()` method returns `true`.

currentThread

`public static native Thread currentThread()`

Returns

A reference to the `Thread` object that controls the currently executing thread.

Description

This method returns a reference to the `Thread` object that controls the currently executing thread.

dumpStack

`public static void dumpStack()`

Description

This method outputs a stack trace of the currently running thread.

enumerate

`public static int enumerate(Thread tarray[])`

Parameters

`tarray`

A reference to an array of `Thread` objects.

Returns

The number of `Thread` objects stored in the array.

Description

This method stores a reference in the array for each of the `Thread` objects in the `ThreadGroup` of the currently running thread for which the `isAlive()` method returns `true`.

Calling this method is equivalent to:

```
currentThread().getThreadGroup().enumerate(tarray)
```

If the array is not big enough to contain references to all the `Thread` objects, only as many references as will fit are put into the array. No indication is given that some `Thread` objects were left out, so it is a good idea to call `activeCount()` before calling this method, to get an idea of how large to make the array.

interrupted

`public static boolean interrupted()`

Returns

`true` if the currently running thread has been interrupted; otherwise `false`.

Description

This method determines whether or not the currently running thread has been interrupted.

sleep

`public static native void sleep(long millis)`

Parameters

`millis`

The number of milliseconds that the currently running thread should sleep.

Throws

`InterruptedException`

If another thread interrupts the currently running thread.

Description

This method causes the currently running thread to sleep. The method does not return until at least the specified number of milliseconds have elapsed.

While a thread is sleeping, it retains ownership of all locks. The `Object` class defines a method called `wait()` that is similar to `sleep()` but causes the currently running thread to temporarily relinquish its locks.

`public static void sleep(long millis, int nanos)`

Parameters

`millis`

The number of milliseconds that the currently running thread should sleep.

`nanos`

An additional number of nanoseconds to sleep.

Throws

`InterruptedException`

If another thread interrupts the currently running thread.

Description

This method causes the currently running thread to sleep. The method does not return until at least the specified number of milliseconds have elapsed.

While a thread is sleeping, it retains ownership of all locks. The `Object` class defines a method called `wait()` that is similar to `sleep()` but causes the currently running thread to temporarily relinquish its locks.

Note that Sun's reference implementation of Java does not attempt to implement the precision implied by this method. Instead, it rounds to the nearest millisecond (unless `millis` is `0`, in which case it rounds up to 1 millisecond) and calls `sleep(long)`.

yield

`public static native void yield()`

Description

> This method causes the currently running thread to yield control of the processor so that another thread can be scheduled.

Instance Methods

checkAccess

`public void checkAccess()`

Throws

> `SecurityException`
>
> > If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

> This method determines if the currently running thread has permission to modify this `Thread` object.

countStackFrames

`public native int countStackFrames()`

Returns

> The number of pending method invocations on this thread's stack.

Description

> This method returns the number of pending method invocations on this thread's stack.

destroy

`public void destroy()`

Description

> This method is meant to terminate this thread without any of the usual cleanup (i.e., any locks held by the thread are not released). This method provides a last-resort way to terminate a thread. While a thread can defeat its `stop()` method by catching objects thrown from it, there is nothing that a thread can do to stop itself from being destroyed.
>
> Note that Sun's reference implementation of Java does not implement the documented functionality of this method. Instead, the implementation of this method just throws a `NoSuchMethodError`.

getName

`public final String getName()`

Returns

> The name of this thread.

Description

> This method returns the name of this `Thread` object.

getPriority

`public final int getPriority()`

Returns

> The priority of this thread.

Description

> This method returns the priority of this `Thread` object.

getThreadGroup

`public final ThreadGroup getThreadGroup()`

Returns

The `ThreadGroup` of this thread.

Description

This method returns a reference to the `ThreadGroup` that this `Thread` object belongs to.

interrupt

`public void interrupt()`

Description

This method interrupts this `Thread` object.

Note that prior to version 1.1, Sun's reference implementation of Java does not implement the documented functionality of this method. Instead, the method just sets a `private` flag that indicates that an interrupt has been requested. None of the methods that should throw an `InterruptedException` currently do. However, the `interrupted()` and `isInterrupted()` methods do return `true` after this method has been called.

isAlive

`public final native boolean isAlive()`

Returns

`true` if this thread is alive; otherwise `false`.

Description

This method determines whether or not this `Thread` object is alive. A `Thread` object is alive if it has been started and has not yet died. In other words, it has been scheduled to run before and can still be scheduled to run again. A thread is generally alive after its `start()` method is called and until its `stop()` method is called.

isDaemon

`public final boolean isDaemon()`

Returns

> `true` if the thread is a daemon thread; otherwise `false`.

Description

> This method determines whether or not this thread is a daemon thread, based on the value of the daemon attribute of this `Thread` object.

isInterrupted

`public boolean isInterrupted()`

Returns

> `true` if this thread has been interrupted; otherwise `false`.

Description

> This method determines whether or not this `Thread` object has been interrupted.

join

`public final void join()`

Throws

> `InterruptedException`
>
> > If another thread interrupts this thread.

Description

> This method allows the thread that calls it to wait for the `Thread` associated with this method to die. The method returns when the `Thread` dies. If this thread is already dead, then this method returns immediately.

`public final synchronized void join(long millis)`

Parameters

`millis`

The maximum number of milliseconds to wait for this thread to die.

Throws

`InterruptedException`

If another thread interrupts this thread.

Description

This method causes a thread to wait to die. The method returns when this `Thread` object dies or after the specified number of milliseconds has elapsed, whichever comes first. However, if the specified number of milliseconds is zero, the method will wait forever for this thread to die. If this thread is already dead, the method returns immediately.

`public final synchronized void join(long millis, int nanos)`

Parameters

`millis`

The maximum number of milliseconds to wait for this thread to die.

`nanos`

An additional number of nanoseconds to wait.

Throws

`InterruptedException`

If another thread interrupts this thread.

Description

This method causes a thread to wait to die. The method returns when this `Thread` object dies or after the specified amount of time has elapsed, whichever comes first. However, if `millis` and `nanos` are zero, the method will wait forever for this thread to die. If this thread is already dead, the method returns immediately.

Note that Sun's reference implementation of Java does not attempt to implement the precision implied by this method. Instead, it rounds to the nearest millisecond (unless `millis` is `0`, in which case it rounds up to 1 millisecond) and calls `join(long)`.

resume

`public final void resume()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method resumes a suspended thread. The method causes this `Thread` object to once again be eligible to be run. Calling this method for a thread that is not suspended has no effect.

run

`public void run()`

Implements

`Runnable.run()`

Description

A `Thread` object's `start()` method causes the thread to invoke a `run()` method. If this `Thread` object was created without a specified `Runnable` object, the `Thread` object's own `run()` method is executed. This behavior is only useful in a subclass of `Thread` that overrides this `run()` method, since the `run()` method of the `Thread` class does not do anything.

setDaemon

`public final void setDaemon(boolean on)`

Parameters

`on`

The new value for this thread's daemon attribute.

Throws

`IllegalThreadStateException`

If this method is called after this thread has been started and while it is still alive.

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the daemon attribute of this `Thread` object to the given value. This method must be called before the thread is started. If a thread dies and there are no other threads except daemon threads alive, the Java virtual machine stops.

setName

`public final void setName(String name)`

Parameters

`name`

The new name for this thread.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a

`SecurityException`.

Description

This method sets the name of this `Thread` object to the given value. The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their name.

setPriority

`public final void setPriority(int newPriority)`

Parameters

`newPriority`

The new priority for this thread.

Throws

`IllegalArgumentException`

If the given priority is less than `MIN_PRIORITY` or greater than `MAX_PRIORITY`.

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the priority of this `Thread` to the given value.

start

`public synchronized native void start()`

Throws

`IllegalThreadStateException`

If this `Thread` object's `start()` method has been called before.

Description

This method starts this `Thread` object, allowing it to be scheduled for execution. The top-level code that is executed by the thread is the `run()` method of the `Runnable` object specified in the constructor that was used to create this object. If no such object was specified, the top-level code executed by the thread is this object's `run()` method.

It is not permitted to start a thread more than once.

stop

`public final void stop()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes this `Thread` object to stop executing by throwing a `ThreadDeath` object. The object is thrown in this thread, even if the method is called from a different thread. This thread is forced to stop whatever it is doing and throw a newly created `ThreadDeath` object. If this thread was suspended, it is resumed; if it was sleeping, it is awakened. Normally, you should not catch `ThreadDeath` objects in a `try` statement. If you need to catch `ThreadDeath` objects to detect a `Thread` is about to die, the `try` statement that catches `ThreadDeath` objects should rethrow them.

When an object is thrown out of the `run()` method associated with a `Thread`, the `uncaughtException()` method of the `ThreadGroup` for that `Thread` is called. The `uncaughtException()` method normally outputs a stack trace. However, `uncaughtException()` treats a `ThreadDeath` object as a special case by not outputting a stack trace. When the `uncaughtException()` method returns, the thread is dead. The thread is never scheduled to run again.

If this `Thread` object's `stop()` method is called before this thread is started, the `ThreadDeath` object is thrown as soon as the thread is started.

`public final synchronized void stop(Throwable o)`

Parameters

`o`

The object to be thrown.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes this `Thread` object to stop executing by throwing the given object. Normally, the `stop()` method that takes no arguments and throws a `ThreadDeath` object should be called instead of this method. However, if it is necessary to stop a thread by throwing some other type of object, this method can be used.

The object is thrown in this thread, even if the method is called from a different thread. This thread is forced to stop whatever it is doing and throw the `Throwable` object `o`. If this thread was suspended, it is resumed; if it was sleeping, it is awakened.

When an object is thrown out of the `run()` method associated with a `Thread`, the `uncaughtException()` method of the `ThreadGroup` for that `Thread` is called. If the thrown object is not an instance of the `ThreadDeath` class, `uncaughtException()` calls the thrown object's `printStackTrace()` method and then the thread dies. The thread is never scheduled to run again.

If this `Thread` object's `stop()` method is called before this thread is started, the `ThreadDeath` object is thrown as soon as the thread is started.

suspend

`public final void suspend()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method suspends a thread. The method causes this `Thread` object to temporarily be ineligible to be run. The thread becomes eligible to be run again after its `resume()` method is called. Calling this method for a thread that is already suspended has no effect.

toString

`public String toString()`

Returns

A string representation of this `Thread` object.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Thread` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

ThreadGroup

Name

ThreadGroup

Synopsis

Class Name:

```
java.lang.ThreadGroup
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The ThreadGroup class implements a grouping scheme for threads. A ThreadGroup object can own Thread objects and other ThreadGroup objects. The ThreadGroup class provides methods that allow a ThreadGroup object to control its Thread and ThreadGroup objects as a group. For example, suspend() and resume() methods of a ThreadGroup object call the suspend() and resume() methods of each of the Thread and ThreadGroup objects that belong to the particular ThreadGroup.

When a Java program starts, a ThreadGroup object is created to own the first Thread. Any additional ThreadGroup objects are explicitly created by the program.

Class Summary

```
public class java.lang.ThreadGroup extends java.lang.Object {
    // Constructors
    public ThreadGroup(String name);
    public ThreadGroup(ThreadGroup parent, String name;
    // Instance Methods
    public int activeCount();
    public int activeGroupCount();
    public boolean allowThreadSuspension(boolean b);       // New in 1.1
    public final void checkAccess();
    public final void destroy();
    public int enumerate(Thread list[]);
    public int enumerate(Thread list[], boolean recurse);
    public int enumerate(ThreadGroup list[]);
    public int enumerate(ThreadGroup list[], boolean recurse);
    public final int getMaxPriority();
    public final String getName();
    public final ThreadGroup getParent();
    public final boolean isDaemon();
    public synchronized boolean isDestroyed();             // New in 1.1
    public void list();
    public final boolean parentOf(ThreadGroup g);
    public final void resume();
    public final void setDaemon(boolean daemon);
    public final void setMaxPriority(int pri);
    public final void stop();
    public final void suspend();
    public String toString();
    public void uncaughtException(Thread t, Throwable e);
}
```

Constructors

ThreadGroup

`public ThreadGroup(String name)`

Parameters

`name`

The name of this `ThreadGroup` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `ThreadGroup` object that has the specified name and the same parent `ThreadGroup` as the current thread.

`public ThreadGroup(ThreadGroup parent, String name)`

Parameters

`parent`

The `ThreadGroup` object that this `ThreadGroup` object is to be added to.

`name`

The name of this `ThreadGroup` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a

`SecurityException`.

Description

Creates a `ThreadGroup` object with the specified name and parent `ThreadGroup` object.

Instance Methods

activeCount

`public int activeCount()`

Returns

An approximation of the current number of threads in this `ThreadGroup` object and any child `ThreadGroup` objects.

Description

This method returns an approximation of the number of threads that belong to this `ThreadGroup` object and any child `ThreadGroup` objects. The count is approximate because a thread can die after it is counted, but before the complete count is returned. Also, after a child `ThreadGroup` is counted but before the total count is returned, additional `Thread` and `ThreadGroup` objects can be added to a child `ThreadGroup`.

activeGroupCount

`public int activeGroupCount()`

Returns

An approximation of the current number of child `ThreadGroup` objects in this `ThreadGroup` object.

Description

This method returns an approximation of the number of child `ThreadGroup` objects that belong to this `ThreadGroup` object. The count is approximate because after a child `ThreadGroup` is counted but before the total count is returned, additional `ThreadGroup` objects can be added to a child `ThreadGroup`.

allowThreadSuspension

`public boolean allowThreadSuspension(boolean b)`

Availability

New as of JDK 1.1

Parameters

`b`

A `boolean` value that specifies whether or not the run-time system is allowed to suspend threads due to low memory.

Returns

The `boolean` value `true`.

Description

This method specifies whether or not the Java virtual machine is allowed to suspend threads due to low memory.

checkAccess

`public final void checkAccess()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method determines if the currently running thread has permission to modify this `ThreadGroup` object.

destroy

`public final void destroy()`

Throws

`IllegalThreadStateException`

If this `ThreadGroup` object is not empty, or if it has already been destroyed.

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method destroys this `ThreadGroup` object and any child `ThreadGroup` objects. The `ThreadGroup` must not contain any `Thread` objects. This method also removes the `ThreadGroup` object from its parent `ThreadGroup` object.

enumerate

`public int enumerate(Thread list[])`

Parameters

`list`

A reference to an array of `Thread` objects.

Returns

The number of `Thread` objects stored in the array.

Description

This method stores a reference in the array for each of the `Thread` objects that belongs to this `ThreadGroup` or any of its child `ThreadGroup` objects.

If the array is not big enough to contain references to all the `Thread` objects, only as many references as will fit are put into the array. No indication is given that some `Thread` objects were left out, so it is a good idea to call `activeCount()` before calling this method, to get an idea of how large to make the array.

`public int enumerate(Thread list[], boolean recurse)`

Parameters

`list`

A reference to an array of `Thread` objects.

`recurse`

A `boolean` value that specifies whether or not to include `Thread` objects that belong to child `ThreadGroup` objects of this `ThreadGroup` object.

Returns

The number of `Thread` objects stored in the array.

Description

This method stores a reference in the array for each of the `Thread` objects that belongs to this `ThreadGroup` object. If `recurse` is `true`, the method also stores a reference for each of the `Thread` objects that belongs to a child `ThreadGroup` object of this `ThreadGroup`.

If the array is not big enough to contain references to all the `Thread` objects, only as many references as will fit are put into the array. No indication is given that some `Thread` objects were left out, so it is a good idea to call `activeCount()` before calling this method, to get an idea of how large to make the array.

`public int enumerate(ThreadGroup list[])`

Parameters

`list`

A reference to an array of `ThreadGroup` objects.

Returns

The number of `ThreadGroup` objects stored in the array.

Description

This method stores a reference in the array for each `ThreadGroup` object that belongs to this `ThreadGroup` or any of its child `ThreadGroup` objects.

If the array is not big enough to contain references to all the `ThreadGroup` objects, only as many references as will fit are put into the array. No indication is given that some `ThreadGroup` objects were left out, so it is a good idea to call `activeGroupCount()` before calling this method, to get an idea of how large to make the array.

`public int enumerate(Thread list[], boolean recurse)`

Parameters

`list`

A reference to an array of `ThreadGroup` objects.

`recurse`

A `boolean` value that specifies whether or not to include `ThreadGroup` objects that belong to child `ThreadGroup` objects of this `ThreadGroup` object.

Returns

The number of `ThreadGroup` objects stored in the array.

Description

This method stores a reference in the array for each of the `ThreadGroup` objects that belongs to this `ThreadGroup` object. If `recurse` is `true`, the method also stores a reference for each of the `ThreadGroup` objects that belongs to a child `ThreadGroup` object of this `ThreadGroup`.

If the array is not big enough to contain references to all the `ThreadGroup` objects, only as many references as will fit are put into the array. No indication is given that some `ThreadGroup` objects were left out, so it is a good idea to call `activeGroupCount()` before calling this method, to get an idea of how large to make the array.

getMaxPriority

`public final int getMaxPriority()`

Returns

> The maximum priority that can be assigned to `Thread` objects that belong to this `ThreadGroup` object.

Description

> This method returns the maximum priority that can be assigned to `Thread` objects that belong to this `ThreadGroup` object.
>
> It is possible for a `ThreadGroup` to contain `Thread` objects that have higher priorities than this maximum, if they were given that higher priority before the maximum was set to a lower value.

getName

```
public final String getName()
```

Returns

> The name of this `ThreadGroup` object.

Description

> This method returns the name of this `ThreadGroup` object.

getParent

```
public final ThreadGroup getParent()
```

Returns

> The parent `ThreadGroup` object of this `ThreadGroup`, or `null` if this `ThreadGroup` is the root of the thread group hierarchy.

Description

> This method returns the parent `ThreadGroup` object of this `ThreadGroup` object. If this `ThreadGroup` is at the root of the thread group hierarchy and has no parent, the method returns `null`.

isDaemon

`public final boolean isDaemon()`

Returns

> `true` if this `ThreadGroup` is a daemon thread group; otherwise `false`.

Description

> This method determines whether or not this `ThreadGroup` is a daemon thread group, based on the value of daemon attribute of this `ThreadGroup` object. A daemon thread group is destroyed when the last `Thread` in it is stopped, or the last `ThreadGroup` in it is destroyed.

isDestroyed

`public synchronized boolean isDestroyed()`

Availability

> New as of JDK 1.1

Returns

> `true` if this `ThreadGroup` has been destroyed; otherwise `false`.

Description

> This method determines whether or not this `ThreadGroup` has been destroyed.

list

`public void list()`

Description

> This method outputs a listing of the contents of this `ThreadGroup` object to `System.out`.

parentOf

`public final boolean parentOf(ThreadGroup g)`

Parameters

`g`

A `ThreadGroup` object.

Returns

`true` if this `ThreadGroup` object is the same `ThreadGroup`, or a direct or indirect parent of the specified `ThreadGroup`; otherwise `false`.

Description

This method determines if this `ThreadGroup` object is the same as the specified `ThreadGroup` or one of its ancestors in the thread-group hierarchy.

resume

`public final void resume()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method resumes each `Thread` object that directly or indirectly belongs to this `ThreadGroup` object by calling its `resume()` method.

setDaemon

`public final void setDaemon(boolean daemon)`

Parameters

`daemon`

The new value for this `ThreadGroup` object's daemon attribute.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the daemon attribute of this `ThreadGroup` object to the given value. A daemon thread group is destroyed when the last `Thread` in it is stopped, or the last `ThreadGroup` in it is destroyed.

setMaxPriority

`public final void setMaxPriority(int pri)`

Parameters

`pri`

The new maximum priority for `Thread` objects that belong to this `ThreadGroup` object.

Description

This method sets the maximum priority that can be assigned to `Thread` objects that belong to this `ThreadGroup` object.

It is possible for a `ThreadGroup` to contain `Thread` objects that have higher priorities than this maximum, if they were given that higher priority before the maximum was set to a lower value.

stop

`public final void stop()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

> This method stops each `Thread` object that directly or indirectly belongs to this `ThreadGroup` object by calling its `stop()` method.

suspend

`public final void suspend()`

Throws

> `SecurityException`
>
> > If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

> This method suspends each `Thread` object that directly or indirectly belongs to this `ThreadGroup` object by calling its `suspend()` method.

toString

`public String toString()`

Returns

> A string representation of this `ThreadGroup` object.

Overrides

> `Object.toString()`

Description

> This method returns a string representation of this `ThreadGroup` object.

uncaughtException

`public void uncaughtException(Thread t, Throwable e)`

Parameters

`t`

A reference to a `Thread` that just died because of an uncaught exception.

`e`

The uncaught exception.

Description

This method is called when a `Thread` object that belongs to this `ThreadGroup` object dies because of an uncaught exception. If this `ThreadGroup` object has a parent `ThreadGroup` object, this method just calls the parent's `uncaughtException()` method. Otherwise, this method must determine whether the uncaught exception is an instance of `ThreadDeath`. If it is, nothing is done. If it is not, the method calls the `printStackTrace()` method of the exception object.

If this method is overridden, the overriding method should end with a call to `super.uncaughtException()`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Object

Name

Object

Synopsis

Class Name:

`java.lang.Object`

Superclass:

None

Immediate Subclasses:

Too many to be listed here

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Object` class is the ultimate superclass of all other classes in Java. Because every other class is a subclass of `Object`, all of the methods accessible from `Object` are inherited by every other class. In other words, all objects in Java, including arrays, have access to implementations of the methods in `Object`.

The methods of `Object` provide some basic object functionality. The `equals()` method compares two objects for equality, while the `hashCode()` method returns a hashcode for an object. The `getClass()` method returns the `Class` object associated with an object. The `wait()`, `notify()`, and `notifyAll()` methods support thread synchronization for an object. The `toString()` method provides a string representation of an object.

Some of these methods should be overridden by subclasses of `Object`. For example, every class should provide its own implementation of the `toString()` method, so that it can provide an appropriate string representation.

Although it is possible to create an instance of the `Object` class, this is rarely done because it is more useful to create specialized objects. However, it is often useful to declare a variable that contains a reference to an `Object` because such a variable can contain a reference to an object of any other class.

Class Summary

```
public class java.lang.Object {
    // Constructors
    public Object();
    // Public Instance Methods
    public boolean equals(Object obj);
    public final native Class getClass();
    public native int hashCode();
    public final native void notify();
    public final native void notifyAll();
    public String toString();
    public final native void wait();
    public final native void wait(long millis);
    public final native void wait(long millis, int nanos);
    // Protected Instance Methods
    protected native Object clone();
    protected void finalize() throws Throwable;
}
```

Constructors

Object

`public Object()`

Description

> Creates an instance of the `Object` class.

Public Instance Methods

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Description

The `equals()` method of `Object` returns `true` if the `obj` parameter refers to the same object as the object this method is associated with. This is equivalent to using the `==` operator to compare two objects.

Some classes, such as `String`, override the `equals()` method to provide a comparison based on the contents of the two objects, rather than on the strict equality of the references. Any subclass can override the `equals()` method to implement an appropriate comparison, as long as the overriding method satisfies the following rules for an equivalence relation:

- The method is *reflexive* : given a reference `x`, `x.equals(x)` returns `true`.
- The method is *symmetric* : given references `x` and `y`, `x.equals(y)` returns `true` if and only if `y.equals(x)` returns `true`.
- The method is *transitive* : given references `x`, `y`, and `z`, if `x.equals(y)` returns `true` and `y.equals(z)` returns `true`, then `x.equals(z)` returns `true`.
- The method is *consistent* : given references `x` and `y`, multiple invocations of `x.equals(y)` consistently return `true` or consistently return `false`, provided that no information contained by the objects referenced by `x` or `y` changes.
- A comparison with `null` returns `false`: given a reference `x` that is non-`null`, `x.equals(null)` returns `false`.

getClass

`public final native Class getClass()`

Returns

A reference to the `Class` object that describes the class of this object.

Description

The `getClass()` method of `Object` returns the `Class` object that describes the class of this object. This method is `final`, so it cannot be overridden by subclasses.

hashCode

`public native int hashCode()`

Returns

A relatively unique value that should be the same for all objects that are considered equal.

Description

The `hashCode()` method of `Object` calculates a hashcode value for this object. The method returns an integer value that should be relatively unique to the object. If the `equals()` method for the object bases its result on the contents of the object, the `hashcode()` method should also base its result on the contents. The `hashCode()` method is provided for the benefit of hashtables, which store and retrieve elements using key values called *hashcodes*. The internal placement of a particular piece of data is determined by its hashcode; hashtables are designed to use hashcodes to provide efficient retrieval.

The `java.util.Hashtable` class provides an implementation of a hashtable that stores values of type `Object`. Each object is stored in the hashtable based on the hash code of its key object. It is important that each object have the most unique hash code possible. If two objects have the same hash code but they are not equal (as determined by `equals()`), a `Hashtable` that stores these two objects may need to spend additional time searching when it is trying to retrieve objects. The implementation of `hashCode()` in `Object` tries to make sure that every object has a distinct hash code by basing its result on the internal representation of a reference to the object.

Some classes, such as `String`, override the `hashCode()` method to produce values based on the contents of individual objects, instead of the objects themselves. In other words, two `String` objects that contain the exact same strings have the same hash code. If `String` did not override the `hashCode()` method inherited from `Object`, these two `String` objects would have different hash code values and it would be impossible to use `String` objects as keys for hashtables.

Any subclass can override the `hashCode()` method to implement an appropriate way of producing hash code values, as long as the overriding method satisfies the following rules:

- If the `hashCode()` method is called on the same object more than once during the execution of a Java application, it must consistently return the same integer value. The integer does not, however, need to be consistent between Java applications, or from one execution of an application to another execution of the same application.

- If two objects compare as equal according to their `equals()` methods, calls to the `hashCode()` methods for the objects must produce the same result.

- If two objects compare as not equal according to their `equals()` methods, calls to the `hashCode()` methods for the two objects are not required to produce distinct results. However, implementations of `hashCode()` that produce distinct results for unequal objects may improve the performance of hashtables.

In general, if a subclass overrides the `equals()` method of `Object`, it should also override the `hashCode()` method.

notify

`public final native void notify()`

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

Description

The `notify()` method wakes up a thread that is waiting to return from a call to this object's `wait()` method. The awakened thread can resume executing as soon as it regains this object's lock. If more than one thread is waiting, the `notify()` method arbitrarily awakens just one of the threads.

The `notify()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

notifyAll

`public final native void notifyAll()`

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

Description

The `notifyAll()` method wakes up all the threads that are waiting to return from a call to this object's `wait()` method. Each awakened thread can resume executing as soon as it regains this object's lock.

The `notifyAll()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

toString

`public String toString()`

Returns

The string representation of this object.

Description

The `toString()` method of `Object` returns a generic string representation of this object. The method returns a `String` that consists of the object's class name, an "at" sign, and the unsigned hexadecimal representation of the value returned by the object's `hashCode()` method.

Many classes override the `toString()` method to provide a string representation that is specific to that type of object. Any subclass can override the `toString()` method; the overriding method should simply return a `String` that represents the contents of the object with which it is associated.

wait

`public final native void wait() throws InterruptedException`

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

`InterruptedException`

If another thread interrupted this thread.

Description

The `wait()` method causes a thread to wait until it is notified by another thread to stop waiting. When `wait()` is called, the thread releases its lock on this object and waits until another thread notifies it to wake up through a call to either `notify()` or `notifyAll()`. After the thread is awakened, it has to regain the lock on this object before it can resume executing.

The `wait()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized` `static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

`public final native void wait(long timeout) throws InterruptedException`

Parameters

`timeout`

The maximum number of milliseconds to wait.

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

`InterruptedException`

If another thread interrupted this thread.

Description

The `wait()` method causes a thread to wait until it is notified by another thread to stop waiting or until the specified amount of time has elapsed, whichever comes first. When `wait()` is called, the thread releases its lock on this object and waits until another thread notifies it to wake up through a call to either `notify()` or `notifyAll()`. If the thread is not notified within the specified `timeout` period, it is automatically awakened when that amount of time has elapsed. If `timeout` is zero, the thread waits indefinitely, just as if `wait()` had been called without a `timeout` argument. After the thread is awakened, it has to regain the lock on this object before it can resume executing.

The `wait()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

`public final native void wait(long timeout, int nanos) throws InterruptedException`

Parameters

`timeout`

The maximum number of milliseconds to wait.

`nanos`

An additional number of nanoseconds to wait.

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

`InterruptedException`

If another thread interrupted this thread.

Description

> The `wait()` method causes a thread to wait until it is notified by another thread to stop waiting or until the specified amount of time has elapsed, whichever comes first. When `wait()` is called, the thread releases its lock on this object and waits until another thread notifies it to wake up through a call to either `notify()` or `notifyAll()`. If the thread is not notified within the specified time period, it is automatically awakened when that amount of time has elapsed. If `timeout` and `nanos` are zero, the thread waits indefinitely, just as if `wait()` had been called without any arguments. After the thread is awakened, it has to regain the lock on this object before it can resume executing.
>
> The `wait()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.
>
> Note that Sun's reference implementation of Java does not attempt to implement the precision implied by this method. Instead, it rounds to the nearest millisecond (unless `timeout` is `0`, in which case it rounds up to 1 millisecond) and calls `wait(long)`.
>
> This method is `final`, so it cannot be overridden by subclasses.

Protected Instance Methods

clone

`protected native Object clone() throws CloneNotSupportedException`

Returns

> A clone of this object.

Throws

> `OutOfMemoryError`
>
> > If there is not enough memory to create the new object.
>
> `CloneNotSupportedException`
>
> > If the object is of a class that does not support `clone()`.

Description

> A *clone* of an object is another object of the same type that has all of its instance variables set to the same values as the object being cloned. In other words, a clone is an exact copy of the original object.
>
> The `clone()` method of `Object` creates a new object that is a clone of this object. No constructor is used in creating the clone. The `clone()` method only clones an object if the class of that object indicates that its instances

can be cloned. A class indicates that its objects can be cloned by implementing the `Cloneable` interface.

Although array objects do not implement the `Cloneable` interface, the `clone()` method works for arrays. The clone of an array is an array that has the same number of elements as the original array, and each element in the clone array has the same value as the corresponding element in the original array. Note that if an array element contains an object reference, the clone array contains a reference to the same object, not a copy of the object.

A subclass of `Object` can override the `clone()` method in `Object` to provide any additional functionality that is needed. For example, if an object contains references to other objects, the `clone()` method should recursively call the `clone()` methods of all the referenced objects. An overriding `clone()` method can throw a `CloneNotSupportedException` to indicate that particular objects cannot be cloned.

finalize

`protected void finalize() throws Throwable`

Throws

`Throwable`

For any reason that suits an overriding implementation of this method.

Description

The `finalize()` method is called by the garbage collector when it decides that an object can never be referenced again. The method gives an object a chance to perform any cleanup operations that are necessary before it is destroyed by the garbage collector.

The `finalize()` method of `Object` does nothing. A subclass overrides the `finalize()` method to perform any necessary cleanup operations. The overriding method should call `super.finalize()` as the very last thing it does, so that any `finalize()` method in the superclass is called.

When the garbage collector calls an object's `finalize()` method, the garbage collector does not immediately destroy the object because the `finalize()` method might do something that results in a reference to the object. Thus the garbage collector waits to destroy the object until it can again prove it is safe to do so. The next time the garbage collector decides it is safe to destroy the object, it does so without calling `finalize()` again. In other words, the garbage collector never calls the `finalize()` method more than once for a particular object.

A `finalize()` method can throw any kind of exception. An exception causes the `finalize()` method to stop running. The garbage collector then catches and ignores the exception, so it has no further effect on a program.

System

Name

System

Synopsis

Class Name:

`java.lang.System`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `System` class provides access to various information about the operating system environment in which a program is running. For example, the `System` class defines variables that allow access to the standard I/O streams and methods that allow a program to run the garbage collector and stop the Java virtual machine.

All of the variables and methods in the `System` class are `static`. In other words, it is not necessary to create an instance of the `System` class in order to use its variables and methods. In fact, the `System` class does not define any `public` constructors, so it cannot be instantiated.

The `System` class supports the concept of system properties that can be queried and set. The following properties are guaranteed always to be defined:

Property Name	**Description**
`file.encoding`	The character encoding for the default locale (Java 1.1 only)
`file.encoding.pkg`	The package that contains converters between local encodings and Unicode (Java 1.1 only)
`file.separator`	File separator (`'/'` on UNIX, `' \'` on Windows)
`java.class.path`	The class path
`java.class.version`	Java class version number
`java.compiler`	The just-in-time compiler to use, if any (Java 1.1 only)
`java.home`	Java installation directory
`java.vendor`	Java vendor-specific string
`java.vendor.url`	Java vendor URL
`java.version`	Java version number
`line.separator`	Line separator(`' \n'` on UNIX, `' \r\n'` on Windows)
`os.arch`	Operating system architecture
`os.name`	Operating system name
`os.version`	Operating system version
`path.separator`	Path separator (`':'` on UNIX, `','` on Windows)
`user.dir`	User's current working directory when the properties were initialized
`user.home`	User's home directory
`user.language`	The two-letter language code of the default locale (Java 1.1 only)
`user.name`	User's account name
`user.region`	The two-letter country code of the default locale (Java 1.1 only)
`user.timezone`	The default time zone (Java 1.1 only)

Additional properties may be defined by the run-time environment. The `-D` command-line option can be used to define system properties when a program is run.

The `Runtime` class is related to the `System` class; it provides access to information about the environment in which a program is running.

Class Summary

```
public final class java.lang.System extends java.lang.Object {
    // Constants
    public static final PrintStream err;
    public static final InputStream in;
    public static final PrintStream out;
    // Class Methods
    public static void arraycopy(Object src, int srcOffset,
                                 Object dst, int dstOffset, int length);
    public static long currentTimeMillis();
    public static void exit(int status);
    public static void gc();
    public static Properties getProperties();
    public static String getProperty(String key);
    public static String getProperty(String key, String default);
    public static SecurityManager getSecurityManager();
    public static String getenv(String name);           // Deprecated in 1.1
    public static native int identityHashCode(Object x);   // New in 1.1
    public static void load(String filename);
    public static void loadLibrary(String libname);
    public static void runFinalization();
    public static void runFinalizersOnExit(boolean value); // New in 1.1
    public static void setErr(PrintStream err);            // New in 1.1
    public static void setIn(InputStream in);              // New in 1.1
    public static void setOut(PrintStream out);            // New in 1.1
    public static void setProperties(Properties props);
    public static void setSecurityManager(SecurityManager s);
}
```

Variables

err

`public static final PrintStream err`

Description

> The standard error stream. In an application environment, this variable refers to a `java.io.PrintStream` object that is associated with the standard error output for the process running the Java virtual machine. In an applet environment, the `PrintStream` is likely to be associated with a separate window, although this is not guaranteed.
>
> The value of `err` can be set using the `setErr()` method. The value of `err` can only be set if the

currenly installed `SecurityManager` does not throw a `SecurityException` when the request is made.

Prior to to Java 1.1, `err` was not `final`. It has been made `final` as of Java 1.1 because the unchecked ability to set `err` is a security hole.

in

`public static final InputStream in`

Description

The standard input stream. In an application environment, this variable refers to a `java.io.InputStream` object that is associated with the standard input for the process running the Java virtual machine.

The value of `in` can be set using the `setIn()` method. The value of `in` can only be set if the currenly installed `SecurityManager` does not throw a `SecurityException` when the request is made.

Prior to to Java 1.1, `in` was not `final`. It has been made `final` as of Java 1.1 because the unchecked ability to set `in` is a security hole.

out

`public static final PrintStream out`

Description

The standard output stream. In an application environment, this variable refers to a `java.io.PrintStream` object that is associated with the standard output for the process running the Java virtual machine. In an applet environment, the `PrintStream` is likely to be associated with a separate window, although this is not guaranteed.

`out` is the most commonly used of the three I/O streams provided by the `System` class. Even in GUI-based applications, sending output to this stream can be useful for debugging. The usual idiom for sending output to this stream is:

```
System.out.println("Some text");
```

The value of `out` can be set using the `setOut()` method. The value of `out` can only be set if the currenly installed `SecurityManager` does not throw a `SecurityException` when the request is made.

Prior to to Java 1.1, `out` was not `final`. It has been made `final` as of Java 1.1 because the unchecked ability to set `out` is a security hole.

Class Methods

arraycopy

`public static void arraycopy(Object src, int src_position, Object dst, int dst_position, int length)`

Parameters

`src`

The source array.

`src_position`

An index into the source array.

`dst`

The destination array.

`dst_position`

An index into the destination array.

`length`

The number of elements to be copied.

Throws

`ArrayIndexOutOfBoundsException`

If the values of the `src_position`, `dst_position`, and `length` arguments imply accessing either array with an index that is less than zero or an index greater than or equal to the number of elements in the array.

`ArrayStoreException`

If the type of value stored in the `src` array cannot be stored in the `dst` array.

`NullPointerException`

If `src` or `dst` is `null`.

Description

This method copies a range of array elements from the `src` array to the `dst` array. The number of elements that are copied is specified by `length`. The elements at positions `src_position` through `src_position+length-1` in `src` are copied to the positions `dst_position` through `dst_position+length-1` in `dst`, respectively.

If `src` and `dst` refer to the same array, the copying is done as if the array elements were first copied to a temporary array and then copied to the destination array.

Before this method does any copying, it performs a number of checks. If either `src` or `dst` are `null`, the method throws a `NullPointerException` and `dst` is not modified.

If any of the following conditions are true, the method throws an `ArrayStoreException`, and `dst` is not modified:

- Either `src` or `dst` refers to an object that is not an array.
- `src` and `dst` refer to arrays whose element types are different primitive types.
- `src` refers to an array that has elements that contain a primitive type, while `dst` refers to an array that has elements that contain a reference type, or vice versa.

If any of the following conditions are true, the method throws an `ArrayIndexOutOfBoundsException`, and `dst` is not modified:

- `srcOffset`, `dstOffset`, or `length` is negative.
- `srcOffset+length` is greater than `src.length()`.
- `dstOffset+length` is greater than `dst.length()`.

Otherwise, if an element in the source array being copied cannot be converted to the type of the destination array using the rules of the assignment operator, the method throws an `ArrayStoreException` when the problem occurs. Since the problem is discovered during the copy operation, the state of the `dst` array reflects the incomplete copy operation.

currentTimeMillis

```
public static native long currentTimeMillis()
```

Returns

The current time as the number of milliseconds since 00:00:00 UTC, January 1, 1970.

Description

This method returns the current time as the number of milliseconds since 00:00:00 UTC, January 1, 1970. It will not overflow until the year 292280995.

The `java.util.Date` class provides more extensive facilities for dealing with times and dates.

exit

`public static void exit(int status)`

Parameters

`status`

The exit status code to use.

Throws

`SecurityException`

If the `checkExit()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes the Java virtual machine to exit with the given status code. This method works by calling the `exit()` method of the current `Runtime` object. By convention, a nonzero status code indicates abnormal termination. This method never returns.

gc

`public static void gc()`

Description

This method causes the Java virtual machine to run the garbage collector in the current thread. This method works by calling the `gc()` method of the current `Runtime` object.

The garbage collector finds objects that will never be used again because there are no live references to them. After it finds these objects, the garbage collector frees the storage occupied by these objects.

The garbage collector is normally run continuously in a thread with the lowest possible priority, so that it works intermittently to reclaim storage. The `gc()` method allows a program to invoke the garbage collector explicitly when necessary.

getProperties

`public static Properties getProperties()`

Returns

A `Properties` object that contains the values of all the system properies.

Throws

`SecurityException`

If the `checkPropertiesAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method returns all of the defined system properties encapsulated in a `java.util.Properties` object. If there are no system properties currently defined, a set of default system properties is created and initialized. As discussed in the description of the `System` class, some system properties are guaranteed always to be defined.

getProperty

`public static String getProperty(String key)`

Parameters

`key`

The name of a system property.

Returns

The value of the named system property or `null` if the named property is not defined.

Throws

`SecurityException`

If the `checkPropertyAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method returns the value of the named system property. If there is no definition for the named property, the method returns `null`. If there are no system properties currently defined, a set of default system properties is created and initialized. As discussed in the description of the `System` class, some system properties are guaranteed always to be defined.

`public static String getProperty(String key, String def)`

Parameters

`key`

The name of a system property.

`def`

A default value for the property.

Returns

The value of the named system property, or the default value if the named property is not defined.

Throws

`SecurityException`

If the `checkPropertyAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method returns the value of the named system property. If there is no definition for the named property, the method returns the default value as specified by the `def` parameter. If there are no system properties currently defined, a set of default system properties is created and initialized. As discussed earlier in the description of the `System` class, some system properties are guaranteed to always be defined.

getSecurityManager

`public static SecurityManager getSecurityManager()`

Returns

A reference to the installed `SecurityManager` object or `null` if there is no `SecurityManager` object installed.

Description

This method returns a reference to the installed `SecurityManager` object. If there is no `SecurityManager` object installed, the method returns `null`.

getenv

`public static String getenv(String name)`

Availability

Deprecated as of JDK 1.1

Parameters

`name`

The name of a system-dependent environment variable.

Returns

The value of the environment variable or `null` if the variable is not defined.

Description

This method is obsolete; it always throws an error. Use `getProperties()` and the `-D` option instead.

identityHashCode

`public static native int identityHashCode(Object x)`

Availability

New as of JDK 1.1

Parameters

`x`

An object.

Returns

The identity hashcode value for the specified object.

Description

This method returns the same hashcode value for the specified object as would be returned by the default `hashCode()` method of `Object`, regardless of whether or not the object's class overrides `hashCode()`.

load

`public void load(String filename)`

Parameters

`filename`

A string that specifies the complete path of the file to be loaded.

Throws

`SecurityException`

If the `checkLink()` method of the `SecurityManager` throws a `SecurityException`.

`UnsatisfiedLinkError`

If the method is unsuccessful in loading the specified dynamically linked library.

Description

This method loads the specified dynamically linked library. This method works by calling the `load()` method of the current `Runtime` object.

loadLibrary

`public void loadLibrary(String libname)`

Parameters

`libname`

A string that specifies the name of a dynamically linked library.

Throws

`SecurityException`

If the `checkLink()` method of the `SecurityManager` throws a `SecurityException`.

`UnsatisfiedLinkError`

If the method is unsuccessful in loading the specified dynamically linked library.

Description

This method loads the specified dynamically linked library. It looks for the specified library in a platform-specific way. This method works by calling the `loadLibrary()` method of the current `Runtime` object.

runFinalization

`public static void runFinalization()`

Description

This method causes the Java virtual machine to run the `finalize()` methods of any objects in the finalization queue in the current thread. This method works by calling the `runFinalization()` method of the current `Runtime` object.

When the garbage collector discovers that there are no references to an object, it checks to see if the object has a `finalize()` method that has never been called. If the object has such a `finalize()` method, the object is placed in the finalization queue. While there is a reference to the object in the finalization queue, the object is no longer considered garbage collectable.

Normally, the objects in the finalization queue are handled by a separate finalization thread that runs continuously at a very low priority. The finalization thread removes an object from the queue and calls its `finalize()` method. As long as the `finalize()` method does not generate a reference to the object, the object again becomes available for garbage collection.

Because the finalization thread runs at a very low priority, there may be a long delay from the time that an object is put on the finalization queue until the time that its `finalize()` method is called. The runFinalization() method allows a program to run the finalize() methods explicitly. This can be useful when there is a shortage of some resource that is released by a finalize() method.

runFinalizersOnExit

public static void runFinalizersOnExit(boolean value)

Availability

New as of JDK 1.1

Parameters

value

A boolean value that specifies whether or not finalization occurs on exit.

Throws

SecurityException

If the checkExit() method of the SecurityManager throws a SecurityException.

Description

This method specifies whether or not the finalize() methods of all objects that have finalize() methods are run before the Java virtual machine exits. By default, the finalizers are not run on exit. This method works by calling the runFinalizersOnExit() method of the current Runtime object.

setErr

public static void setErr(PrintStream err)

Availability

New as of JDK 1.1

Parameters

err

A PrintStream object to use for the standard error stream.

Throws

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the standard error stream to be this `PrintStream` object.

setIn

`public static void setIn(InputStream in)`

Availability

New as of JDK 1.1

Parameters

`in`

A `InputStream` object to use for the standard input stream.

Throws

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the standard input stream to be this `InputStream` object.

setOut

`public static void setOut(PrintStream out)`

Availability

New as of JDK 1.1

Parameters

`out`

A `PrintStream` object to use for the standard output stream.

Throws

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the standard output stream to be this `PrintStream` object.

setProperties

`public static void setProperties(Properties props)`

Parameters

`props`

A reference to a `Properties` object.

Throws

`SecurityException`

If the `checkPropertiesAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method replaces the current set of system property definitions with a new set of system property definitions that are encapsulated by the given `Properties` object. As discussed in the description of the `System` class, some system properties are guaranteed to always be defined.

setSecurityManager

`public static void setSecurityManager(SecurityManager s)`

Parameters

`s`

A reference to a `SecurityManager` object.

Throws

`SecurityException`

If a `SecurityManager` object has already been installed.

Description

This method installs the given `SecurityManager` object. If `s` is `null`, then no `SecurityManager` object is installed. Once a `SecurityManager` object is installed, any subsequent calls to this method throw a `SecurityException`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

28.22 java.net.URL (JDK 1.0)

This class represents a URL (a Uniform Resource Locator) and allows the data referred to by the URL to be downloaded. A URL may be specified as a single string or with separate protocol, host, port, and file specifications. Relative URLs may also be specified with a `String` and the `URL` object that it is relative to.

`getFile()`, `getHost()`, `getPort()`, `getProtocol()`, and `getRef()` return the various portions of the URL specified by a `URL` object. `sameFile()` determines whether a `URL` object refers to the same file as this one.

The data or object referred to by a URL may be downloaded from the Internet in three ways: through a `URLConnection` created with `openConnection()`, through an `InputStream` created by `openStream()`, or through `getContent()`, which returns the URL contents directly, if an appropriate `ContentHandler` can be found.

```
public final class URL extends Object implements Serializable {
    // Public Constructors
            public URL(String protocol, String host, int port, String file) throws 
MalformedURLException;
            public URL(String protocol, String host, String file) throws 
MalformedURLException;
            public URL(String spec) throws MalformedURLException;
            public URL(URL context, String spec) throws MalformedURLException;
    // Class Methods
            public static synchronized void 
setURLStreamHandlerFactory(URLStreamHandlerFactory fac);
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
            public final Object getContent() throws IOException;
            public String getFile();
            public String getHost();
            public int getPort();
            public String getProtocol();
            public String getRef();
            public int hashCode();  // Overrides Object
            public URLConnection openConnection() throws IOException;
            public final InputStream openStream() throws IOException;
            public boolean sameFile(URL other);
            public String toExternalForm();
            public String toString();  // Overrides Object
    // Protected Instance Methods
            protected void set(String protocol, String host, int port, String file, 
String ref);
}
```

28.26 java.net.URLStreamHandlerFactory (JDK 1.0)

This interface defines a method that creates a `URLStreamHandler` object for a specified protocol.

Normal applications never need to use or implement this interface.

```
public abstract interface URLStreamHandlerFactory {
    // Public Instance Methods
            public abstract URLStreamHandler createURLStreamHandler(String protocol);
}
```

Passed To:

URL.setURLStreamHandlerFactory()

13. Java Syntax

Contents:

13.1 Primitive Data Types

Java supports a complete set of primitive data types, listed in Table 13.1. In Java, the size of each type is defined by the language, and is *not* implementation dependent, as it is in C.

Table 13.1: Java Primitive Data Types

				Min Value
Type	**Contains**	**Default**	**Size**	**Max Value**
boolean	`true` or `false`	`false`	1 bit	N.A.
				N.A.
char	Unicode character	`\u0000`	16 bits	`\u0000`
				`\uFFFF`
byte	signed integer	`0`	8 bits	-128
				127
short	signed integer	`0`	16 bits	-32768
				32767

int	signed integer	`0`	32 bits	-2147483648
				2147483647
long	signed integer	`0`	64 bits	-9223372036854775808
				9223372036854775807
float	IEEE 754	`0.0`	32 bits	+/-3.40282347E+38
	floating-point			+/-1.40239846E-45
double	IEEE 754	`0.0`	64 bits	+/-1.79769313486231570E+308

Character Escape Sequences

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

String

Name

String

Synopsis

Class Name:

`java.lang.String`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `String` class represents sequences of characters. Once a `String` object is created, it is immutable. In other words, the sequence of characters that a `String` represents cannot be changed after it is created. The `StringBuffer` class, on the other hand, represents a sequence of characters that can be changed. `StringBuffer` objects are used to perform computations on `String` objects.

The `String` class includes a number of utility methods, such as methods for fetching individual characters or ranges of contiguous characters, for translating characters to upper- or lowercase, for searching strings, and for parsing numeric values in strings.

`String` literals are compiled into `String` objects. Where a `String` literal appears in an expression, the compiled code contains a `String` object. If `s` is declared as `String`, the following two expressions are identical:

```
s.equals("ABC")
"ABC".equals(s)
```

The string concatenation operator implicitly creates `String` objects.

Class Summary

```
public final class java.lang.String extends java.lang.Object {
    // Constructors
    public String();
    public String(byte[] bytes);                          // New in 1.1
    public String(byte[] bytes, String enc);              // New in 1.1
    public String(byte[] bytes, int offset, int length);  // New in 1.1
    public String(byte[] bytes, int offset,
                  int length, String enc);                // New in 1.1
    public String(byte[] lowbytes, int hibyte);        // Deprecated in 1.1
    public String(byte[] lowbytes, int hibyte,
                  int offset, int count);              // Deprecated in 1.1
    public String(char[] value);
    public String(char[] value, int offset, int;
    public String(String value);
    public String(StringBuffer buffer);
    // Class Methods
    public static String copyValueOf(char data[]);
    public static String copyValueOf(char data[], int offset, int count);
    public static String valueOf(boolean b);
    public static String valueOf(char c);
    public static String valueOf(char[] data);
    public static String valueOf(char[] data, int offset, int count);
    public static String valueOf(double d);
    public static String valueOf(float f);
    public static String valueOf(int i);
    public static String valueOf(long l);
    public static String valueOf(Object obj);
    // Instance Methods
    public char charAt(int index);
    public int compareTo(String anotherString);
    public String concat(String str);
    public boolean endsWith(String suffix);
    public boolean equals(Object anObject);
    public boolean equalsIgnoreCase(String anotherString);
    public byte[] getBytes();                               // New in 1.1
    public byte[] getBytes(String enc);                     // New in 1.1
    public void getBytes(int srcBegin, int srcEnd,
                         byte[] dst, int dstBegin);     // Deprecated in 1.1
    public void getChars(int srcBegin, int srcEnd, char[] dst, int dstBegin);
    public int hashCode();
    public int indexOf(int ch);
    public int indexOf(int ch, int fromIndex);
    public int indexOf(String str);
    public int indexOf(String str, int fromIndex);
    public native String intern();
    public int lastIndexOf(int ch);
    public int lastIndexOf(int ch, int fromIndex);
    public int lastIndexOf(String str);
    public int lastIndexOf(String str, int fromIndex;
    public int length();
    public boolean regionMatches(boolean ignoreCase, int toffset,
                                 String other, int ooffset, int len);
    public boolean regionMatches(int toffset, String other,
                                 int ooffset, int len);
    public String replace(char oldChar, char newChar);
    public boolean startsWith(String prefix);
    public boolean startsWith(String prefix, int toffset);
    public String substring(int beginIndex);
    public String substring(int beginIndex, int endIndex);
    public char[] toCharArray();
    public String toLowerCase();
    public String toLowerCase(Locale locale);               // New in 1.1
    public String toString();
    public String toUpperCase();
    public String toUpperCase(Locale locale);               // New in 1.1
    public String trim();
}
```

Constructors

String

`public String()`

Description

Creates a new `String` object that represents the empty string (i.e., a string with zero characters).

`public String(byte[] bytes)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

Description

Creates a new `String` object that represents the sequence of characters stored in the given `bytes` array. The bytes in the array are converted to characters using the system's default character encoding scheme.

`public String(byte[] bytes, String enc)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

`enc`

The name of an encoding scheme.

Throws

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

Creates a new `String` object that represents the sequence of characters stored in the given `bytes` array. The bytes in the array are converted to characters using the specified character encoding scheme.

`public String(byte[] bytes, int offset, int length)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

`offset`

An offset into the array.

`length`

The number of bytes to be included.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `length` indexes an element that is outside the bounds of the `bytes` array.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the given `bytes` array. The bytes in the array are converted to characters using the system's default character encoding scheme.

`public String(byte[] bytes, int offset, int length, String enc)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

`offset`

An offset into the array.

`length`

The number of bytes to be included.

`enc`

The name of an encoding scheme.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `length` indexes an element that is outside the bounds of the `bytes` array.

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the given `bytes` array. The bytes in the array are converted to characters using the specified character encoding scheme.

`public String(byte[] lowbytes, int hibyte)`

Availability

Deprecated as of JDK 1.1

Parameters

`lowbytes`

An array of `byte` values.

`hibyte`

The value to be put in the high-order byte of each 16-bit character.

Description

Creates a new `String` object that represents the sequence of characters stored in the given `lowbytes` array. The type of the array elements is `byte`, which is an 8-bit data type, so each element must be converted to a `char`, which is a 16-bit data type. The value of the `hibyte` argument is used to provide the value of the high-order byte when the `byte` values in the array are converted to `char` values.

More specifically, for each element `i` in the array `lowbytes`, the character at position `i` in the created `String` object is:

```
((hibyte & 0xff)<<8) | lowbytes[i]
```

This method is deprecated as of JDK 1.1 because it does not convert bytes into characters properly. You should instead use one of the constructors that takes a specific character encoding argument or that uses the default encoding.

`public String(byte[] lowbytes, int hibyte, int offset, int count)`

Availability

Deprecated as of JDK 1.1

Parameters

`lowbytes`

An array of `byte` values.

`hibyte`

The value to be put in the high-order byte of each 16-bit character.

`offset`

An offset into the array.

`count`

The number of bytes from the array to be included in the string.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `lowbytes` array.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the `lowbytes` array. That is, the portion of the array that starts at `offset` elements from the beginning of the array and is `count` elements long.

The type of the array elements is `byte`, which is an 8-bit data type, so each element must be converted to a `char`, which is a 16-bit data type. The value of the `hibyte` argument is used to provide the value of the high-order byte when the `byte` values in the array are converted to `char` values.

More specifically, for each element `i` in the array `lowbytes` that is included in the `String` object, the character at position `i` in the created `String` is:

```
 ((hibyte & 0xff)<<8) | lowbytes[I]
```

This method is deprecated as of JDK 1.1 because it does not convert bytes into characters properly. You should instead use one of the constructors that takes a specific character encoding argument or that uses the default encoding.

`public String(char[] value)`

Parameters

`value`

An array of `char` values.

Description

Creates a new `String` object that represents the sequence of characters stored in the given array.

`public String(char[] value, int offset, int count)`

Parameters

`value`

An array of `char` values.

`offset`

An offset into the array.

`count`

The number of characters from the array to be included in the string.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `value` array.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the given array. That is, the portion of the given array that starts at `offset` elements from the beginning of the array and is `count` elements long.

`public String(String value)`

Parameters

`value`

A `String` object.

Description

Creates a new `String` object that represents the same sequence of characters as the given `String` object.

`public String(StringBuffer value)`

Parameters

`value`

A `StringBuffer` object.

Description

Creates a new `String` object that represents the same sequence of characters as the given object.

Class Methods

copyValueOf

`public static String copyValueOf(char data[])`

Parameters

`data`

An array of `char` values.

Returns

A new `String` object that represents the sequence of characters stored in the given array.

Description

This method returns a new `String` object that represents the character sequence contained in the given array. The `String` object produced by this method is guaranteed not to refer to the given array, but instead to use a copy. Because the `String` object uses a copy of the array, subsequent changes to the array do not change the contents of this `String` object.

This method is now obsolete. The same result can be obtained using the `valueOf()` method that takes an array of `char` values.

`public static String copyValueOf(char data[], int offset, int count)`

Parameters

`data`

An array of `char` values.

`offset`

An offset into the array.

`count`

The number of characters from the array to be included in the string.

Returns

A new `String` object that represents the sequence of characters stored in the specified portion of the given array.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `data` array.

Description

This method returns a new `String` object that represents the character sequence contained in the specified portion of the given array. That is, the portion of the given array that starts at `offset` elements from the beginning of the array and is `count` elements long. The `String` object produced by this method is guaranteed not to refer to the given array, but instead to use a copy. Because the `String` object uses a copy of the array, subsequent changes to the array do not change the contents of this `String` object.

This method is obsolete. The same result can be obtained by using the `valueOf()` method that takes an array of `char` values, an offset, and a count.

valueOf

`public static String valueOf(boolean b)`

Parameters

`b`

A `boolean` value.

Returns

A new `String` object that contains `'true'` if `b` is `true` or `'false'` if `b` is `false`.

Description

This method returns a string representation of a `boolean` value. In other words, it returns `'true'` if `b` is `true` or `'false'` if `b` is `false`.

`public static String valueOf(char c)`

Parameters

`c`

A `char` value.

Returns

A new `String` object that contains just the given character.

Description

This method returns a string representation of a `char` value. In other words, it returns a `String` object that contains just the given character.

`public static String valueOf(char[] data)`

Parameters

`data`

An array of `char` values.

Returns

A new `String` object that contains the sequence of characters stored in the given array.

Description

This method returns a string representation of an array of `char` values. In other words, it returns a `String` object that contains the sequence of characters stored in the given array.

`public static String valueOf(char[] data, int offset, int count)`

Parameters

`data`

An array of `char` values.

`offset`

An offset into the array.

`count`

The number of characters from the array to be included in the string.

Returns

A new `String` object that contains the sequence of characters stored in the specified portion of the given array.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `data` array.

Description

This method returns a string representation of the specified portion of an array of char values. In other words, it returns a `String` object that contains the sequence of characters in the given array that starts `offset` elements from the beginning of the array and is `count` elements long.

`public static String valueOf(double d)`

Parameters

`d`

A `double` value.

Returns

A new `String` object that contains a string representation of the given `double` value.

Description

This method returns a string representation of a `double` value. In other words, it returns the `String` object returned by `Double.toString(d)`.

`public static String valueOf(float f)`

Parameters

`f`

A `float` value.

Returns

A new `String` object that contains a string representation of the given `float` value.

Description

This method returns a string representation of a `float` value. In other words, it returns the `String` object returned by `Float.toString(f)`.

`public static String valueOf(int i)`

Parameters

`i`

An `int` value.

Returns

A new `String` object that contains a string representation of the given `int` value.

Description

This method returns a string representation of an `int` value. In other words, it returns the `String` object returned by `Integer.toString(i)`.

`public static String valueOf(long l)`

Parameters

`l`

A `long` value.

Returns

A new `String` object that contains a string representation of the given `long` value.

Description

This method returns a string representation of a `long` value. In other words, it returns the `String` object returned by `Long.toString(l)`.

`public static String valueOf (Object obj)`

Parameters

`obj`

A reference to an object.

Returns

A new `String` that contains a string representation of the given object.

Description

This method returns a string representation of the given object. If `obj` is `null`, the method returns`'null'`. Otherwise, the method returns the `String` object returned by the `toString()` method of the object.

Instance Methods

charAt

`public char charAt(int index)`

Parameters

`index`

An index into the string.

Returns

The character at the specified position in this string.

Throws

`StringIndexOutOfBoundsException`

If `index` is less than zero or greater than or equal to the length of the string.

Description

This method returns the character at the specified position in the `String` object; the first character in the string is at position `0`.

compareTo

`public int compareTo(String anotherString)`

Parameters

`anotherString`

The `String` object to be compared.

Returns

A positive value if this string is greater than `anotherString`, `0` if the two strings are the same, or a negative value if this string is less than `anotherString`.

Description

This method lexicographically compares this `String` object to `anotherString`.

Here is how the comparison works: the two `String` objects are compared character-by-character, starting at index `0` and continuing until a position is found in which the two strings contain different characters or until all of the characters in the shorter string have been compared. If the characters at `k` are different, the method returns:

```
this.charAt(k)-anotherString.charAt(k)
```

Otherwise, the comparison is based on the lengths of the strings and the method returns:

```
this.length()-anotherString.length()
```

concat

`public String concat(String str)`

Parameters

`str`

The `String` object to be concatenated.

Returns

A new `String` object that contains the character sequences of this string and `str` concatenated together.

Description

This method returns a new `String` object that concatenates the characters from the argument string `str` onto the characters from this `String` object. Although this is a good way to concatenate two strings, concatenating more than two strings can be done more efficiently using a `StringBuffer` object.

endsWith

`public boolean endsWith(String suffix)`

Parameters

`suffix`

The `String` object suffix to be tested.

Returns

`true` if this string ends with the sequence of characters specified by `suffix`; otherwise `false`.

Description

This method determines whether or not this `String` object ends with the specified `suffix`.

equals

`public boolean equals(Object anObject)`

Parameters

`anObject`

The `Object` to be compared.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `anObject` is an instance of `String` and it contains the same sequence of characters as this `String` object.

Note the difference between this method and the `==` operator, which only returns `true` if both of its arguments are references to the same object.

equalsIgnoreCase

`public boolean equalsIgnoreCase(String anotherString)`

Parameters

`anotherString`

The `String` object to be compared.

Returns

`true` if the strings are equal, ignoring case; otherwise `false`.

Description

This method determines whether or not this `String` object contains the same sequence of characters, ignoring case, as `anotherString`. More specifically, corresponding characters in the two strings are considered equal if any of the following conditions are true:

- The two characters compare as equal using the `==` operator.
- The `Character.toUppercase()` method returns the same result for both characters.
- The `Character.toLowercase()` method returns the same result for both characters.

getBytes

`public byte[] getBytes()`

Availability

New as of JDK 1.1

Returns

A `byte` array that contains the characters of this `String`.

Description

This method converts the characters in this `String` object to an array of `byte` values. The characters in the string are converted to bytes using the system's default character encoding scheme.

`public byte[] getBytes(String enc)`

Availability

New as of JDK 1.1

Parameters

`enc`

The name of an encoding scheme.

Returns

A `byte` array that contains the characters of this `String`.

Throws

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

This method converts the characters in this `String` object to an array of `byte` values. The characters in the string are converted to bytes using the specified character encoding scheme.

`public void getBytes(int srcBegin, int srcEnd, byte[] dst, int dstBegin)`

Availability

Deprecated as of JDK 1.1

Parameters

`srcBegin`

The index of the first character to be copied.

`srcEnd`

The index after the last character to be copied.

`dst`

The destination `byte` array.

`dstBegin`

An offset into the destination array.

Throws

`StringIndexOutOfBoundsException`

If `srcBegin`, `srcEnd`, or `dstBegin` is out of range.

Description

This method copies the low-order byte of each character in the specified range of this `String` object to the given array of `byte` values. More specifically, the first character to be copied is at index `srcBegin`; the last character to be copied is at index `srcEnd-1`. The low-order bytes of these characters are copied into `dst`, starting at index `dstBegin` and ending at index:

```
dstBegin + (srcEnd-srcBegin) - 1
```

This method is deprecated as of JDK 1.1 because it does not convert characters into bytes properly. You should instead use the `getBytes()` method that takes a specific character encoding argument or the one that uses the default encoding.

getChars

```
public void getChars(int srcBegin, int srcEnd, char[] dst, int dstBegin)
```

Parameters

`srcBegin`

The index of the first character to be copied.

`srcEnd`

The index after the last character to be copied.

`dst`

The destination `char` array.

`dstBegin`

An offset into the destination array.

Throws

`StringIndexOutOfBoundsException`

If `srcBegin`, `srcEnd`, or `dstBegin` is out of range.

Description

This method copies each character in the specified range of this `String` object to the given array of `char` values. More specifically, the first character to be copied is at index `srcBegin`; the last character to be copied is at index `srcEnd-1`. These characters are copied into `dst`, starting at index `dstBegin` and ending at index:

```
dstBegin + (srcEnd-srcBegin) - 1
```

hashCode

`public int hashCode()`

Returns

A hashcode based on the sequence of characters in this string.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode based on the sequence of characters this `String` object represents.

More specifically, one of two algorithms is used to compute a hash code for the string, depending on its length. If *n* is the length of the string and *S_i* is the character at position *i* in the string, then if *n* = 15 the method returns:

If *n* > 15, the method returns:

indexOf

`public int indexOf(int ch)`

Parameters

`ch`

A `char` value.

Returns

The index of the first occurrence of the given character in this string or `-1` if the character does not occur.

Description

This method returns the index of the first occurrence of the given character in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int indexOf(int ch, int fromIndex)`

Parameters

`ch`

A `char` value.

`fromIndex`

The index where the search is to begin.

Returns

The index of the first occurrence of the given character in this string after `fromIndex` or `-1` if the character does not occur.

Description

This method returns the index of the first occurrence of the given character in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

`public int indexOf(String str)`

Parameters

`str`

A `String` object.

Returns

The index of the first occurrence of `str` in this string or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the first occurrence of the substring `str` in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int indexOf(String str, int fromIndex)`

Parameters

`str`

A `String` object.

`fromIndex`

The index where the search is to begin.

Returns

The index of the first occurrence of `str` in this string after `fromIndex` or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the first occurrence of the substring `str` in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

intern

`public native String intern()`

Returns

A `String` object that is guaranteed to be the same object for every `String` that contains the same character sequence.

Description

This method returns a canonical representation for this `String` object. The returned `String` object is guaranteed to be the same `String` object for every `String` object that contains the same character sequence. In other words, if:

```
s1.equals(s2)
```

then:

```
s1.intern() == s2.intern()
```

The `intern`() method is used by the Java environment to ensure that `String` literals and constant-value `String` expressions that contain the same sequence of characters are all represented by a single `String` object.

lastIndexOf

`public int lastIndexOf(int ch)`

Parameters

`ch`

A `char` value.

Returns

The index of the last occurrence of the given character in this string or `-1` if the character does not occur.

Description

This method returns the index of the last occurrence of the given character in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int lastIndexOf(int ch, int fromIndex)`

Parameters

`ch`

A `char` value.

`fromIndex`

The index where the search is to begin.

Returns

The index of the last occurrence of the given character in this string after `fromIndex` or `-1` if the character does not occur.

Description

This method returns the index of the last occurrence of the given character in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

`public int lastIndexOf(String str)`

Parameters

`str`

A `String` object.

Returns

The index of the last occurrence of `str` in this string or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the last occurrence of the substring `str` in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int lastIndexOf(String str, int fromIndex)`

Parameters

`str`

A `String` object.

`fromIndex`

The index where the search is to begin.

Returns

The index of the last occurrence of `str` in this string after `fromIndex` or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the last occurrence of the substring `str` in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

length

`public int length()`

Returns

The length of the character sequence represented by this string.

Description

This method returns the number of characters in the character sequence represented by this `String` object.

regionMatches

`public boolean regionMatches(int toffset, String other, int ooffset, int len)`

Parameters

`toffset`

The index of the first character in this string.

`other`

The `String` object to be used in the comparison.

`ooffset`

The index of the first character in `other`.

`len`

The length of the sub-sequences to be compared.

Returns

`true` if the sub-sequences are identical; otherwise `false`.

Description

This method determines whether or not the specified sub-sequences in this `String` object and `other` are identical. The method returns false if `toffset` is negative, if `ooffset` is negative, if `toffset+len` is greater than the length of this string, or if `ooffset+len` is greater than the length of `other`. Otherwise, the method returns `true` if for all nonnegative integers `k` less than `len` it is true that:

```
this.charAt(toffset+k) == other.charAt(ooffset+k)
```

public boolean regionMatches(boolean ignoreCase, int toffset, String other, int ooffset, int len)

Parameters

`ignoreCase`

A `boolean` value that indicates whether case should be ignored.

`toffset`

The index of the first character in this string.

`other`

The `String` object to be used in the comparison.

`ooffset`

The index of the first character in `other`.

`len`

The length of the sub-sequences to be compared.

Returns

`true` if the sub-sequences are identical; otherwise `false`. The `ignoreCase` argument controls whether or not case is ignored in the comparison.

Description

This method determines whether or not the specified sub-sequences in this `String` object and `other` are identical. The method returns false if `toffset` is negative, if `ooffset` is negative, if `toffset+len` is greater than the length of this string, or if `ooffset+len` is greater than the length of `other`. Otherwise, if `ignoreCase` is `false`, the method returns `true` if for all nonnegative integers `k` less than `len` it is true that:

```
this.charAt(toffset+k) == other.charAt(ooffset+k)
```

If `ignoreCase` is `true`, the method returns `true` if for all nonnegative integers `k` less than `len` it is true that:

```
Character.toLowerCase(this.charAt(toffset+k))
== Character.toLowerCase(other.charAt(ooffset+k))
```

or:

```
Character.toUpperCase(this.charAt(toffset+k))
== Character.toUpperCase(other.charAt(ooffset+k))
```

replace

`public String replace(char oldChar, char newChar)`

Parameters

`oldChar`

The character to be replaced.

`newChar`

The replacement character.

Returns

A new `String` object that results from replacing every occurrence of `oldChar` in the string with `newChar`.

Description

This method returns a new `String` object that results from replacing every occurrence of `oldChar` in this `String` object with `newChar`. If there are no occurrences of `oldChar`, the method simply returns this `String` object.

startsWith

`public boolean startsWith(String prefix)`

Parameters

`prefix`

The `String` object prefix to be tested.

Returns

`true` if this string begins with the sequence of characters specified by `prefix`; otherwise `false`.

Description

This method determines whether or not this `String` object begins with the specified `prefix`.

`public boolean startsWith(String prefix, int toffset)`

Parameters

`prefix`

The `String` object prefix to be tested.

`toffset`

The index where the search is to begin.

Returns

`true` if this string contains the sequence of characters specified by `prefix` starting at the index `toffset`; otherwise `false`.

Description

This method determines whether or not this `String` object contains the specified `prefix` at the index specified by `toffset`.

substring

`public String substring(int beginIndex)`

Parameters

`beginIndex`

The index of the first character in the substring.

Returns

A new `String` object that contains the sub-sequence of this string that starts at `beginIndex` and extends to the end of the string.

Throws

`StringIndexOutOfBoundsException`

If `beginIndex` is less than zero or greater than or equal to the length of the string.

Description

This method returns a new `String` object that represents a sub-sequence of this `String` object. The sub-sequence consists of the characters starting at `beginIndex` and extending through the end of this `String` object.

`public String substring(int beginIndex, int endIndex)`

Parameters

`beginIndex`

The index of the first character in the substring.

`endIndex`

The index after the last character in the substring.

Returns

A new `String` object that contains the sub-sequence of this string that starts at `beginIndex` and extends to the character at `endindex-1`.

Throws

`StringIndexOutOfBoundsException`

If `beginIndex` or `endIndex` is less than zero or greater than or equal to the length of the string.

Description

This method returns a new `String` object that represents a sub-sequence of this `String` object. The sub-sequence consists of the characters starting at `beginIndex` and extending through `endIndex-1` of this `String` object.

toCharArray

`public char[] toCharArray()`

Returns

A new `char` array that contains the same sequence of characters as this string.

Description

This method returns a new `char` array that contains the same sequence of characters as this `String`object. The length of the array is the same as the length of this `String` object.

toLowerCase

`public String toLowerCase()`

Returns

A new `String` object that contains the characters of this string converted to lowercase.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its lowercase equivalent if it has one. If no character in the string has a lowercase equivalent, the method returns this `String` object.

`public String toLowerCase(Locale locale)`

Availability

New as of JDK 1.1

Parameters

`locale`

The `Locale` to use.

Returns

A new `String` object that contains the characters of this string converted to lowercase using the rules of the specified locale.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its lowercase equivalent if it has one according to the rules of the specified locale. If no character in the string has a lowercase equivalent, the method returns this `String` object.

toString

`public String toString()`

Returns

This `String` object.

Overrides

`Object.toString()`

Description

This method returns this `String` object.

toUpperCase

`public String toUpperCase()`

Returns

A new `String` object that contains the characters of this string converted to uppercase.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its uppercase equivalent if it has one. If no character in the string has an uppercase equivalent, the method returns this `String` object.

`public String toUpperCase(Locale locale)`

Availability

New as of JDK 1.1

Parameters

`locale`

The `Locale` to use.

Returns

A new `String` object that contains the characters of this string converted to uppercase using the rules of the specified locale.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its uppercase equivalent if it has one according to the rules of the specified locale. If no character in the string has an uppercase equivalent, the method returns this `String` object.

trim

`public String trim()`

Returns

A new `String` object that represents the same character sequence as this string, but with leading and trailing whitespace and control characters removed.

Description

If the first and last character in this `String` object are greater than `'\u0020'` (the space character), the method returns this `String` object. Otherwise, the method returns a new `String` object that contains the same character sequence as this `String` object, but with leading and trailing characters that are less than `'\u0020''` removed.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`

StringBuffer

Name

StringBuffer

Synopsis

Class Name:

```
java.lang.StringBuffer
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

```
java.io.Serializable
```

Availability:

JDK 1.0 or later

Description

The `StringBuffer` class represents a variable-length sequence of characters. `StringBuffer` objects are used in computations that involve creating new `String` objects. The `StringBuffer` class provides a number of utility methods for working with StringBuffer objects, including append() and insert() methods that add characters to a StringBuffer and methods that fetch the contents of StringBuffer objects.

When a StringBuffer object is created, the constructor determines the initial contents and capacity of the StringBuffer. The capacity of a StringBuffer is the number of characters that its internal data structure can hold. This is distinct from the length of the contents of a StringBuffer, which is the number of characters that are actually stored in the StringBuffer object. The capacity of a StringBuffer can vary. When a StringBuffer object is asked to hold more characters than its current capacity allows, the StringBuffer enlarges its internal data structure. However, it is more costly in terms of execution time and memory when a StringBuffer has to repeatedly increase its capacity than when a StringBuffer object is created with sufficient capacity.

Because the intended use of StringBuffer objects involves modifying their contents, all methods of the StringBuffer class that modify StringBuffer objects are synchronized. This means that is it safe for multiple threads to try to modify a StringBuffer object at the same time.

StringBuffer objects are used implicitly by the string concatenation operator. Consider the following code:

```
String s, s1, s2;
s = s1 + s2;
```

To compute the string concatenation, the Java compiler generates code like:

```
s = new StringBuffer().append(s1).append(s2).toString();
```

Class Summary

```
public class java.lang.StringBuffer extends java.lang.Object {
    // Constructors
    public StringBuffer();
    public StringBuffer(int length);
    public StringBuffer(String str);
    // Instance Methods
    public StringBuffer append(boolean b);
    public synchronized StringBuffer append(char c);
    public synchronized StringBuffer append(char[] str);
    public synchronized StringBuffer append(char[] str, int offset, int len);
    public StringBuffer append(double d);
    public StringBuffer append(float f);
    public StringBuffer append(int i);
    public StringBuffer append(long l);
    public synchronized StringBuffer append(Object obj);
    public synchronized StringBuffer append(String str);
    public int capacity();
    public synchronized char charAt(int index);
    public synchronized void ensureCapacity(int minimumCapacity);
    public synchronized void getChars(int srcBegin, int srcEnd,
                             char[] dst, int dstBegin);
    public StringBuffer insert(int offset, boolean b);
    public synchronized StringBuffer insert(int offset, char c);
    public synchronized StringBuffer insert(int offset, char[] str);
    public StringBuffer insert(int offset, double d);
    public StringBuffer insert(int offset, float f);
    public StringBuffer insert(int offset, int i);
    public StringBuffer insert(int offset, long l);
    public synchronized StringBuffer insert(int offset, Object obj);
    public synchronized StringBuffer insert(int offset, String str);
    public int length();
    public synchronized StringBuffer reverse();
    public synchronized void setCharAt(int index, char ch);
    public synchronized void setLength(int newLength);
    public String toString();
}
```

Constructors

StringBuffer

`public StringBuffer()`

Description

> Creates a `StringBuffer` object that does not contain any characters and has a capacity of 16 characters.

`public StringBuffer(int capacity)`

Parameters

> `capacity`
>
> > The initial capacity of this `StringBufffer` object.

Throws

> `NegativeArraySizeException`
>
> > If `capacity` is negative.

Description

Creates a `StringBuffer` object that does not contain any characters and has the specified capacity.

`public StringBuffer(String str)`

Parameters

`str`

A `String` object.

Description

Creates a `StringBuffer` object that contains the same sequence of characters as the given `String` object and has a capacity 16 greater than the length of the `String`.

Instance Methods

append

`public StringBuffer append(boolean b)`

Parameters

`b`

A `boolean` value.

Returns

This `StringBuffer` object.

Description

This method appends either `"true"` or `"false"` to the end of the sequence of characters stored in ths `StringBuffer` object, depending on the value of `b`.

`public synchronized StringBuffer append(char c)`

Parameters

`c`

A `char` value.

Returns

This `StringBuffer` object.

Description

This method appends the given character to the end of the sequence of characters stored in this `StringBuffer` object.

`public synchronized StringBuffer append(char str[])`

Parameters

`str`

An array of `char` values.

Returns

This `StringBuffer` object.

Description

This method appends the characters in the given array to the end of the sequence of characters stored in this `StringBuffer` object.

`public synchronized StringBuffer append(char str[], int offset, int len)`

Parameters

`str`

An array of `char` values.

`offset`

An offset into the array.

`len`

The number of characters from the array to be appended.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `len` are out of range.

Description

This method appends the specified portion of the given array to the end of the character sequence stored in this `StringBuffer` object. The portion of the array that is appended starts `offset` elements from the beginning of the array and is `len` elements long.

`public StringBuffer append(double d)`

Parameters

`d`

A `double` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `double` value to a string using `Double.toString(d)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public StringBuffer append(float f)`

Parameters

`f`

A `float` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `float` value to a string using `Float.toString(f)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public StringBuffer append(int i)`

Parameters

`i`

An `int` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `int` value to a string using `Integer.toString(i)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public StringBuffer append(long l)`

Parameters

`l`

A `long` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `long` value to a string using `Long.toString(l)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public synchronized StringBuffer append(Object obj)`

Parameters

`obj`

A reference to an object.

Returns

This `StringBuffer` object.

Description

This method gets the string representation of the given object by calling `String.valueOf(obj)` and appends the resulting string to the end of the character sequence stored in this `StringBuffer` object.

`public synchronized StringBuffer append(String str)`

Parameters

`str`

A `String` object.

Returns

This `StringBuffer` object.

Description

This method appends the sequence of characters represented by the given `String` to the characters in this `StringBuffer` object. If `str` is `null`, the string `"null"` is appended.

capacity

`public int capacity()`

Returns

The capacity of this `StringBuffer` object.

Description

This method returns the current capacity of this object. The capacity of a `StringBuffer` object is the number of characters that its internal data structure can hold. A `StringBuffer` object automatically increases its capacity when it is asked to hold more characters than its current capacity allows.

charAt

`public synchronized char charAt(int index)`

Parameters

index

An index into the StringBuffer.

Returns

The character stored at the specified position in this StringBuffer object.

Throws

StringIndexOutOfBoundsException

If index is less than zero or greater than or equal to the length of the StringBuffer object.

Description

This method returns the character at the specified position in the StringBuffer object. The first character in the StringBuffer is at index 0.

ensureCapacity

public synchronized void ensureCapacity(int minimumCapacity)

Parameters

minimumCapacity

The minimum desired capacity.

Description

This method ensures that the capacity of this StringBuffer object is at least the specified number of characters. If necessary, the capacity of this object is increased to the greater of minimumCapacity or double its current capacity plus two.

It is more efficient to ensure that the capacity of a StringBuffer object is sufficient to hold all of the additions that will be made to its contents, rather than let the StringBuffer increase its capacity in multiple increments.

getChars

public synchronized void getChars(int srcBegin, int srcEnd, char dst[], int

`dstBegin)`

Parameters

`srcBegin`

The index of the first character to be copied.

`srcEnd`

The index after the last character to be copied.

`dst`

The destination `char` array.

`dstBegin`

An offset into the destination array.

Throws

`StringIndexOutOfBoundsException`

If `srcBegin`, `srcEnd`, or `dstBegin` is out of range.

Description

This method copies each character in the specified range of this `StringBuffer` object to the given array of `char` values. More specifically, the first character to be copied is at index `srcBegin`; the last character to be copied is at index `srcEnd-1`.

These characters are copied into `dst`, starting at index `dstBegin` and ending at index:

```
dstBegin + (srcEnd-srcBegin) - 1
```

insert

public StringBuffer insert(int offset, boolean b)

Parameters

`offset`

An offset into the `StringBuffer`.

`b`

A `boolean` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is out of range.

Description

This method inserts either `"true"` or `"false"` into the sequence of characters stored in this `StringBuffer` object, depending on the value of `b`. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public synchronized StringBuffer insert(int offset, char c)`

Parameters

`offset`

An offset into the `StringBuffer`.

`c`

A `char` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method inserts the given character into the sequence of characters stored in this `StringBuffer` object. The character is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the character is inserted before the first character in the `StringBuffer`.

public synchronized StringBuffer insert(int offset, char str[])

Parameters

`offset`

An offset into the `StringBuffer`.

`str`

An array of `char` values.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method inserts the characters in the given array into the sequence of characters stored in this `StringBuffer` object. The characters are inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the characters are inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, double d)`

Parameters

`offset`

An offset into the `StringBuffer`.

`d`

A `double` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `double` value to a string using `Double.toString(d)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, float f)`

Parameters

`offset`

An offset into the `StringBuffer`.

`f`

A `float` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `float` value to a string using `Float.toString(f)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, int i)`

Parameters

`offset`

An offset into the `StringBuffer`.

`i`

An `int` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `int` value to a string using `Integer.toString(i)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, long l)`

Parameters

`offset`

An offset into the `StringBuffer`.

`l`

A `long` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `long` value to a string using `Long.toString(l)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

public synchronized StringBuffer insert(int offset, Object obj)

Parameters

`offset`

An offset into the `StringBuffer`.

`obj`

A reference to an object.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method gets the string representation of the given object by calling `String.valueOf(obj)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

public synchronized StringBuffer insert(int offset, String str)

Parameters

`offset`

An offset into the `StringBuffer`.

`str`

A `String` object.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method inserts the sequence of characters represented by the given `String` into the sequence of characters stored in this `StringBuffer` object. If `str` is `null`, the string `"null"` is inserted. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

length

`public int length()`

Returns

The number of characters stored in this `StringBuffer` object.

Description

This method returns the number of characters stored in this `StringBuffer` object. The length is distinct from the capacity of a `StringBuffer`, which is the number of characters that its internal data structure can hold.

reverse

`public synchronized StringBuffer reverse()`

Returns

> This `StringBuffer` object.

Description

> This method reverses the sequence of characters stored in this `StringBuffer` object.

setCharAt

`public synchronized void setCharAt(int index, char ch)`

Parameters

> `index`
>
> > The index of the character to be set.
>
> `ch`
>
> > A `char` value.

Throws

> `StringIndexOutOfBoundsException`
>
> > If `index` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

> This method modifies the character located `index` characters from the beginning of the sequence of characters stored in this `StringBuffer` object. The current character at this position is replaced by the character `ch`.

setLength

`public synchronized void setLength(int newLength)`

Parameters

> `newLength`

The new length for this `StringBuffer`.

Throws

`StringIndexOutOfBoundsException`

If `index` is less than zero.

Description

This method sets the length of the sequence of characters stored in this `StringBuffer` object. If the length is set to be less than the current length, characters are lost from the end of the character sequence. If the length is set to be more than the current length, NUL characters (`\u0000`) are added to the end of the character sequence.

toString

`public String toString()`

Returns

A new `String` object that represents the same sequence of characters as the sequence of characters stored in this `StringBuffer` object.

Overrides

`Object.toString()`

Description

This method returns a new `String` object that represents the same sequence of characters as the sequence of characters stored in this `StringBuffer` object. Note that any subsequent changes to the contents of this `StringBuffer` object do not affect the contents of the `String` object created by this method.

Inherited Methods

Number

Name

Number

Synopsis

Class Name:

`java.lang.Number`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.lang.Byte`, `java.lang.Double`,

`java.lang.Float`, `java.lang.Integer`,

`java.lang.Long`, `java.lang.Short`,

`java.math.BigDecimal`,

`java.math.BigInteger`

Interfaces Implemented:

```
java.io.Serializable
```

Availability:

JDK 1.0 or later

Description

The `Number` class is an `abstract` class that serves as the superclass for all of the classes that provide object wrappers for primitive numeric values: `byte`, `short`, `int`, `long`, `float`, and `double`. Wrapping a primitive value is useful when you need to treat such a value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a primitive value for one of these arguments, but you can provide a reference to an object that encapsulates the primitive value. Furthermore, as of JDK 1.1, these wrapper classes are necessary to support the Reflection API and class literals.

The `Number` class defines six methods that must be implemented by its subclasses: `byteValue()`, `shortValue()`, `intValue()`, `longValue()`, `floatValue()`, and `doubleValue()`. This means that a `Number` object can be fetched as an `byte`, `short`, `int`, `long`, `float`, or `double` value, without regard for its actual class.

Class Summary

```
public abstract class java.lang.Number extends java.lang.Number
                                       implements java.io.Serializable {
    // Instance Methods
    public abstract byte byteValue();                  // New in 1.1
    public abstract double doubleValue();
    public abstract float floatValue();
    public abstract int intValue();
    public abstract long longValue();
    public abstract short shortValue();                // New in 1.1
}
```

Instance Methods

byteValue

`public abstract byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Description

This method returns the value of this object as a `byte`. If the data type of the value is not `byte`, rounding may occur.

doubleValue

`public abstract double doubleValue()`

Returns

The value of this object as a `double`.

Description

This method returns the value of this object as a `double`. If the data type of the value is not `double`, rounding may occur.

floatValue

`public abstract float floatValue()`

Returns

The value of this object as a `float`.

Description

This method returns the value of this object as a `float`. If the data type of the value is not `float`, rounding may occur.

intValue

`public abstract int intValue()`

Returns

> The value of this object as an `int`.

Description

> This method returns the value of this object as an `int`. If the type of value is not an `int`, rounding may occur.

longValue

`public abstract long longValue()`

Returns

> The value of this object as a `long`.

Description

> This method returns the value of this object as a `long`. If the type of value is not a `long`, rounding may occur.

shortValue

`public abstract short shortValue()`

Availability

> New as of JDK 1.1

Returns

> The value of this object as a `short`.

Description

> This method returns the value of this object as a `short`. If the type of value is not a `short`, rounding may occur.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Math

Name

Math

Synopsis

Class Name:

`java.lang.Math`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Math` class contains constants for the mathematical values pi and *e*. The class also defines methods that compute various mathematical functions, such as trigonometric and exponential functions. All of these constants and methods are `static`. In other words, it is not necessary to create an instance of the `Math` class in order to use its constants and methods. In fact, the `Math` class does not define any `public` constructors, so it cannot be instantiated.

To ensure that the methods in this class return consistent results under different implementations of Java, all of the methods use the algorithms from the well-known Freely-Distributable Math Library package, *fdlibm*. This package is part of the network library *netlib*. The library can be obtained through the URL *http://netlib.att.com*. The algorithms used in this class are from the version of *fdlibm* dated January 4, 1995. *fdlibm* provides more than one definition for some functions. In those cases, the "IEEE 754 core function" version is used.

Class Summary

```
public final class java.lang.Math extends java.lang.Object {
    // Constants
    public static final double E;
    public static final double PI;
    // Class Methods
    public static int abs(int a);
    public static long abs(long a);
    public static float abs(float a);
    public static double abs(double a);
    public static native double acos(double a);
    public static native double asin(double a);
    public static native double atan(double a);
    public static native double atan2(double a, double b);
    public static native double ceil(double a);
    public static native double cos(double a);
    public static native double exp(double a);
    public static native double floor(double a);
    public static native double IEEEremainder(double f1, double f2);
    public static native double log(double a);
    public static int max(int a, int b);
    public static long max(long a, long b);
    public static float max(float a, float b);
    public static double max(double a, double b);
    public static int min(int a, int b);
    public static long min(long a, long b);
    public static float min(float a, float b);
    public static double min(double a, double b);
    public static native double pow(double a, double b);
    public static synchronized double random();
    public static native double rint(double a);
    public static int round(float a);
    public static long round(double a);
    public static native double sin(double a);
    public static native double sqrt(double a);
    public static native double tan(double a);
}
```

Constants

E

`public static final double E = 2.7182818284590452354`

Description

> The value of this constant is *e*, the base for natural logarithms.

PI

`public static final double PI = 3.14159265358979323846`

Description

> The value for this constant is pi.

Class Methods

abs

`public static double abs(double a)`

Parameters

`a`

A `double` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument to this method is negative or positive zero, the method should return positive zero. If the argument is positive or negative infinity, the method returns positive infinity. If the argument is NaN, the method returns NaN.

`public static float abs(float a)`

Parameters

`a`

A `float` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument to this method is negative or positive zero, the method should return positive zero. If the argument is positive or negative infinity, the method returns positive infinity. If the argument is NaN, the method returns NaN.

`public static int abs(int a)`

Parameters

`a`

An `int` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument is `Integer.MIN_VALUE`, the method actually returns `Integer.MIN_VALUE` because the true absolute value of `Integer.MIN_VALUE` is one greater than the largest positive value that can be represented by an `int`.

`public static long abs(long a)`

Parameters

`a`

A `long` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument is `Long.MIN_VALUE`, the method actually returns `Long.MIN_VALUE` because the true absolute value of `Long.MIN_VALUE` is one greater than the largest positive value represented by a `long`.

acos

`public static native double acos(double a)`

Parameters

`a`

A `double` value greater than or equal to `-1.0` and less than or equal to `1.0`.

Returns

The arc cosine measured in radians; the result is greater than or equal to `0.0` and less than or equal to pi.

Description

This method returns the arc cosine of the given value.

If the value is NaN or its absolute value is greater than `1.0`, the method returns NaN.

asin

`public static native double asin(double a)`

Parameters

`a`

A `double` value greater than or equal to `-1.0` and less than or equal to `1.0`.

Returns

The arc sine measured in radians; the result is greater than or equal to -pi/2 and less than or equal to pi/2.

Description

This method returns the arc sine of the given value.

If the value is NaN or its absolute value is greater than `1.0`, the method returns NaN. If the value is positive zero, the method returns positive zero. If the value is negative zero, the method returns negative zero.

atan

`public static native double atan(double a)`

Parameters

`a`

A `double` value greater than or equal to `-1.0` and less than or equal to `1.0`.

Returns

The arc tangent measured in radians; the result is greater than or equal to -pi/2 and less than or equal to pi/2.

Description

This method returns the principle value of the arc tangent of the given value.

If the value is NaN, the method returns NaN. If the value is positive zero, the method returns positive zero. If the value is negative zero, the method returns negative zero.

atan2

`public static native double atan2(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The theta component of the polar coordinate (*r*,theta) that corresponds to the cartesian coordinate (`a`,`b`); the result is measured in radians and is greater than or equal to -pi and less than or equal to pi.

Description

This method returns the theta component of the polar coordinate (*r*,theta) that corresponds to the cartesian coordinate (`a`,`b`). It computes theta as the principle value of the arc tangent of `b`/`a`, using the signs of both arguments to determine the quadrant (and sign) of the return value.

If either argument is NaN, the method returns NaN.

If the first argument is positive zero and the second argument is positive, then the method returns positive zero. If the first argument is positive zero and the second argument is negative, then the method returns the `double` value closest to pi.

If the first argument is negative zero and the second argument is positive, the method returns negative zero. If the first argument is negative zero and the second argument is negative, the method returns the `double` value closest to -pi.

If the first argument is positive and finite and the second argument is positive infinity, the method returns positive zero. If the first argument is positive and finite and the second argument is negative infinity, the method returns the `double` value closest to pi.

If the first argument is negative and finite and the second argument is positive infinity, the method returns negative zero. If the first argument is negative and finite and the second argument is negative infinity, the method returns the `double` value closest to -pi.

If the first argument is positive and the second argument is positive zero or negative zero, the method returns the `double` value closest to pi/2. If the first argument is negative and the second argument is positive or negative zero, the method returns the `double` value closest to -pi/2.

If the first argument is positive infinity and the second argument is finite, the method returns the `double` value closest to pi/2. If the first argument is negative infinity and the second argument is finite, the method returns the `double` value closest to -pi/2.

If both arguments are positive infinity, the method returns the `double` value closest to pi/4. If the first argument is positive infinity and the second argument is negative infinity, the method returns the `double` value closest to 3pi/4. If the first argument is negative infinity and the second argument is positive infinity, the method returns the `double` value closest to -pi/4. If both arguments are negative infinity, the method returns the `double` value closest to -3pi/4.

ceil

```
public static native double ceil(double a)
```

Parameters

`a`

A `double` value.

Returns

The smallest integer greater than or equal to the given value.

Description

This method performs the ceiling operation. It returns the smallest integer that is greater than or equal to its argument.

If the argument is NaN, an infinity value, or a zero value, the method returns that same value. If the argument is less than zero but greater than `-1.0`, the method returns negative zero.

cos

`public static native double cos(double a)`

Parameters

`a`

A `double` value that's an angle measured in radians.

Returns

The cosine of the given angle.

Description

This method returns the cosine of the given angle measured in radians.

If the angle is NaN or an infinity value, the method returns NaN.

exp

`public static native double exp(double a)`

Parameters

`a`

A `double` value.

Returns

`e^a`

Description

This method returns the exponential function of `a`. In other words, *e* is raised to the value specified by the parameter `a`, where *e* is the base of the natural logarithms.

If the value is NaN, the method returns NaN. If the value is positive infinity, the method returns positive infinity. If the value is negative infinity, the method returns positive zero.

floor

`public static native double floor(double a)`

Parameters

`a`

A `double` value.

Returns

The greatest integer less than or equal to the given value.

Description

This method performs the floor operation. It returns the largest integer that is less than or equal to its argument.

If the argument is NaN, an infinity value, or a zero value, the method returns that same value.

IEEEremainder

`public static native double IEEEremainder(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The remainder of `a` divided by `b` as defined by the IEEE 754 standard.

Description

This method returns the remainder of `a` divided by `b` as defined by the IEEE 754 standard. This operation involves first determining the mathematical quotient of `a`/`b` rounded to the nearest integer. If the quotient is equally close to two integers, it is rounded to the even integer. The method then returns `a-(b x `*`Q`*`)`, where *`Q`* is the rounded quotient.

If either argument is NaN, the method returns NaN. If the first argument is positive or negative infinity and the second argument is positive or negative zero, the method also returns NaN. If the first argument is a finite value and the second argument is positive or negative infinity, the method returns its first argument.

log

`public static native double log(double a)`

Parameters

`a`

A `double` value that is greater than `0.0`.

Returns

The natural logarithm of `a`.

Description

This method returns the natural logarithm (base *e*) of its argument.

In particular, if the argument is positive infinity, the method returns positive infinity. If the argument is positive or negative zero, the method returns negative infinity. If the argument is less than zero, the method returns NaN. If the argument is NaN, the method returns NaN.

max

`public static double max(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to positive infinity.

If one argument is positive zero and the other is negative zero, the method returns positive zero. If either argument is NaN, the method returns NaN.

`public static float max(float a, float b)`

Parameters

`a`

A `float` value.

`b`

A `float` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to positive infinity.

If one argument is positive zero and the other is negative zero, the method returns positive zero. If either argument is NaN, the method returns NaN.

`public static int max(int a, int b)`

Parameters

`a`

An `int` value.

`b`

An `int` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to `Integer.MAX_VALUE`.

`public static long max(long a, long b)`

Parameters

`a`

A `long` value.

`b`

A `long` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to `Long.MAX_VALUE`.

min

`public static double min(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to negative infinity.

If one argument is positive zero and the other is negative zero, the method returns negative zero. If either argument is NaN, the method returns NaN.

`public static float min(float a, float b)`

Parameters

`a`

A `float` value.

`b`

A `float` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to negative infinity.

If one argument is positive zero and the other is negative zero, the method returns negative zero. If either argument is NaN, the method returns NaN.

`public static int min(int a, int b)`

Parameters

`a`

An `int` value.

`b`

An `int` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to `Integer.MIN_VALUE`.

`public static long min(long a, long b)`

Parameters

`a`

A `long` value.

`b`

A `long` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to `Long.MIN_VALUE`.

pow

`public static native double pow(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

`a^b`

Description

This method computes the value of raising `a` to the power of `b`.

If the second argument is positive or negative zero, the method returns `1.0`. If the second argument is `1.0`, the method returns its first argument. If the second argument is NaN, the method returns NaN. If the first argument is NaN and the second argument is nonzero, the method returns NaN.

If the first argument is positive zero and the second argument is greater than zero, the method returns positive zero. If the first argument is positive zero and the second argument is less than zero, the method returns positive infinity.

If the first argument is positive infinity and the second argument is less than zero, the method returns positive zero. If the first argument is positive infinity and the second argument is greater than zero, the method returns positive infinity.

If the absolute value of the first argument is greater than `1` and the second argument is positive infinity, the method returns positive infinity. If the absolute value of the first argument is greater than `1` and the second argument is negative infinity, the method returns positive zero. If the absolute value of the first argument is less than `1` and the second argument is negative infinity, the method returns positive infinity. If the absolute value of the first argument is less than `1` and the second argument is positive infinity, the method returns positive zero. If the absolute value of the first argument is `1` and the second argument is positive or negative infinity, the method returns NaN.

If the first argument is negative zero and the second argument is greater than zero but not a finite odd integer, the method returns positive zero. If the first argument is negative zero and the second argument is a positive finite odd integer, the method returns negative zero. If the first argument is negative zero and the second argument is less than zero but not a finite odd integer, the method returns positive infinity. If the first argument is negative zero and the second argument is a negative finite odd integer, the method returns negative infinity.

If the first argument is negative infinity and the second argument is less than zero but not a finite odd integer, the method returns positive zero. If the first argument is negative infinity and the second argument is a negative finite odd integer, the method returns negative zero. If the first argument is negative infinity and the second argument is greater than zero but not a finite odd integer, the method returns positive infinity. If the first argument is negative infinity and the second argument is a positive finite odd integer, the method returns negative infinity.

If the first argument is less than zero and the second argument is a finite even integer, the method returns the result of the absolute value of the first argument raised to the power of the second argument. If the first argument is less than zero and the second argument is a finite odd integer, the method returns the negative of the result of the absolute value of the first argument raised to the power of the second argument. If the first argument is finite and less than zero and the second argument is finite and not an integer, the method returns NaN.

If both arguments are integer values, the method returns the first argument raised to the power of the second argument.

random

`public static synchronized double random()`

Returns

A random number between `0.0` and `1.0`.

Description

This method returns a random number greater than or equal to `0.0` and less than `1.0`. The implementation of this method uses the `java.util.Random` class. You may prefer to use the `Random` class directly, in order to gain more control over the distribution, type, and repeatability of the random numbers you are generating.

rint

`public static native double rint(double a)`

Parameters

`a`

A `double` value.

Returns

The value of its argument rounded to the nearest integer.

Description

This method returns its argument rounded to the nearest integer; the result is returned as a `double` value. If the argument is equidistant from two integers (e.g., `1.5`), the method returns the even integer.

If the argument is an infinity value, a zero value, or NaN, the method returns that same value.

round

`public static long round(double a)`

Parameters

`a`

A `double` value.

Returns

The value of its argument rounded to the nearest `long`.

Description

This method returns its `double` argument rounded to the nearest integral value and converted to a `long`. If the argument is equidistant from two integers, the method returns the greater of the two integers.

If the argument is positive infinity or any other value greater than `Long.MAX_VALUE`, the method returns `Long.MAX_VALUE`. If the argument is negative infinity or any other value less than `Long.MIN_VALUE`, the method returns `Long.MIN_VALUE`. If the argument is NaN, the method returns `0`.

public static int round(float a)

Parameters

a

A float value.

Returns

The value of its argument rounded to the nearest int.

Description

This method returns its float argument rounded to the nearest integral value and converted to an int. If the argument is equidistant from two integers, the method returns the greater of the two integers.

If the argument is positive infinity or any other value greater than the Integer.MAX_VALUE, the method returns Integer.MAX_VALUE. If the argument is negative infinity or any other value less than Integer.MIN_VALUE, the method returns Integer.MIN_VALUE. If the argument is NaN, the method returns 0.

sin

public static native double sin(double a)

Parameters

a

A double value that's an angle measured in radians.

Returns

The sine of the given angle.

Description

This method returns the sine of the given angle measured in radians.

If the angle is NaN or an infinity value, the method returns NaN. If the angle is positive zero, the method returns positive zero. If the angle is negative zero, the method returns negative zero.

sqrt

`public static native double sqrt(double a)`

Parameters

`a`

A `double` value.

Returns

The square root of its argument.

Description

This method returns the square root of its argument.

If the argument is negative or NaN, the method returns NaN. If the argument is positive infinity, the method returns positive infinity. If the argument is positive or negative zero, the method returns that same value.

tan

`public static native double tan(double a)`

Parameters

`a`

A `double` value that is an angle measured in radians.

Returns

The tangent of the given angle.

Description

This method returns the tangent of the given angle measured in radians.

If the angle is NaN or an infinity value, the method returns NaN. If the angle is positive zero, the method returns positive zero. If the angle is negative zero, the method returns negative zero.

SecurityManager

Name

SecurityManager

Synopsis

Class Name:

> `java.lang.SecurityManager`

Superclass:

> `java.lang.Object`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> JDK 1.0 or later

Description

The SecurityManager class provides a way of implementing a comprehensive security policy for a Java program. As of this writing, SecurityManager objects are used primarily by Web browsers to establish security policies for applets. However, the use of a SecurityManager object is appropriate in any situation where a hosting environment wants to limit the actions of hosted programs.

The SecurityManager class contains methods that are called by methods in other classes to ask for permission to do something that can affect the security of the system. These permission methods all have names that begin with check. If a check method does not permit an action, it throws a SecurityException or returns a value that indicates the lack of permission. The SecurityManager class provides default implementations of all of the check methods. These default implementations are the most restrictive possible implementations; they simply deny permission to do anything that can affect the security of the system.

The SecurityManager class is an abstract class. A hosting environment should define a subclass of SecurityManager that implements an appropriate security policy. To give the subclass of SecurityManager control over security, the hosting environment creates an instance of the class and installs it by passing it to the setSecurityManager() method of the System class. Once a SecurityManager object is installed, it cannot be changed. If the setSecurityManager() method is called any additional times, it throws a SecurityException.

The methods in other classes that want to ask the SecurityManager for permission to do something are able to access the SecurityManager object by calling the getSecurityManager() method of the System class. This method returns the SecurityManager object, or null to indicate that there is no SecurityManager installed.

Class Summary

```
public abstract class java.lang.SecurityManager extends java.lang.Object {
    // Constructors
    protected SecurityManager();
    // Variables
    protected boolean inCheck;
    // Instance Methods
    public void checkAccept(String host, int port);
    public void checkAccess(Thread t);
    public void checkAccess(ThreadGroup g);
    public void checkAwtEventQueueAccess();                  // New in 1.1
    public void checkConnect(String host, int port);
    public void checkConnect(String host, int port, Object context);
    public void checkCreateClassLoader();
    public void checkDelete(String file);
    public void checkExec(String cmd);
    public void checkExit(int status);
    public void checkLink(String libname);
    public void checkListen(int port);
    public void checkMemberAccess(Class clazz, int which);   // New in 1.1
    public void checkMulticast(InetAddress maddr);           // New in 1.1
    public void checkMulticast(InetAddress maddr, byte ttl); // New in 1.1
    public void checkPackageAccess();
    public void checkPackageDefinition();
    public void checkPrintJobAccess();                       // New in 1.1
    public void checkPropertiesAccess();
    public void checkPropertyAccess(String key);
    public void checkRead(int fd);
    public void checkRead(String file);
    public void checkRead(String file, Object context);
    public void checkSecurityAccess(String action);          // New in 1.1
    public void checkSetFactory();
    public void checkSystemClipboardAccess();                // New in 1.1
    public boolean checkTopLevelWindow();
    public void checkWrite(int fd);
    public void checkWrite(String file);
    public boolean getInCheck();
    public Object getSecurityContext();
    public ThreadGroup getThreadGroup();                     // New in 1.1
    // Protected Instance Methods
    protected int classDepth(String name);
    protected int classLoaderDepth();
    protected ClassLoader currentClassLoader();
    protected Class currentLoadedClass();                    // New in 1.1
    protected Class[] getClassContext();
    protected boolean inClass(String name);
    protected boolean inClassLoader();
}
```

Variables

inCheck

`protected boolean inCheck = false`

Description

> This variable indicates whether or not a security check is in progress. A subclass of `SecurityManager` should set this variable to `true` while a security check is in progress.
>
> This variable can be useful for security checks that require access to resources that a hosted program may not be permitted to access. For example, a security policy might be based on the contents of a

permissions file. This means that the various `check` methods need to read information from a file to decide what to do. Even though a hosted program may not be allowed to read files, the `check` methods can allow such reads when `inCheck` is `true` to support this style of security policy.

Constructors

SecurityManager

`protected SecurityManager()`

Throws

`SecurityException`

If a `SecurityManager` object already exists. In other words, if `System.getSecurityManager()` returns a value other than `null`.

Description

Creates a new `SecurityManager` object. This constructor cannot be called if there is already a current `SecurityManager` installed for the program.

Public Instance Methods

checkAccept

`public void checkAccept(String host, int port)`

Parameters

`host`

The name of the host machine.

`port`

A port number.

Throws

`SecurityException`

If the caller does not have permission to accept the connection.

Description

This method decides whether or not to allow a connection from the given host on the given port to be accepted. An implementation of the method should throw a `SecurityException` to deny permission to accept the connection. The method is called by the `accept()` method of the `java.net.ServerSocket` class.

The `checkAccept()` method of `SecurityManager` always throws a `SecurityException`.

checkAccess

`public void checkAccess(Thread g)`

Parameters

`g`

A reference to a `Thread` object.

Throws

`SecurityException`

If the current thread does not have permission to modify the specified thread.

Description

This method decides whether or not to allow the current thread to modify the specified `Thread`. An implementation of the method should throw a `SecurityException` to deny permission to modify the thread. Methods of the `Thread` class that call this method include `stop()`, `suspend()`, `resume()`, `setPriority()`, `setName()`, and `setDaemon()`.

The `checkAccess()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkAccess(ThreadGroup g)`

Parameters

`g`

A reference to a `ThreadGroup` object.

Throws

`SecurityException`

If the current thread does not have permission to modify the specified thread group.

Description

This method decides whether or not to allow the current thread to modify the specified `ThreadGroup`. An implementation of the method should throw a `SecurityException` to deny permission to modify the thread group. Methods of the `ThreadGroup` class that call this method include `setDaemon()`, `setMaxPriority()`, `stop()`, `suspend()`, `resume()`, and `destroy()`.

The `checkAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkAwtEventQueueAccess

`public void checkAwtEventQueueAccess()`

Availability

New as of JDK 1.1

Throws

`SecurityException`

If the caller does not have permission to access the AWT event queue.

Description

This method decides whether or not to allow access to the AWT event queue. An implementation of the method should throw a `SecurityException` to deny permission to access the event queue. The method is called by the `getSystemEventQueue()` method of the `java.awt.Toolkit` class.

The `checkAwtEventQueueAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkConnect

`public void checkConnect(String host, int port)`

Parameters

`host`

The name of the host.

`port`

A port number. A value of `-1` indicates an attempt to determine the IP address of given hostname.

Throws

`SecurityException`

If the caller does not have permission to open the socket connection.

Description

This method decides whether or not to allow a socket connection to the given host on the given port to be opened. An implementation of the method should throw a `SecurityException` to deny permission to open the connection. The method is called by the constructors of the `java.net.Socket` class, the `send()` and `receive()` methods of the `java.net.DatagramSocket` class, and the `getByName()` and `getAllByName()` methods of the `java.net.InetAddress` class.

The `checkConnect()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkConnect(String host, int port, Object context)`

Parameters

`host`

The name of the host.

`port`

A port number. A value of `-1` indicates an attempt to determine the IP address of given host name.

`context`

A security context object returned by this object's `getSecurityContext()` method.

Throws

`SecurityException`

If the specified security context does not have permission to open the socket connection.

Description

This method decides whether or not to allow a socket connection to the given host on the given port to be opened for the specified security context. An implementation of the method should throw a `SecurityException` to deny permission to open the connection.

The `checkConnect()` method of `SecurityManager` always throws a `SecurityException`.

checkCreateClassLoader

`public void checkCreateClassLoader()`

Throws

`SecurityException`

If the caller does not have permission to create a `ClassLoader` object.

Description

This method decides whether or not to allow a `ClassLoader` object to be created. An implementation of the method should throw a `SecurityException` to deny permission to create a `ClassLoader`. The method is called by the constructor of the `ClassLoader` class.

The `checkCreateClassLoader()` method of `SecurityManager` always throws a `SecurityException`.

checkDelete

`public void checkDelete(String file)`

Parameters

`file`

The name of a file.

Throws

`SecurityException`

If the caller does not have permission to delete the specified file.

Description

This method decides whether or not to allow a file to be deleted. An implementation of the method should throw a `SecurityException` to deny permission to delete the specified file. The method is called by the `delete()` method of the `java.io.File` class.

The `checkDelete()` method of `SecurityManager` always throws a `SecurityException`.

checkExec

`public void checkExec(String cmd)`

Parameters

`cmd`

The name of an external command.

Throws

`SecurityException`

If the caller does not have permission to execute the specified command.

Description

This method decides whether or not to allow an external command to be executed. An implementation of the method should throw a `SecurityException` to deny permission to execute the specified command. The method is called by the `exec()` methods of the `Runtime` and `System` classes.

The `checkExec()` method of `SecurityManager` always throws a `SecurityException`.

checkExit

`public void checkExit(int status)`

Parameters

`status`

An exit status code.

Throws

`SecurityException`

If the caller does not have permission to exit the Java virtual machine with the given status code.

Description

This method decides whether or not to allow the Java virtual machine to exit with the given status code. An implementation of the method should throw a `SecurityException` to deny permission to exit with the specified status code. The method is called by the `exit()` methods of the `Runtime` and `System` classes.

The `checkExit()` method of `SecurityManager` always throws a `SecurityException`.

checkLink

`public void checkLink(String lib)`

Parameters

`lib`

The name of a library.

Throws

`SecurityException`

If the caller does not have permission to load the specified library.

Description

This method decides whether to allow the specified library to be loaded. An implementation of the method should throw a `SecurityException` to deny permission to load the specified library. The method is called by the `load()` and `loadLibrary()` methods of the `Runtime` and `System` classes.

The `checkLink()` method of `SecurityManager` always throws a `SecurityException`.

checkListen

`public void checkListen(int port)`

Parameters

`port`

A port number.

Throws

`SecurityException`

If the caller does not have permission to listen on the specified port.

Description

This method decides whether or not to allow the caller to listen on the specified port. An implementation of the method should throw a `SecurityException` to deny permission to listen on the specified port. The method is called by the constructors of the `java.net.ServerSocket` class and by the constructor of the `java.net.DatagramSocket` class that takes one argument.

The `checkListen()` method of `SecurityManager` always throws a `SecurityException`.

checkMemberAccess

`public void checkMemberAccess(Class clazz, int which)`

Availability

New as of JDK 1.1

Parameters

clazz

A Class object.

which

The value Member.PUBLIC for the set of all public members including inherited members or the value Member.DECLARED for the set of all declared members of the specified class or interface.

Throws

SecurityException

If the caller does not have permission to access the members of the specified class or interface.

Description

This method decides whether or not to allow access to the members of the specified Class object. An implementation of the method should throw a SecurityException to deny permission to access the members. Methods of the Class class that call this method include getField(), getFields(), getDeclaredField(), getDeclaredFields(), getMethod(), getMethods(), getDeclaredMethod(), getDeclaredMethods(), getConstructor(), getConstructors(), getDeclaredConstructor(), getDeclaredConstructors(), and getDeclaredClasses().

The checkMemberAccess() method of SecurityManager always throws a SecurityException.

checkMulticast

public void checkMulticast(InetAddress maddr)

Availability

New as of JDK 1.1

Parameters

maddr

An InetAddress object that represents a multicast address.

Throws

`SecurityException`

If the current thread does not have permission to use the specified multicast address.

Description

This method decides whether or not to allow the current thread to use the specified multicast `InetAddress`. An implementation of the method should throw a `SecurityException` to deny permission to use the multicast address. The method is called by the `send()` method of `java.net.DatagramSocket` if the packet is being sent to a multicast address. The method is also called by the `joinGroup()` and `leaveGroup()` methods of `java.net.MulticastSocket`.

The `checkMulticast()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkMulticast(InetAddress maddr, byte ttl)`

Availability

New as of JDK 1.1

Parameters

`maddr`

An `InetAddress` object that represents a multicast address.

`ttl`

The time-to-live (TTL) value.

Throws

`SecurityException`

If the current thread does not have permission to use the specified multicast address and TTL value.

Description

This method decides whether or not to allow the current thread to use the specified multicast

InetAddress and TTL value. An implementation of the method should throw a SecurityException to deny permission to use the multicast address. The method is called by the send() method of java.net.MulticastSocket.

The checkMulticast() method of SecurityManager always throws a SecurityException.

checkPackageAccess

public void checkPackageAccess(String pkg)

Parameters

pkg

The name of a package.

Throws

SecurityException

If the caller does not have permission to access the specified package.

Description

This method decides whether or not to allow the specified package to be accessed. An implementation of the method should throw a SecurityException to deny permission to access the specified package. The method is intended to be called by implementations of the loadClass() method in subclasses of the ClassLoader class.

The checkPackageAccess() method of SecurityManager always throws a SecurityException.

checkPackageDefinition

public void checkPackageDefinition(String pkg)

Parameters

pkg

The name of a package.

Throws

`SecurityException`

If the caller does not have permission to define classes in the specified package.

Description

This method decides whether or not to allow the caller to define classes in the specified package. An implementation of the method should throw a `SecurityException` to deny permission to create classes in the specified package. The method is intended to be called by implementations of the `loadClass()` method in subclasses of the `ClassLoader` class.

The `checkPackageDefinition()` method of `SecurityManager` always throws a `SecurityException`.

checkPrintJobAccess

`public void checkPrintJobAccess()`

Availability

New as of JDK 1.1

Throws

`SecurityException`

If the caller does not have permission to initiate a print job request.

Description

This method decides whether or not to allow the caller to initiate a print job request. An implementation of the method should throw a `SecurityException` to deny permission to initiate the request.

The `checkPrintJobAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkPropertiesAccess

`public void checkPropertiesAccess()`

Throws

`SecurityException`

If the caller does not have permission to access the system properties.

Description

This method decides whether or not to allow the caller to access and modify the system properties. An implementation of the method should throw a `SecurityException` to deny permission to access and modify the properties. Methods of the `System` class that call this method include `getProperties()` and `setProperties()`.

The `checkPropertiesAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkPropertyAccess

```
public void checkPropertyAccess(String key)
```

Parameters

`key`

The name of an individual system property.

Throws

`SecurityException`

If the caller does not have permission to access the specified system property.

Description

This method decides whether or not to allow the caller to access the specified system property. An implementation of the method should throw a `SecurityException` to deny permission to access the property. The method is called by the `getProperty()` method of the `System` class.

The `checkPropertyAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkRead

`public void checkRead(FileDescriptor fd)`

Parameters

`fd`

A reference to a `FileDescriptor` object.

Throws

`SecurityException`

If the caller does not have permission to read from the given file descriptor.

Description

This method decides whether or not to allow the caller to read from the specified file descriptor. An implementation of the method should throw a `SecurityException` to deny permission to read from the file descriptor. The method is called by the constructor of the `java.io.FileInputStream` class that takes a `FileDescriptor` argument.

The `checkRead()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkRead(String file)`

Parameters

`file`

The name of a file.

Throws

`SecurityException`

If the caller does not have permission to read from the named file.

Description

This method decides whether or not to allow the caller to read from the named file. An implementation of the method should throw a `SecurityException` to deny permission to read from the file. The method is called by constructors of the `java.io.FileInputStream` and java.io.RandomAccessFile classes, as well as by the canRead(), exists(), isDirectory(), isFile(), lastModified(), length(), and list() methods of the java.io.File class.

The checkRead() method of SecurityManager always throws a SecurityException.

public void checkRead(String file, Object context)

Parameters

file

The name of a file.

context

A security context object returned by this object's getSecurityContext() method.

Throws

SecurityException

If the specified security context does not have permission to read from the named file.

Description

This method decides whether or not to allow the specified security context to read from the named file. An implementation of the method should throw a SecurityException to deny permission to read from the file.

The checkRead() method of SecurityManager always throws a SecurityException.

checkSecurityAccess

public void checkSecurityAccess(String action)

Availability

New as of JDK 1.1

Parameters

action

A string that specifies a security action.

Throws

`SecurityException`

If the caller does not have permission to perform the specified security action.

Description

This method decides whether to allow the caller to perform the specified security action. An implementation of the method should throw a `SecurityException` to deny permission to perform the action. The method is called by many of the methods in the `java.security.Identity` and `java.security.Security` classes.

The `checkSecurityAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkSetFactory

`public void checkSetFactory()`

Throws

`SecurityException`

If the caller does not have permission to set the factory class to be used by another class.

Description

This method decides whether to allow the caller to set the factory class to be used by another class. An implementation of the method should throw a `SecurityException` to deny permission to set the factory class. The method is called by the `setSocketFactory()` method of the `java.net.ServerSocket` class, the `setSocketImplFactory()` method of the `java.net.Socket` class, the `setURLStreamHandlerFactory()` method of the `java.net.URL` class, and the `setContentHandlerFactory()` method of the `java.net.URLConnection` class.

The `checkSetFactory()` method of `SecurityManager` always throws a `SecurityException`.

checkSystemClipboardAccess

`public void checkSystemClipboardAccess()`

Availability

New as of JDK 1.1

Throws

`SecurityException`

If the caller does not have permission to access the system clipboard.

Description

This method decides whether or not to allow the caller to access the system clipboard. An implementation of the method should throw a `SecurityException` to deny permission to access the system clipboard.

The `checkSystemClipboardAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkTopLevelWindow

`public boolean checkTopLevelWindow(Object window)`

Parameters

`window`

A window object.

Returns

`true` if the caller is trusted to put up the specified top-level window; otherwise `false`.

Description

This method decides whether or not to trust the caller to put up the specified top-level window. An implementation of the method should return `false` to indicate that the caller is not trusted. In this case, the hosting environment can still decide to display the window, but the window should include a visual indication that it is not trusted. If the caller is trusted, the method should return `true`, and the window can be displayed without any special indication.

The `checkTopLevelWindow()` method of `SecurityManager` always returns `false`.

checkWrite

`public void checkWrite(FileDescriptor fd)`

Parameters

`fd`

A `FileDescriptor` object.

Throws

`SecurityException`

If the caller does not have permission to write to the given file descriptor.

Description

This method decides whether or not to allow the caller to write to the specified file descriptor. An implementation of the method should throw a `SecurityException` to deny permission to write to the file descriptor. The method is called by the constructor of the `java.io.FileOutputStream` class that takes a `FileDescriptor` argument.

The `checkWrite()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkWrite(String file)`

Parameters

`file`

The name of a file.

Throws

`SecurityException`

If the caller does not have permission to read from the named file.

Description

This method decides whether or not to allow the caller to write to the named file. An implementation of the method should throw a `SecurityException` to deny permission to write to the file. The method is called by constructors of the `java.io.FileOutputStream` and `java.io.RandomAccessFile` classes, as well as by the `canWrite()`, `mkdir()`, and `renameTo()` methods of the `java.io.File` class.

The `checkWrite()` method of `SecurityManager` always throws a `SecurityException`.

getInCheck

`public boolean getInCheck()`

Returns

`true` if a security check is in progress; otherwise `false`.

Description

This method returns the value of the `SecurityManager` object's `inCheck` variable, which is `true` if a security check is in progress and `false` otherwise.

getSecurityContext

`public Object getSecurityContext()`

Returns

An implementation-dependent object that contains enough information about the current execution environment to perform security checks at a later time.

Description

This method is meant to create an object that encapsulates information about the current execution environment. The resulting security context object is used by specific versions of the `checkConnect()` and `checkRead()` methods. The intent is that such a security context object can be used by a trusted method to determine whether or not another, untrusted method can perform a particular operation.

The `getSecurityContext()` method of `SecurityManager` simply returns `null`. This method should be overridden to return an appropriate security context object for the security policy that is being implemented.

getThreadGroup

`public ThreadGroup getThreadGroup()`

Availability

New as of JDK 1.1

Returns

A `ThreadGroup` in which to place any threads that are created when this method is called.

Description

This method returns the appropriate parent `ThreadGroup` for any threads that are created when the method is called. The `getThreadGroup()` method of `SecurityManager` simply returns the `ThreadGroup` of the current thread. This method should be overridden to return an appropriate `ThreadGroup`.

Protected Instance Methods

classDepth

`protected native int classDepth(String name)`

Parameters

`name`

The fully qualified name of a class.

Returns

The number of pending method invocations from the top of the stack to a call to a method of the given class; `-1` if no stack frame in the current thread is associated with a call to a method in the given class.

Description

This method returns the number of pending method invocations between this method invocation and an invocation of a method associated with the named class.

classLoaderDepth

`protected native int classLoaderDepth()`

Returns

> The number of pending method invocations from the top of the stack to a call to a method that is associated with a class that was loaded by a `ClassLoader` object; `-1` if no stack frame in the current thread is associated with a call to such a method.

Description

> This method returns the number of pending method invocations between this method invocation and an invocation of a method associated with a class that was loaded by a `ClassLoader` object.

currentClassLoader

`protected native ClassLoader currentClassLoader()`

Returns

> The most recent `ClassLoader` object executing on the stack.

Description

> This method finds the most recent pending invocation of a method associated with a class that was loaded by a `ClassLoader` object. The method then returns the `ClassLoader` object that loaded that class.

currentLoadedClass

`protected Class currentLoadedClass()`

Availability

> New as of JDK 1.1

Returns

> The most recent `Class` object loaded by a `ClassLoader`.

Description

This method finds the most recent pending invocation of a method associated with a class that was loaded by a `ClassLoader` object. The method then returns the `Class` object for that class.

getClassContext

`protected native Class[] getClassContext()`

Returns

An array of `Class` objects that represents the current execution stack.

Description

This method returns an array of `Class` objects that represents the current execution stack. The length of the array is the number of pending method calls on the current thread's stack, not including the call to `getClassContext()`. Each element of the array references a `Class` object that describes the class associated with the corresponding method call. The first element of the array corresponds to the most recently called method, the second element is that method's caller, and so on.

inClass

`protected boolean inClass(String name)`

Parameters

`name`

The fully qualified name of a class.

Returns

`true` if there is a pending method invocation on the stack for a method of the given class; otherwise `false`.

Description

This method determines whether or not there is a pending method invocation that is associated with the named class.

inClassLoader

`protected boolean inClassLoader()`

Returns

> `true` if there is a pending method invocation on the stack for a method of a class that was loaded by a `ClassLoader` object; otherwise `false`.

Description

> This method determines whether or not there is a pending method invocation that is associated with a class that was loaded by a `ClassLoader` object. The method returns `true` only if the `currentClassLoader()` method does not return `null`.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`

Compiler

Name

Compiler

Synopsis

Class Name:

```
java.lang.Compiler
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Compiler` class encapsulates a facility for compiling Java classes to native code. As provided by Sun, the methods of this class do not actually do anything. However, if the system property `java.compiler` has been defined and if the method `System.loadLibrary()` is able to load the library named by the property, the methods of this class use the implementations provided in the library.

The `Compiler` class has no `public` constructors, so it cannot be instantiated.

Class Summary

```
public final class java.lang.Compiler extends java.lang.Object {
    // Class Methods
    public static native Object command(Object any);
    public static native boolean compileClass(Class clazz);
    public static native boolean compileClasses(String string);
    public static native void disable();
    public static native void enable();
}
```

Class Methods

command

`public static native Object command(Object any)`

Parameters

`any`

The permissible value and its meaning is determined by the compiler library.

Returns

A value determined by the compiler library, or `null` if no compiler library is loaded.

Description

This method directs the compiler to perform an operation specified by the given argument. The available operations, if any, are determined by the compiler library.

compileClass

`public static native boolean compileClass(Class clazz)`

Parameters

`clazz`

The class to be compiled to native code.

Returns

`true` if the compilation succeeds, or `false` if the compilation fails or no compiler library is loaded.

Description

This method requests the compiler to compile the specified class to native code.

compileClasses

`public static native boolean compileClasses(String string)`

Parameters

`string`

A string that specifies the names of the classes to be compiled.

Returns

`true` if the compilation succeeds or `false` if the compilation fails or no compiler library is loaded.

Description

This method requests the compiler to compile all of the classes named in the string.

disable

```
public static native void disable()
```

Description

> This method disables the compiler if one is loaded.

enable

```
public static native void enable()
```

Description

> This method enables the compiler if one is loaded.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

ClassLoader

Name

ClassLoader

Synopsis

Class Name:

> `java.lang.ClassLoader`

Superclass:

> `java.lang.Object`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> JDK 1.0 or later

Description

The `ClassLoader` class provides a mechanism for Java to load classes over a network or from any source other than the local filesystem. The default class-loading mechanism loads classes from files found relative to directories specified by the `CLASSPATH` environment variable. This default mechanism does not use an instance of the `ClassLoader` class.

An application can implement another mechanism for loading classes by declaring a subclass of the `abstract ClassLoader` class. A subclass of `ClassLoader` must override the `loadClass()` to define a class-loading policy.

This method implements any sort of security that is necessary for the class-loading mechanism. The other methods of ClassLoader are final, so they cannot be overridden.

A ClassLoader object is typically used by calling its loadClass() method to explicitly load a top-level class, such as a subclass of Applet. The ClassLoader that loads the class becomes associated with the class; it can be obtained by calling the getClassLoader() method of the Class object that represents the class.

Once a class is loaded, it must be resolved before it can be used. Resolving a class means ensuring that all of the other classes it references are loaded. In addition, all of the classes that they reference must be loaded, and so on, until all of the needed classes have been loaded. Classes are resolved using the resolveClass() method of the ClassLoader object that loaded the initial class. This means that when a ClassLoader object is explicitly used to load a class, the same ClassLoader is used to load all of the classes that it references, directly or indirectly.

Classes loaded using a ClassLoader object may attempt to load additional classes without explicitly using a ClassLoader object. They can do this by calling the Class class' forName() method. However, in such a situation, a ClassLoader object is implicitly used. See the description of Class.forName() for more information.

Java identifies a class by a combination of its fully qualified name and the class loader that was used to load the class. If you write a subclass of ClassLoader, it should not attempt to directly load local classes. Instead, it should call findSystemClass(). A local class that is loaded directly by a ClassLoader is considered to be a different class than the same class loaded by findSystemClass(). This can lead to having two copies of the same class loaded, which can cause a number of inconsistencies. For example, the class' equals() method may decide that the same object is not equal to itself.

Class Summary

```
public abstract class java.lang.ClassLoader extends java.lang.Object {
    // Constructors
    protected ClassLoader();
    // Class Methods
    public static final URL
           getSystemResource(String name);                  // New in 1.1
    public static final InputStream
           getSystemResourceAsStream(String name);          // New in 1.1
    // Public Instance Methods
    public URL getResource(String name);                    // New in 1.1
    public InputStream getResourceAsStream(String name);    // New in 1.1
    public Class loadClass(String name);                    // New in 1.1

    // Protected Instance Methods
    protected final Class defineClass(byte data[],
              int offset, int length);               // Deprecated in 1.1
    protected final Class defineClass(String name,
              byte[] data, int offset, int length);         // New in 1.1
    protected final Class findLoadedClass(String name);     // New in 1.1
    protected final Class findSystemClass(String name);
    protected abstract Class loadClass(String name, boolean resolve);
    protected final void resolveClass(Class c);
    protected final void setSigners(Class cl,
              Object[] signers);                            // New in 1.1
}
```

Constructors

ClassLoader

`protected ClassLoader()`

Throws

`SecurityException`

If there is a `SecurityManager` object installed and its `checkCreateClassLoader()` method throws a `SecurityException` when called by this constructor.

Description

Initializes a `ClassLoader` object. Because `ClassLoader` is an `abstract` class, only subclasses of the class can access this constructor.

Class Methods

getSystemResource

`public static final URL getSystemResource(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A system resource name.

Returns

A `URL` object that is connected to the specified system resource or `null` if the resource cannot be found.

Description

This method finds a system resource with the given name and returns a `URL` object that is connected to the resource. The resource name can be any system resource.

getSystemResourceAsStream

`public static final InputStream getSystemResourceAsStream(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A system resource name.

Returns

An `InputStream` object that is connected to the specified system resource or `null` if the resource cannot be found.

Description

This method finds a system resource with the given name and returns an `InputStream` object that is connected to the resource. The resource name can be any system resource.

Public Instance Methods

getResource

`public URL getResource(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

A `URL` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name and returns a `URL` object that is connected to the resource.

A resource is a file that contains data (e.g., sound, images, text) and it can be part of a package. The name of a resource is a sequence of identifiers separated by "`/`". For example, a resource might have the name *help/american/logon.html* . System resources are found on the host machine using the conventions of the host implementation. For example, the "/" in the resource name may be treated as a path separator, with the entire resource name treated as a relative path to be found under a directory in `CLASSPATH`.

The implementation of `getResource()` in `ClassLoader` simply returns `null`. A subclass can override this method to provide more useful functionality.

getResourceAsStream

`public InputStream getResourceAsStream(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

An `InputStream` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name and returns an `InputStream` object that is connected to the resource.

A resource is a file that contains data (e.g., sound, images, text) and it can be part of a package. The name of a resource is a sequence of identifiers separated by `/'. For example, a resource might have the name *help/american/logon.html*. System resources are found on the host machine using the conventions of the host implementation. For example, the `/' in the resource name may be treated as a path separator, with the entire resource name treated as a relative path to be found under a directory in `CLASSPATH`.

The implementation of `getResourceAsStream()` in `ClassLoader` simply returns `null`. A subclass can override this method to provide more useful functionality.

loadClass

public Class loadClass(String name) throws ClassNotFoundException

Availability

New as of JDK 1.1

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

Returns

The `Class` object for the specified class.

Throws

`ClassNotFoundException`

If it cannot find a definition for the named class.

Description

This method loads the named class by calling `loadClass(name, true)`.

Protected Instance Methods

defineClass

```
protected final Class defineClass(byte data[], int offset, int length)
```

Availability

Deprecated as of JDK 1.1

Parameters

`data`

An array that contains the byte codes that define a class.

`offset`

The offset in the array of byte codes.

`length`

The number of byte codes in the array.

Returns

The newly created `Class` object.

Throws

`ClassFormatError`

If the `data` array does not constitute a valid class definition.

Description

This method creates a `Class` object from the byte codes that define the class. Before the class can be used, it must be resolved. The method is intended to be called from an implementation of the `loadClass()` method.

Note that this method is deprecated as of Java 1.1. You should use the version of `defineClass()` that takes a `name` parameter and is therefore more secure.

`protected final Class defineClass(String name, byte data[], int offset, int length)`

Availability

New as of JDK 1.1

Parameters

`name`

The expected name of the class to be defined or `null` if it is not known. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

`data`

An array that contains the byte codes that define a class.

`offset`

The offset in the array of byte codes.

`length`

The number of byte codes in the array.

Returns

The newly created `Class` object.

Throws

`ClassFormatError`

If the `data` array does not constitute a valid class definition.

Description

This method creates a `Class` object from the byte codes that define the class. Before the class can be used, it must be resolved. The method is intended to be called from an implementation of the `loadClass()` method.

findLoadedClass

`protected final Class findLoadedClass(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

Returns

The `Class` object for the specified loaded class or `null` if the class cannot be found.

Description

This method finds the specified class that has already been loaded.

findSystemClass

`protected final Class findSystemClass(String name) throws ClassNotFoundException`

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

Returns

The `Class` object for the specified system class.

Throws

`ClassNotFoundException`

If the default class-loading mechanism cannot find a definition for the class.

`NoClassDefFoundError`

If the default class-loading mechanism cannot find the class.

Description

This method finds and loads a system class if it has not already been loaded. A *system class* is a class that is loaded by the default class-loading mechanism from the local filesystem. An implementation of the `loadClass()` method typically calls this method to attempt to load a class from the locations specified by the `CLASSPATH` environment variable.

loadClass

`protected abstract Class loadClass(String name, boolean resolve) throws ClassNotFoundException`

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

`resolve`

Specifies whether or not the class should be resolved by calling the `resolveClass()` method.

Returns

The `Class` object for the specified class.

Throws

`ClassNotFoundException`

If it cannot find a definition for the named class.

Description

An implementation of this `abstract` method loads the named class and returns its `Class` object. It is permitted and encouraged for an implementation to cache the classes it loads, rather than load one each time the method is called. An implementation of this method should do at least the following:

1. Load the byte codes that comprise the class definition into a `byte[]`.
2. Call the `defineClass()` method to create a `Class` object to represent the class definition.
3. If the `resolve` parameter is `true`, call the `resolveClass()` method to resolve the class.

If an implementation of this method caches the classes that it loads, it is recommended that it use an instance of the `java.util.Hashtable` to implement the cache.

resolveClass

```
protected final void resolveClass(Class c)
```

Parameters

`c`

The `Class` object for the class to be resolved.

Description

This method resolves the given `Class` object. Resolving a class means ensuring that all of the other classes that the `Class` object references are loaded. In addition, all of the classes that they reference must be loaded, and so on, until all of the needed classes have been loaded.

The `resolveClass()` method should be called by an implementation of the `loadClass()` method when the value of the `loadClass()` method's `resolve` parameter is `true`.

setSigners

```
protected final void setSigners(Class cl, Object[] signers)
```

Availability

New as of JDK 1.1

Parameters

`cl`

The `Class` object for the class to be signed.

`signers`

An array of `Object`s that represents the signers of this class.

Description

This method specifies the objects that represent the digital signatures for this class.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

8.4 Data Transfer with Cut-and-Paste

Java 1.1 adds cut-and-paste capabilities to Java applications through the classes and interfaces of the `java.awt.datatransfer` package. The `DataFlavor` class is perhaps the most central of these classes. It represents the type of data to be transferred. Every data flavor consists of a human-readable name and a data type specification. The data type can be specified in one of two ways: with a Java `Class` object or with a MIME type string. These two different ways of specifying the data type reflect two different ways of transferring the data. When the data type is specified as a class object, objects of that type are transferred using the object serialization mechanism (which is discussed in Chapter 9, *Object Serialization*). In Example 8.1, for example, the `DataFlavor` is specified using the `Class` object for `java.util.Vector`. This means that data is transferred as a serialized `Vector` object. It also means that the `DataFlavor` object has an implicit MIME type of:

```
application/x-java-serialized-object; class=java.util.Vector
```

The data type of a `DataFlavor` can also be specified as a MIME type. In this case, data is transferred through a stream--the recipient of the data receives a `Reader` stream from which it can read textual data. In this case, the recipient usually has to parse the data according to the rules of the specified MIME type.

The `Transferable` interface is another important piece of the AWT data transfer picture. This interface specifies methods that must be implemented by any object that wants to make data available for transfer. One of its methods returns an array of all the `DataFlavor` types it can use to transfer its data. Another method checks whether the `Transferable` object supports a given method. The most important method, `getTransferData()`, actually returns the data in a format appropriate for the requested `DataFlavor`.

While `DataFlavor` and `Transferable` provide the underlying infrastructure for data transfer, it is the `Clipboard` class and `ClipboardOwner` interface that support the cut-and-paste style of data transfer. A typical cut-and-paste scenario works like this:

- When the user issues a command to "copy" or "cut" something, the initiating application first obtains the system `Clipboard` object by calling the `getSystemClipboard()` method of the `Toolkit` object. Next, it creates a `Transferable` object that represents the data to be transferred. Finally, it passes this transferable object to the clipboard by calling the `setContents()` method of the clipboard. The initiating application must also pass an object that implements the `ClipboardOwner` interface to `setContents()`. By doing so, it becomes the "clipboard owner" and must maintain its `Transferable` object until it ceases to be the clipboard owner.

- When the user issues a command to "paste," the receiving application first obtains the system `Clipboard` object in the same way that the initiating application did. Then, it calls the `getContents()` method of the system clipboard to receive the `Transferable` object stored there. Now it can use the methods defined by the `Transferable` interface to choose a `DataFlavor` for the data transfer and actually transfer the data.
- When the user copies or cuts some other piece of data, a new data transfer is initiated, and the new initiating application (it may be the same one) becomes the new clipboard owner. The previous owner is notified that it is no longer the clipboard owner when the system invokes the `lostOwnership()` method of the `ClipboardOwner` object specified in the initiating call to `setContents()`.

Note that untrusted applets are not allowed to work with the system clipboard because there might be sensitive data on it from other applications. This means that applets cannot participate in inter-application cut-and-paste. Instead, an applet must create a private clipboard object that it can use for intra-applet data transfer.

The `cut()`, `copy()`, and `paste()` methods of Example 8.1 implement cut-and-paste functionality for scribbled lines. They rely on the nested `SimpleSelection` class that implements the `Transferable` and `ClipboardOwner` interfaces. Note the definition of a `DataFlavor` object that serves to specify the type of data transfer. [1]

[1] Although the example application uses the system clipboard, scribbles can only be pasted between windows of the same application, not between separate instances of the application running in separate Java interpreters. In Java 1.1.1, inter-application cut-and-paste only works with the pre-defined `DataFlavor.stringFlavor` and `DataFlavor.textFlavor` data flavors. Custom types like the one used in the example do not correctly interface with the system clipboard.

Printing BOOK INDEX New Feature Demo

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9. Object Serialization

Contents:

Object serialization is one of the important new features of Java 1.1. Despite its importance, however, serialization is done with a very simple API. This chapter demonstrates several uses of serialization.

9.1 Simple Serialization

Objects are serialized with the `ObjectOutputStream` and they are deserialized with the `ObjectInputStream`. Both of these classes are part of the `java.io` package, and they function, in many ways, like `DataOutputStream` and `DataInputStream` because they define the same methods for writing and reading binary representations of Java primitive types to and from streams. What `ObjectOutputStream` and `ObjectInputStream` add, however, is the ability to write and read non-primitive object and array values to and from a stream.

An object is serialized by passing it to the `writeObject()` method of an `ObjectOutputStream`. This writes out the values of all of its fields, including private fields and fields inherited from superclasses. The values of primitive fields are simply written to the stream as they would be with a `DataOutputStream`. When a field in an object refers to another object, an array, or a string, however, the `writeObject()` method is invoked recursively to serialize that object as well. If that object (or an array element) refers to another object, `writeObject()` is again invoked recursively. Thus, a single call to `writeObject()` may result in an entire "object graph" being serialized. When two or more objects each refer to the other, the serialization algorithm is careful to only output each object once--`writeObject()` cannot enter infinite recursion.

Deserializing an object simply follows the reverse of this process. An object is read from a stream of data by calling the `readObject()` method of an `ObjectInputStream`. This re-creates the object in the state it was in when serialized. If the object refers to other objects, they are recursively deserialized as well.

This ability to serialize an entire graph of objects and read those objects back in later is a very powerful feature that hides itself in two simple looking methods. We used object serialization in Example 8.1, but unless you were paying attention, you might have missed those crucial `writeObject()` and `readObject()` calls. Serialization is used in that `Scribble` example to give the program an automatic file format for saving the user's scribbles.

To refresh your memory, Example 9.1 shows the `save()` method of that application. Note the creation of the `ObjectOutputStream` and the use of the `writeObject()` method. The corresponding `load()` method simply reverses the streams to read the scribble back in. You may want to refer to the complete example in Chapter 8, *New AWT Features* to examine the `save()` and `load()` methods in context. Also note the use of a `GZIPOutputStream` (from `java.util.zip`) to compress the serialized object data before writing it to disk.

Example 9.1: Using Serialized Objects as an Application File Format

```
/**
 * Prompt the user for a filename, and save the scribble in that file.
 * Serialize the vector of lines with an ObjectOutputStream.
 * Compress the serialized objects with a GZIPOutputStream.
 * Write the compressed, serialized data to a file with a FileOutputStream.
 * Don't forget to flush and close the stream.
 */
public void save() {
  // Create a file dialog to query the user for a filename.
  FileDialog f = new FileDialog(frame, "Save Scribble", FileDialog.SAVE);
  f.show();                        // Display the dialog and block.
  String filename = f.getFile();   // Get the user's response
  if (filename != null) {          // If user didn't click "Cancel."
    try {
      // Create the necessary output streams to save the scribble.
      FileOutputStream fos = new FileOutputStream(filename);  // Save to file.
      GZIPOutputStream gzos = new GZIPOutputStream(fos);      // Compress.
      ObjectOutputStream out = new ObjectOutputStream(gzos);  // Save objects
      out.writeObject(lines);      // Write the entire Vector of scribbles.
      out.flush();                 // Always flush the output.
      out.close();                 // And close the stream.
    }
    // Print out exceptions.  We should really display them in a dialog...
    catch (IOException e) { System.out.println(e); }
  }
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

12.2 Invoking a Named Method

Example 12.2 demonstrates another use of the Reflection API. This `UniversalActionListener` object uses reflection to invoke a named method of a specified object, passing another optionally specified object as an argument. It does this in the framework of the `ActionListener` interface, so that it can serve as an action listener within a Java 1.1 GUI. By using the reflection capabilities of the `UniversalActionListener`, a program can avoid having to create a lot of trivial `ActionListener` implementations to handle action events. The `main()` method at the end of this example is a simple test GUI that demonstrates how you could use the `UniversalActionListener` object. Contrast it with the anonymous class event-handling techniques demonstrated in Chapter 7, *Events*.

Java does not allow methods to be passed directly as data values, but the Reflection API makes it possible for methods passed by name to be invoked indirectly. Note that this technique is not particularly efficient. For asynchronous event handling in a GUI, though, it is certainly efficient enough: indirect method invocation through the Reflection API will always be much faster than the response time required by the limits of human perception. Invoking a method by name is not an appropriate technique, however, when repetitive, synchronous calls are required. Thus, you should not use this technique for passing a comparison method to a sorting routine or passing a filename filter to a directory listing method. In cases like these, you should use the standard technique of implementing a class that contains the desired method and passing an instance of the class to the appropriate routine.

Example 12.2: Invoking a Named Method with Reflection

```
import java.awt.event.*;
import java.lang.reflect.*;
import java.awt.*;   // Only used for the test program below.
public class UniversalActionListener implements ActionListener {
  protected Object target;
  protected Object arg;
  protected Method m;
  public UniversalActionListener(Object target, String methodname, Object arg)
       throws NoSuchMethodException, SecurityException
  {
    this.target = target;                            // Save the target object.
    this.arg = arg;                                  // And method argument.
    // Now look up and save the Method to invoke on that target object.
    Class c, parameters[];
    c = target.getClass();                           // The Class object.
    if (arg == null) parameters = new Class[0];      // Method parameter.
    else parameters = new Class[] { arg.getClass() };
    m = c.getMethod(methodname, parameters);         // Find matching method.
  }
  public void actionPerformed(ActionEvent event) {
    Object[] arguments;
    if (arg == null) arguments = new Object[0];      // Set up arguments.
    else arguments = new Object[] { arg };
    try { m.invoke(target, arguments); }             // And invoke the method.
    catch (IllegalAccessException e) {               // Should never happen.
      System.err.println("UniversalActionListener: " + e);
    } catch (InvocationTargetException e) {          // Should never happen.
      System.err.println("UniversalActionListener: " + e);
    }
  }
  // A simple test program for the UniversalActionListener.
  public static void main(String[] args) throws NoSuchMethodException {
    Frame f = new Frame("UniversalActionListener Test");// Create window.
    f.setLayout(new FlowLayout());                      // Set layout manager.
    Button b1 = new Button("tick");                     // Create buttons.
    Button b2 = new Button("tock");
    Button b3 = new Button("Close Window");
    f.add(b1); f.add(b2); f.add(b3);                    // Add them to window.
    // Specify what the buttons do.  Invoke a named method with
    // the UniversalActionListener object.
    b1.addActionListener(new UniversalActionListener(b1, "setLabel", "tock"));
    b1.addActionListener(new UniversalActionListener(b2, "setLabel", "tick"));
    b1.addActionListener(new UniversalActionListener(b3, "hide", null));
    b2.addActionListener(new UniversalActionListener(b1, "setLabel", "tick"));
    b2.addActionListener(new UniversalActionListener(b2, "setLabel", "tock"));
    b2.addActionListener(new UniversalActionListener(b3, "show", null));
    b3.addActionListener(new UniversalActionListener(f, "dispose", null));
    f.pack();                                             // Set window size.
    f.show();                                             // And pop it up.
  }
}
```

32. Class, Method, and Field Index

The following index allows you to look up a class or interface and find out what package it is defined in. It also allows you to look up a method or field and find out what class it is defined in. Use it when you want to look up a class but don't know its package, or want to look up a method but don't know its class.

`addFocusListener()`

java.awt.Component (JDK 1.0)

`addHelpMenu()`

java.awt.peer.MenuBarPeer (JDK 1.0)

`addImage()`

java.awt.MediaTracker (JDK 1.0)

`addImpl()`

java.awt.Container (JDK 1.0), java.awt.ScrollPane (JDK 1.1)

`addInternal()`

java.awt.AWTEventMulticaster (JDK 1.1)

`addItem()`

java.awt.Choice (JDK 1.0), java.awt.peer.ChoicePeer (JDK 1.0), java.awt.List (JDK 1.0), java.awt.peer.ListPeer (JDK 1.0), java.awt.peer.MenuPeer (JDK 1.0)

`addItemListener()`

java.awt.Checkbox (JDK 1.0), java.awt.CheckboxMenuItem (JDK 1.0), java.awt.Choice (JDK 1.0), java.awt.ItemSelectable (JDK 1.1), java.awt.List (JDK 1.0)

`addKeyListener()`

java.awt.Component (JDK 1.0)

`addLayoutComponent()`

java.awt.BorderLayout (JDK 1.0), java.awt.CardLayout (JDK 1.0), java.awt.FlowLayout (JDK 1.0), java.awt.GridBagLayout (JDK 1.0), java.awt.GridLayout (JDK 1.0), java.awt.LayoutManager (JDK 1.0), java.awt.LayoutManager2 (JDK 1.1)

`addMenu()`

java.awt.peer.MenuBarPeer (JDK 1.0)

`addMouseListener()`

java.awt.Component (JDK 1.0)

`addMouseMotionListener()`

java.awt.Component (JDK 1.0)

`addNotify()`

java.awt.Button (JDK 1.0), java.awt.Canvas (JDK 1.0), java.awt.Checkbox (JDK 1.0), java.awt.CheckboxMenuItem (JDK 1.0), java.awt.Choice (JDK 1.0), java.awt.Component (JDK 1.0), java.awt.Container (JDK 1.0), java.awt.Dialog (JDK 1.0), java.awt.FileDialog (JDK 1.0), java.awt.Frame (JDK 1.0), java.awt.Label (JDK 1.0), java.awt.List (JDK 1.0), java.awt.Menu (JDK 1.0), java.awt.MenuBar (JDK 1.0), java.awt.MenuItem (JDK 1.0), java.awt.Panel (JDK 1.0), java.awt.PopupMenu (JDK 1.1), java.awt.Scrollbar (JDK 1.0), java.awt.ScrollPane (JDK 1.1), java.awt.TextArea (JDK 1.0), java.awt.TextField (JDK 1.0), java.awt.Window (JDK 1.0)

`addObserver()`

java.util.Observable (JDK 1.0)

`addPoint()`

java.awt.Polygon (JDK 1.0)

`addPropertyChangeListener()`

java.beans.Customizer (JDK 1.1), java.beans.PropertyChangeSupport (JDK 1.1), java.beans.PropertyEditor (JDK 1.1), java.beans.PropertyEditorSupport (JDK 1.1)

`address`

java.net.SocketImpl (JDK 1.0)

addSeparator()

java.awt.Menu (JDK 1.0), java.awt.peer.MenuPeer (JDK 1.0)

addTextListener()

java.awt.TextComponent (JDK 1.0)

addVetoableChangeListener()

java.beans.VetoableChangeSupport (JDK 1.1)

addWindowListener()

java.awt.Window (JDK 1.0)

Adjustable

The java.awt Package

AdjustForGravity()

java.awt.GridBagLayout (JDK 1.0)

ADJUSTMENT_EVENT_MASK

java.awt.AWTEvent (JDK 1.1)

ADJUSTMENT_FIRST

java.awt.event.AdjustmentEvent (JDK 1.1)

ADJUSTMENT_LAST

java.awt.event.AdjustmentEvent (JDK 1.1)

ADJUSTMENT_VALUE_CHANGED

java.awt.image.ImageConsumer (JDK 1.0)

`Component`

The java.awt Package

`COMPONENT_ADDED`

java.awt.event.ContainerEvent (JDK 1.1)

`COMPONENT_EVENT_MASK`

java.awt.AWTEvent (JDK 1.1)

`COMPONENT_FIRST`

java.awt.event.ComponentEvent (JDK 1.1)

`COMPONENT_HIDDEN`

java.awt.event.ComponentEvent (JDK 1.1)

`COMPONENT_LAST`

java.awt.event.ComponentEvent (JDK 1.1)

`COMPONENT_MOVED`

java.awt.event.ComponentEvent (JDK 1.1)

`COMPONENT_REMOVED`

java.awt.event.ContainerEvent (JDK 1.1)

`COMPONENT_RESIZED`

java.awt.event.ComponentEvent (JDK 1.1)

`COMPONENT_SHOWN`

createCheckboxMenuItem()

java.awt.Toolkit (JDK 1.0)

createChoice()

java.awt.Toolkit (JDK 1.0)

createComponent()

java.awt.Toolkit (JDK 1.0)

createContentHandler()

java.net.ContentHandlerFactory (JDK 1.0)

createDialog()

java.awt.Toolkit (JDK 1.0)

createFileDialog()

java.awt.Toolkit (JDK 1.0)

createFrame()

java.awt.Toolkit (JDK 1.0)

createImage()

java.awt.Component (JDK 1.0), java.awt.peer.ComponentPeer (JDK 1.0), java.awt.Toolkit (JDK 1.0)

createLabel()

java.awt.Toolkit (JDK 1.0)

createList()

`delMenu()`

java.awt.peer.MenuBarPeer (JDK 1.0)

`deselect()`

java.awt.List (JDK 1.0), java.awt.peer.ListPeer (JDK 1.0)

`DESELECTED`

java.awt.event.ItemEvent (JDK 1.1)

`desktop`

java.awt.SystemColor (JDK 1.1)

`DESKTOP`

java.awt.SystemColor (JDK 1.1)

`destHeight`

java.awt.image.ReplicateScaleFilter (JDK 1.1)

`destroy()`

java.applet.Applet (JDK 1.0), java.lang.Process (JDK 1.0), java.lang.Thread (JDK 1.0), java.lang.ThreadGroup (JDK 1.0)

`destWidth`

java.awt.image.ReplicateScaleFilter (JDK 1.1)

`detail`

java.io.WriteAbortedException (JDK 1.1)

`Dialog`

`enableEvents()`

java.awt.Component (JDK 1.0), java.awt.MenuItem (JDK 1.0)

`enableReplaceObject()`

java.io.ObjectOutputStream (JDK 1.1)

`enableResolveObject()`

java.io.ObjectInputStream (JDK 1.1)

`ENCLOSING_MARK`

java.lang.Character (JDK 1.0)

`encode()`

java.net.URLEncoder (JDK 1.0)

`END`

java.awt.Event (JDK 1.0)

`end()`

java.util.zip.Deflater (JDK 1.1), java.util.zip.Inflater (JDK 1.1), java.awt.PrintJob (JDK 1.1)

`END_PUNCTUATION`

java.lang.Character (JDK 1.0)

`endsWith()`

java.lang.String (JDK 1.0)

`endValidate()`

java.awt.peer.ContainerPeer (JDK 1.0)

java.awt.image.ColorModel (JDK 1.0), java.util.zip.Deflater (JDK 1.1), java.io.FileInputStream (JDK 1.0), java.io.FileOutputStream (JDK 1.0), java.awt.Graphics (JDK 1.0), java.util.zip.Inflater (JDK 1.1), java.lang.Object (JDK 1.0), java.awt.PrintJob (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

31.17 java.util.zip.ZipOutputStream (JDK 1.1)

This class is a subclass of `DeflaterOutputStream` that writes data in ZIP file format to an output stream. Before writing any data to the `ZipOutputStream`, you must begin an entry within the ZIP file with `putNextEntry()`. The `ZipEntry` object passed to this method should specify at least a name for the entry. Once you have begun an entry with `putNextEntry()`, you can write the contents of that entry with the `write()` methods. When you reach the end of an entry, you can begin a new one by calling `putNextEntry()` again, or you can close the current entry with `closeEntry()`, or you can close the stream itself with `close()`.

Before beginning an entry with `putNextEntry()`, you can set the compression method and level with `setMethod()` and `setLevel()`. The constants `DEFLATED` and `STORED` are the two legal values for `setMethod()`. If you use `STORED`, the entry is stored in the ZIP file without any compression. If you use `DEFLATED`, you can also specify the compression speed/strength trade-off by passing a number from 1 to 9 to `setLevel()`, where 9 gives the strongest and slowest level of compression. You can also use the constants `Deflater.BEST_SPEED`, `Deflater.BEST_COMPRESSION`, and `Deflater.DEFAULT_COMPRESSION` with the `setLevel()` method.

Note that if you are simply storing an entry without compression, the ZIP file format requires that you specify, in advance, the entry size and CRC-32 checksum in the `ZipEntry` object for the entry. An exception is thrown if these values are not specified or are incorrectly specified.

```
public class ZipOutputStream extends DeflaterOutputStream {
    // Public Constructor
            public ZipOutputStream(OutputStream out);
    // Constants
            public static final int DEFLATED;
            public static final int STORED;
    // Public Instance Methods
            public void close() throws IOException;  // Overrides 
DeflaterOutputStream
            public void closeEntry() throws IOException;
            public void finish() throws IOException;  // Overrides 
DeflaterOutputStream
            public void putNextEntry(ZipEntry e) throws IOException;
            public void setComment(String comment);
            public void setLevel(int level);
            public void setMethod(int method);
            public synchronized void write(byte[] b, int off, int len) throws
IOException;  // Overrides DeflaterOutputStream
}

18.3 java.awt.AWTEventMulticaster (JDK 1.1)

`AWTEventMulticaster` is a convenience class used when writing a custom AWT component. It provides an easy way to maintain a list of AWT `EventListener` objects, and to notify the listeners on that list when an event occurs.

`AWTEventMulticaster` implements each of the event listener interfaces defined in the `java.awt.event` package, which means that an `AWTEventMulticaster` object can serve as any desired type of event listener. (It also means, as you can see below, that the class defines quite a few methods.) `AWTEventMulticaster` implements what amounts to a linked list of `EventListener` objects. When you invoke one of the `EventListener` methods of an `AWTEventMulticaster`, it invokes the same method on all of the `EventListener` objects in the linked list.

Rather than instantiate an `AWTEventMulticaster` object directly, you use the static `add()` and `remove()` methods of the class to add and remove `EventListener` objects from the linked list. Doing so returns an `AWTEventMulticaster` with the appropriate `EventListener` object registered. The API for using an `AWTEventMulticaster` is somewhat non-intuitive. Here is some example code that shows its use:

```
public class MyList extends Component {   // a class that sends ItemEvents
  // this will be the head of a linked list of AWTEventMulticaster objects
  protected ItemListener listener = null;
  public void addItemListener(ItemListener l) {      // add a listener
    listener = AWTEventMulticaster.add(listener, l);
  }
  public void removeItemListener(ItemListener l) {   // remove a listener
    listener = AWTEventMulticaster.remove(listener, l);
  }
  protected void fireItemEvent(ItemEvent e) {        // notify all listeners
    if (listener != null) listener.itemStateChanged(e);
  }
  // The rest of the class goes here
}
```

```
public class AWTEvent Multicaster  extends Object
                                   implements ComponentListener, ContainerListener,
FocusListener, KeyListener, MouseListener, MouseMotionListener, WindowListener,
ActionListener,ItemListener, AdjustmentListener, TextListener {
    // Protected Constructor
            protected AWTEventMulticaster(EventListener a, EventListener b);
    // Protected Instance Variables
            protected EventListener a;
            protected EventListener b;
    // Class Methods
```

```
            public static ComponentListener add(ComponentListener a,
ComponentListener b);
            public static ContainerListener add(ContainerListener a,
ContainerListener b);
            public static FocusListener add(FocusListener a, FocusListener b);

AdjustmentListener(EventListener), TextListener(EventListener))
```

21.8 java.awt.image.ImageObserver (JDK 1.0)

This interface defines a method and associated constants used by classes that want to receive information asynchronously about the status of an image. Many methods that query information about an image take an `ImageObserver` as an argument. If the specified information is not available when requested, it is passed to the `ImageObserver` when it becomes available. `Component` implements this interface, and components are the most commonly used image observers.

```
public abstract interface ImageObserver {
    // Constants
            public static final int ABORT;
            public static final int ALLBITS;
            public static final int ERROR;
            public static final int FRAMEBITS;
            public static final int HEIGHT;
            public static final int PROPERTIES;
            public static final int SOMEBITS;
            public static final int WIDTH;
    // Public Instance Methods
            public abstract boolean imageUpdate(Image img, int infoflags, int x, int
y, int width, int height);
}
```

Implemented By:

`Component`

Passed To:

`Component.checkImage(), Component.prepareImage(), ComponentPeer.checkImage(), ComponentPeer.prepareImage(), Graphics.drawImage(), Image.getHeight(), Image.getProperty(), Image.getWidth(), Toolkit.checkImage(), Toolkit.prepareImage()`

18.39 java.awt.MediaTracker (JDK 1.0)

This class provides a very convenient way to asynchronously load and keep track of the status of any number of `Image` objects. You can use it to load one or more images and to wait until those images have been completely loaded and are ready to be used.

The `addImage()` method registers an image to be loaded and tracked and assigns it a specified identifier value. `waitForID()` loads all images that have been assigned the specified identifier and returns when they have all finished loading or it has received an error. `isErrorAny()` and `isErrorID()` check whether any errors have occurred while loading images. `statusAll()` and `statusID()` return the status of all images or of all images with the specified identifier. The return value of these two methods is one of the defined constants.

```
public class MediaTracker extends Object implements Serializable {
    // Public Constructor
            public MediaTracker(Component comp);
    // Constants
            public static final int ABORTED;
            public static final int COMPLETE;
            public static final int ERRORED;
            public static final int LOADING;
    // Public Instance Methods
            public void addImage(Image image, int id);
            public synchronized void addImage(Image image, int id, int w, int h);
            public boolean checkAll();
            public boolean checkAll(boolean load);
            public boolean checkID(int id);
            public boolean checkID(int id, boolean load);
            public synchronized Object[] getErrorsAny();
            public synchronized Object[] getErrorsID(int id);
            public synchronized boolean isErrorAny();
            public synchronized boolean isErrorID(int id);
        1.1  public synchronized void removeImage(Image image);
        1.1  public synchronized void removeImage(Image image, int id);
        1.1  public synchronized void removeImage(Image image, int id, int width, int
height);
            public int statusAll(boolean load);
            public int statusID(int id, boolean load);
            public void waitForAll() throws InterruptedException;
            public synchronized boolean waitForAll(long ms) throws
InterruptedException;
            public void waitForID(int id) throws InterruptedException;

21.12 java.awt.image.PixelGrabber (JDK 1.0)

This class is an `ImageConsumer` that extracts a specified rectangular array of pixels (in the default RGB color model) from a specified `Image` or `ImageProducer` and stores them into a specified array (using the specified offset into the array and specified scanline size). Use this class when you want to inspect or manipulate the data of an image or some rectangular portion of an image.

The method `grabPixels()` makes the `PixelGrabber` start grabbing pixels. `status()` returns the status of the pixel-grabbing process. The return value uses the same flag value constants as the `ImageObserver` class does. The remaining methods are the standard `ImageConsumer` methods and should not be called directly.

```
public class PixelGrabber extends Object implements ImageConsumer {
    // Public Constructors
            public PixelGrabber(Image img, int x, int y, int w, int h, int[] pix, int 
off, int scansize);
            public PixelGrabber(ImageProducer ip, int x, int y, int w, int h, int[] 
pix, int off, int scansize);
        1.1  public PixelGrabber(Image img, int x, int y, int w, int h, boolean 
forceRGB);
    // Public Instance Methods
        1.1  public synchronized void abortGrabbing();
        1.1  public synchronized ColorModel getColorModel();
        1.1  public synchronized int getHeight();
        1.1  public synchronized Object getPixels();
        1.1  public synchronized int getStatus();
        1.1  public synchronized int getWidth();
            public boolean grabPixels() throws InterruptedException;
            public synchronized boolean grabPixels(long ms) throws 
InterruptedException;
            public synchronized void imageComplete(int status);  // From 
ImageConsumer
            public void setColorModel(ColorModel model);  // From ImageConsumer
            public void setDimensions(int width, int height);  // From ImageConsumer

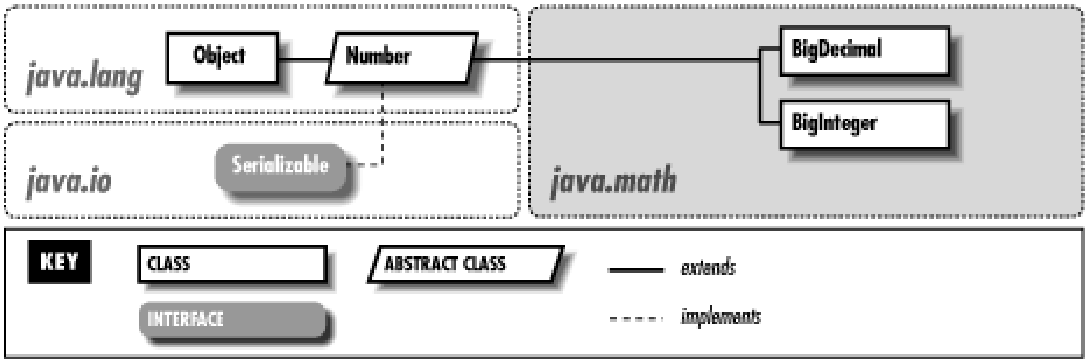
27. The java.math Package

Contents:

The `java.math` package, new in Java 1.1, contains classes for arbitrary-precision integer and floating-point arithmetic. Arbitrary-length integers are required for cryptography, and arbitrary-precision floating-point values are useful for financial applications that need to be careful about rounding errors. The class hierarchy of this extremely small package is shown in Figure 27.1.

Figure 27.1: The java.math package



27.1 java.math.BigDecimal (JDK 1.1)

This subclass of `java.lang.Number` represents a floating-point number of arbitrary size and precision. Its methods duplicate the functionality of the standard Java arithmetic operators. The `compareTo()` method compares the value of two `BigDecimal` objects and returns -1, 0, or 1 to indicate the result of the comparison.

`BigDecimal` objects are represented as an integer of arbitrary size and an integer scale that specifies the number of decimal places in the value. When working with `BigDecimal` values, you can explicitly specify the amount of precision (the number of decimal places) you are interested in. Also, whenever a `BigDecimal` method may discard precision (in a division operation, for example), you are required to specify what sort of rounding should be performed on the digit to the left of the discarded digit or digits. The eight constants defined by this class specify the available rounding modes. Because the `BigDecimal` class provides arbitrary precision and gives you explicit control over rounding and the number of decimal places you are interested in, it can be useful when dealing with quantities that represent money, or in other circumstances where the tolerance for rounding errors is low.

```
public class BigDecimal extends Number {
    // Public Constructors
            public BigDecimal(String val) throws NumberFormatException;
            public BigDecimal(double val) throws NumberFormatException;
            public BigDecimal(BigInteger val);
            public BigDecimal(BigInteger val, int scale) throws
NumberFormatException;
    // Constants
            public static final int ROUND_CEILING;
            public static final int ROUND_DOWN;
            public static final int ROUND_FLOOR;
            public static final int ROUND_HALF_DOWN;
            public static final int ROUND_HALF_EVEN;
            public static final int ROUND_HALF_UP;
            public static final int ROUND_UNNECESSARY;
            public static final int ROUND_UP;
    // Class Methods
            public static BigDecimal valueOf(long val, int scale) throws
NumberFormatException;
            public static BigDecimal valueOf(long val);
    // Public Instance Methods
            public BigDecimal abs();
            public BigDecimal add(BigDecimal val);
            public int compareTo(BigDecimal val);
            public BigDecimal divide(BigDecimal val, int scale, int roundingMode)
throws ArithmeticException, IllegalArgumentException;
            public BigDecimal divide(BigDecimal val, int roundingMode) throws
ArithmeticException, IllegalArgumentException;
            public double doubleValue();  // Defines Number
            public boolean equals(Object x);  // Overrides Object
            public float floatValue();  // Defines Number
            public int hashCode();  // Overrides Object
            public int intValue();  // Defines Number
            public long longValue();  // Defines Number
            public BigDecimal max(BigDecimal val);
            public BigDecimal min(BigDecimal val);
            public BigDecimal movePointLeft(int n);
            public BigDecimal movePointRight(int n);
            public BigDecimal multiply(BigDecimal val);
            public BigDecimal negate();
            public int scale();
            public BigDecimal setScale(int scale, int roundingMode) throws
ArithmeticException, IllegalArgumentException;
            public BigDecimal setScale(int scale) throws ArithmeticException,
IllegalArgumentException;
            public int signum();
            public BigDecimal subtract(BigDecimal val);
            public BigInteger toBigInteger();
            public String toString();  // Overrides Object
}
```

Hierarchy:

Object->Number(Serializable)->BigDecimal

27.2 java.math.BigInteger (JDK 1.1)

This subclass of `java.lang.Number` represents integers that can be arbitrarily large--i.e., integers that are not limited to the 64 bits available with the `long` data type. `BigInteger` defines methods that duplicate the functionality of the standard Java arithmetic and bit-manipulation operators. The `compareTo()` method compares two `BigInteger` objects, and returns -1, 0, or 1 to indicate the result of the comparison.

The `gcd()`, `modPow()`, `modInverse()`, and `isProbablePrime()` methods perform advanced operations and are used primarily in cryptography and related algorithms.

```
public class BigInteger extends Number {
    // Public Constructors
            public BigInteger(byte[] val) throws NumberFormatException;
            public BigInteger(int signum, byte[] magnitude) throws 
NumberFormatException;
            public BigInteger(String val, int radix) throws NumberFormatException;
            public BigInteger(String val) throws NumberFormatException;
            public BigInteger(int numBits, Random rndSrc) throws

java.math.BigDecimal (JDK 1.1) BOOK INDEX The java.net Package

25.37 java.lang.Math (JDK 1.0)

This class defines constants for the mathematical values *e* and pi, and defines static methods for floating-point trigonometry, exponentiation, and other operations. It is the equivalent of the C <*math.h*> functions. It also contains methods for computing minimum and maximum values and for generating pseudo-random numbers.

```
public final class Math extends Object {
    // No Constructor
    // Constants
            public static final double E;
            public static final double PI;
    // Class Methods
            public static native double IEEEremainder(double f1, double f2);
            public static int abs(int a);
            public static long abs(long a);
            public static float abs(float a);
            public static double abs(double a);
            public static native double acos(double a);
            public static native double asin(double a);
            public static native double atan(double a);
            public static native double atan2(double a, double b);
            public static native double ceil(double a);
            public static native double cos(double a);
            public static native double exp(double a);
            public static native double floor(double a);
            public static native double log(double a);
            public static int max(int a, int b);
            public static long max(long a, long b);
            public static float max(float a, float b);
            public static double max(double a, double b);
            public static int min(int a, int b);
            public static long min(long a, long b);
            public static float min(float a, float b);
            public static double min(double a, double b);
            public static native double pow(double a, double b);
            public static synchronized double random();
            public static native double rint(double a);
            public static int round(float a);
            public static long round(double a);

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

26.7 java.lang.reflect.Modifier (JDK 1.1)

This class defines a number of constants and static methods that are used to interpret the integer values returned by the `getModifiers()` methods of the `Field`, `Method`, and `Constructor` classes. The `isPublic()`, `isAbstract()`, and related methods return `true` if the modifiers value includes the specified modifier, otherwise they return `false`.

The constants defined by this class specify the various bit flags used in the modifiers value. You can use these constants to test for modifiers if you want to perform your own boolean algebra.

```
public class Modifier extends Object {
    // Default Constructor: public Modifier()
    // Constants
            public static final int ABSTRACT;
            public static final int FINAL;
            public static final int INTERFACE;
            public static final int NATIVE;
            public static final int PRIVATE;
            public static final int PROTECTED;
            public static final int PUBLIC;
            public static final int STATIC;
            public static final int SYNCHRONIZED;
            public static final int TRANSIENT;
            public static final int VOLATILE;
    // Class Methods
            public static boolean isAbstract(int mod);
            public static boolean isFinal(int mod);
            public static boolean isInterface(int mod);
            public static boolean isNative(int mod);
            public static boolean isPrivate(int mod);
            public static boolean isProtected(int mod);
            public static boolean isPublic(int mod);
            public static boolean isStatic(int mod);
            public static boolean isSynchronized(int mod);
            public static boolean isTransient(int mod);
            public static boolean isVolatile(int mod);
            public static String toString(int mod);
}

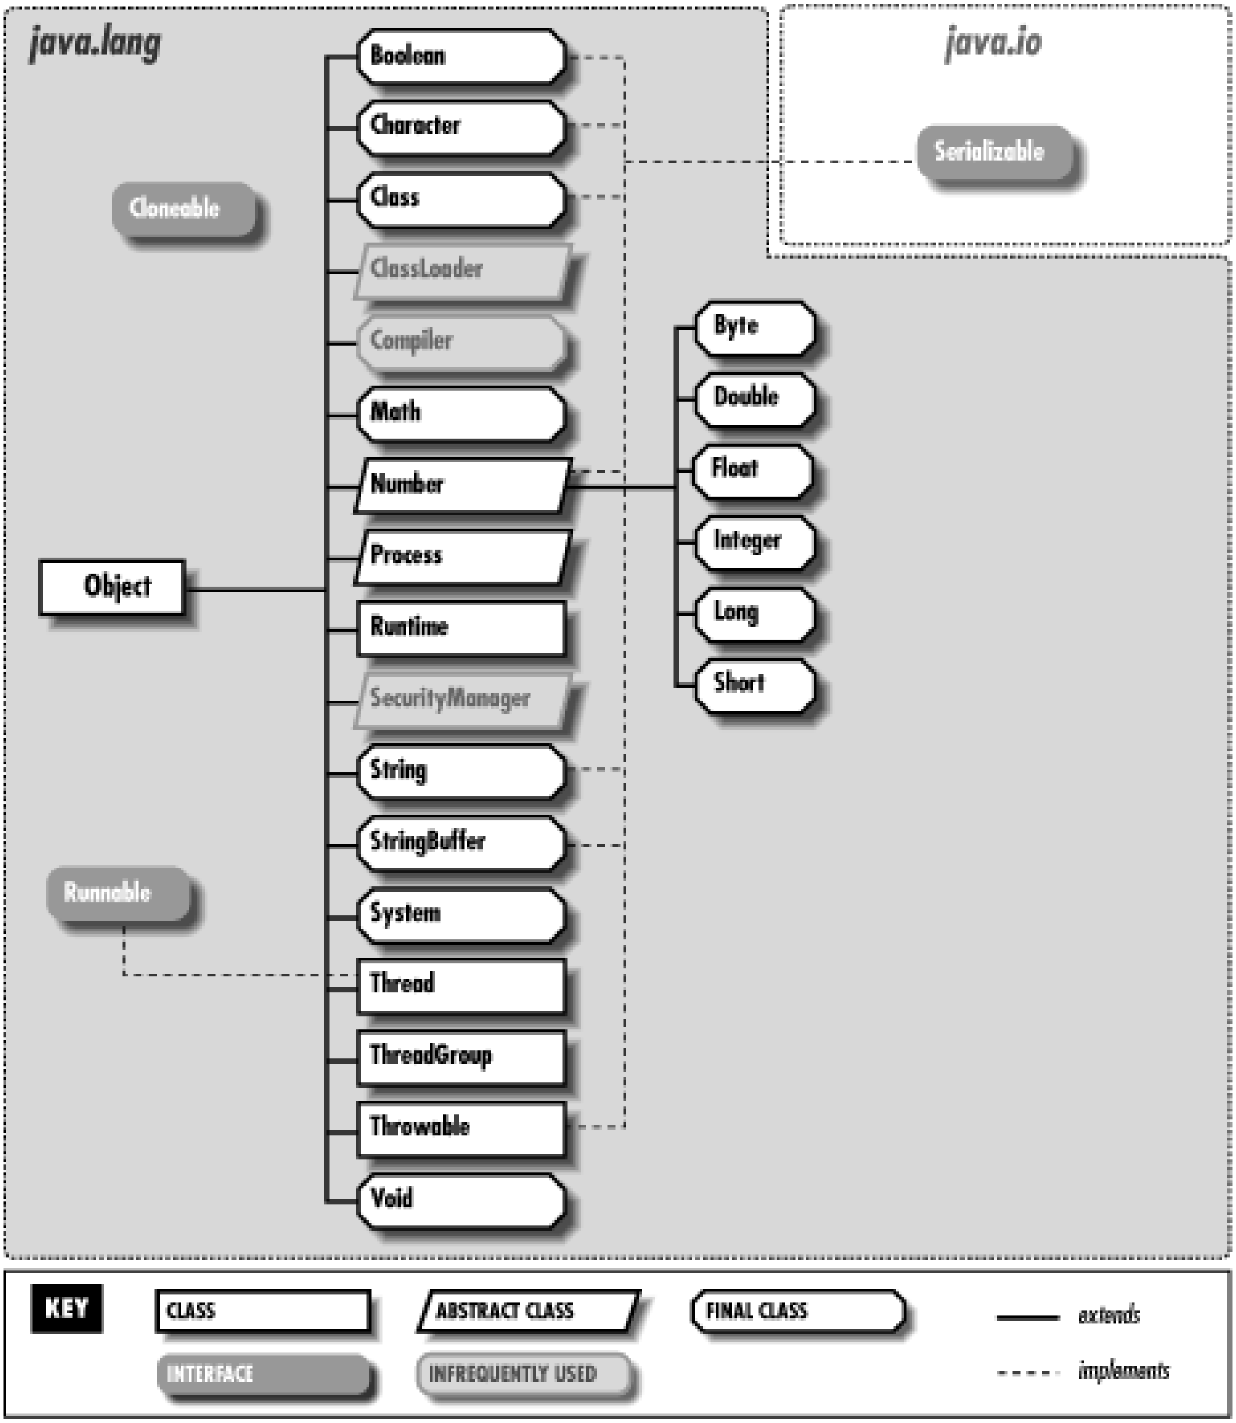
java.lang.Runtime (JDK 1.0)
java.lang.RuntimeException (JDK 1.0)
java.lang.SecurityException (JDK 1.0)
java.lang.SecurityManager (JDK 1.0)
java.lang.Short (JDK 1.1)
java.lang.StackOverflowError (JDK 1.0)
java.lang.String (JDK 1.0)
java.lang.StringBuffer (JDK 1.0)
java.lang.StringIndexOutOfBoundsException (JDK 1.0)
java.lang.System (JDK 1.0)
java.lang.Thread (JDK 1.0)
java.lang.ThreadDeath (JDK 1.0)
java.lang.ThreadGroup (JDK 1.0)
java.lang.Throwable (JDK 1.0)
java.lang.UnknownError (JDK 1.0)
java.lang.UnsatisfiedLinkError (JDK 1.0)

java.lang.VerifyError (JDK 1.0)
java.lang.VirtualMachineError (JDK 1.0)
java.lang.Void (JDK 1.1)

The `java.lang` package contains the classes that are most central to the Java language. As you can see from Figure 25.1, the class hierarchy is broad rather than deep, which means that the classes are independent of each other.

Figure 25.1: The java.lang package



`Object` is the ultimate superclass of all Java classes and is therefore at the top of all class hierarchies. `Class` is a class that describes a Java class. There is one `Class` object for each class that is loaded into Java.

`Boolean`, `Character`, `Byte`, `Short`, `Integer`, `Long`, `Float`, and `Double` are immutable class wrappers around each of the primitive Java data types. These classes are useful when you need to manipulate primitive types as objects. They also contain useful conversion and utility methods.

`String` and `StringBuffer` are objects that represent strings. `String` is an immutable type; `StringBuffer` may have its string changed in place.

`Runtime` provides a number of low-level methods associated with the Java run-time system. `System` provides similar low-level system methods. All the `System` methods are class methods, and this class may not be instantiated. `Math` is a similar class that supports only class methods--its methods provide floating-point math support.

The `Thread` class provides support for multiple threads of control running within the same Java interpreter. `Process` defines a platform-independent interface to platform-dependent processes running externally to the Java interpreter.

`Throwable` is the root class of the exception and error hierarchy. `Throwable` objects are used with the Java `throw` and `catch` statements. `java.lang` defines quite a few subclasses of `Throwable`. `Exception` and `Error` are the superclasses of all exceptions and errors. Figure 25.2 and Figure 25.3 show the class hierarchies for these core Java exceptions and errors.

Figure 25.2: The exception classes in the java.lang package

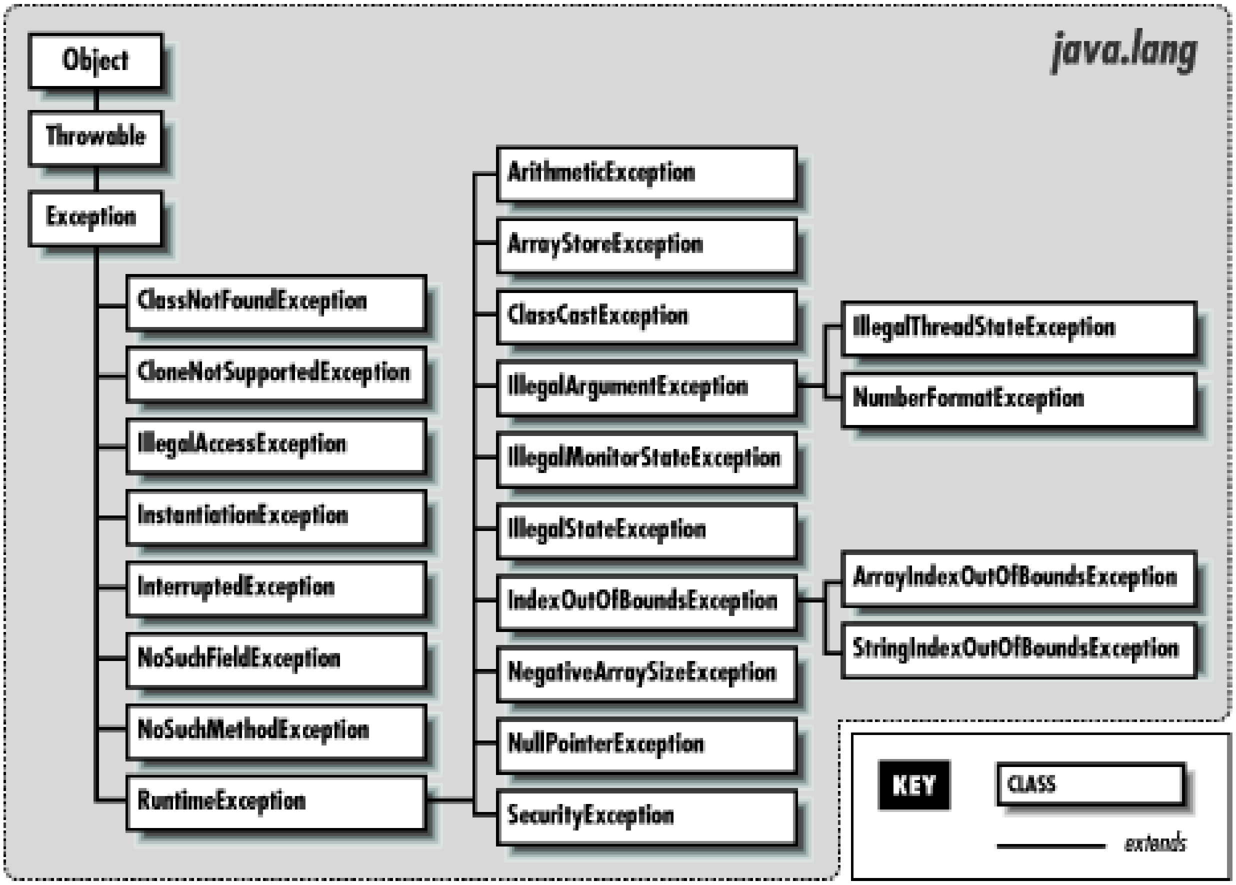


Figure 25.3: The error classes in the java.lang package

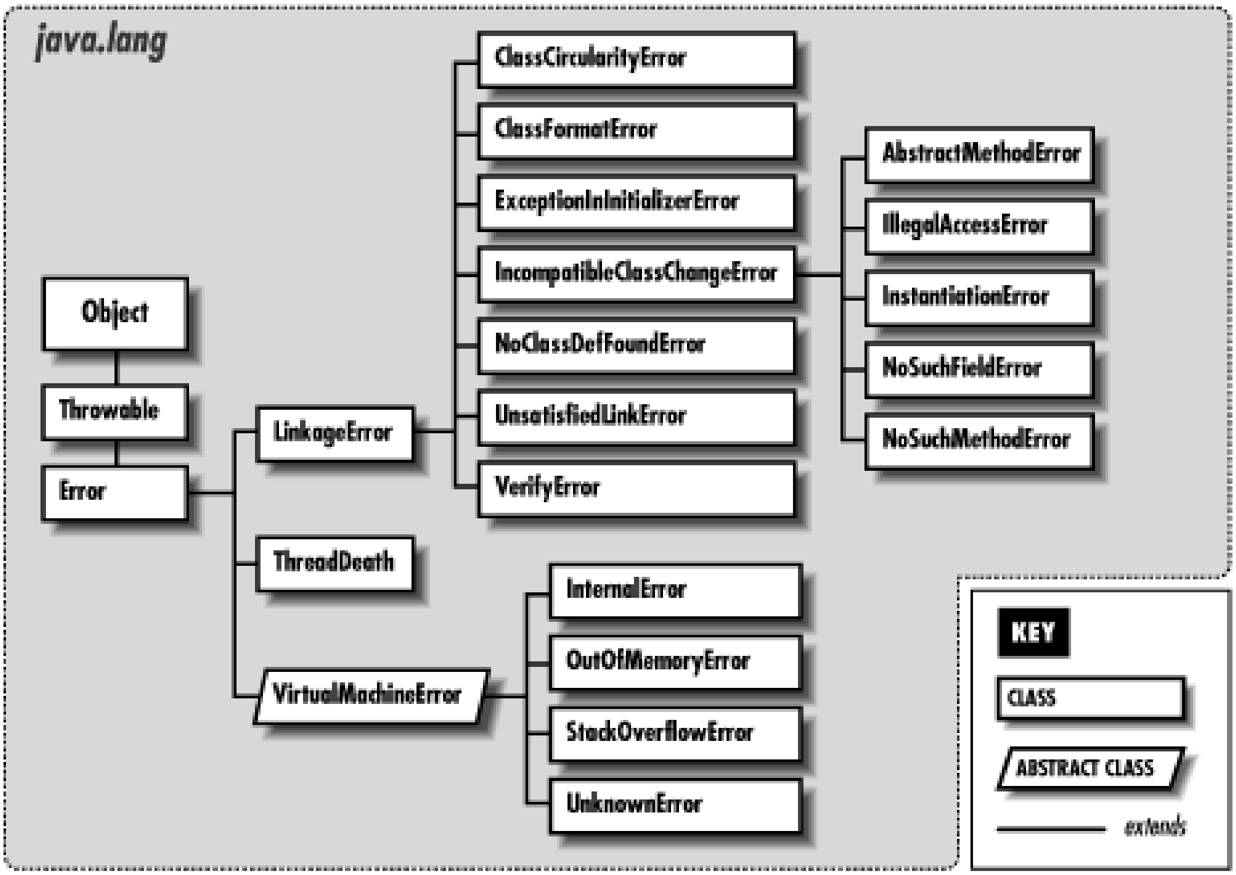

25.1 java.lang.AbstractMethodError (JDK 1.0)

Signals an attempt to invoke an abstract method.

```
public class AbstractMethodError extends IncompatibleClassChangeError {
    // Public Constructors
            public AbstractMethodError();
            public AbstractMethodError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->IncompatibleClassChangeError->AbstractMethodError

BOOK INDEX

NEXT java.lang.ArithmeticException (JDK 1.0)

24.23 java.io.FilenameFilter (JDK 1.0)

This interface defines the `accept()` method that must be implemented by any object that filters filenames (i.e., selects a subset of filenames from a list of filenames). There are no standard `FilenameFilter` classes implemented by Java, but objects that implement this interface are used by the `java.awt.FileDialog` object, and by the `File.list()` method. A typical `FilenameFilter` object might check that the specified `File` represents a file (not a directory), is readable (and possibly writable as well), and that its name ends with some desired extension.

```
public abstract interface FilenameFilter {
    // Public Instance Methods
            public abstract boolean accept(File dir, String name);
}
```

Passed To:

File.list(), FileDialog.setFilenameFilter(), FileDialogPeer.setFilenameFilter()

Returned By:

FileDialog.getFilenameFilter()

28.15 java.net.ServerSocket (JDK 1.0)

This class is used by servers to listen for connection requests from clients. When you create a `ServerSocket`, you specify the port to listen on. The `accept()` method begins listening on that port, and blocks until a client requests a connection on that port. At that point, `accept()` accepts the connection, creating and returning a `Socket` that the server can use to communicate with the client.

```
public class ServerSocket extends Object {
    // Public Constructors
            public ServerSocket(int port) throws IOException;
            public ServerSocket(int port, int backlog) throws IOException;
        1.1public ServerSocket(int port, int backlog, InetAddress bindAddr) throws 
IOException;
    // Class Methods
            public static synchronized void setSocketFactory(SocketImplFactory fac) 
throws IOException;
    // Public Instance Methods
            public Socket accept() throws IOException;
            public void close() throws IOException;
            public InetAddress getInetAddress();
            public int getLocalPort();
        1.1public synchronized int getSoTimeout() throws IOException;
        1.1public synchronized void setSoTimeout(int timeout) throws SocketException;
            public String toString();  // Overrides Object
    // Protected Instance Methods
        1.1  protected final void implAccept(Socket s) throws IOException;
}
```

28.18 java.net.SocketImpl (JDK 1.0)

This abstract class defines the methods necessary to implement communication through sockets. Different subclasses of this class may provide different implementations suitable in different environments (such as behind firewalls). These socket implementations are used by the `Socket` and `ServerSocket` classes.

Normal applications never need to use or subclass this class.

```
public abstract class SocketImpl extends Object {
    // Default Constructor: public SocketImpl()
    // Protected Instance Variables
            protected InetAddress address;
            protected FileDescriptor fd;
            protected int localport;
            protected int port;
    // Public Instance Methods
            public String toString();  // Overrides Object
    // Protected Instance Methods
            protected abstract void accept(SocketImpl s) throws IOException;
            protected abstract int available() throws IOException;
            protected abstract void bind(InetAddress host, int port) throws 
IOException;
            protected abstract void close() throws IOException;
            protected abstract void connect(String host, int port) throws 
IOException;
            protected abstract void connect(InetAddress address, int port) throws 
IOException;
            protected abstract void create(boolean stream) throws IOException;
            protected FileDescriptor getFileDescriptor();
            protected InetAddress getInetAddress();
            protected abstract InputStream getInputStream() throws IOException;
            protected int getLocalPort();
            protected abstract OutputStream getOutputStream() throws IOException;
            protected int getPort();
            protected abstract void listen(int backlog) throws IOException;
}
```

Passed To:

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18.15 java.awt.Component (JDK 1.0)

`Component` is the superclass of all GUI components (except menu components) in the `java.awt` package. You may not instantiate a `Component` directly; you must use a subclass.

`Component` defines many methods. Some of these are intended to be implemented by subclasses. Some are used internally by the AWT. Some are to be implemented to handle events. And many are useful utility methods for working with GUI components. `getParent()` returns the `Container` that a `Component` is contained in. `setBackground()`, `setForeground()`, and `setFont()` set the specified display attributes of a component. `hide()`, `show()`, `enable()`, and `disable()` perform the specified actions for a component. `createImage()` creates an `Image` object from a specified `ImageProducer`, or creates an offscreen image that can be draw into and used for double-buffering during animation. `Component` also has quite a few deprecated methods as a result of the Java 1.1 event model and the introduction of the JavaBeans method naming conventions. The class defines quite a few methods for handling many types of events using the 1.0 model and the 1.1 model in both its high-level and low-level forms.

```
public abstract class Component extends Object implements ImageObserver,
MenuContainer, Serializable {
    // Protected Constructor
        1.1  protected Component();
    // Constants
        1.1  public static final float BOTTOM_ALIGNMENT;
        1.1  public static final float CENTER_ALIGNMENT;
        1.1  public static final float LEFT_ALIGNMENT;
        1.1  public static final float RIGHT_ALIGNMENT;
        1.1  public static final float TOP_ALIGNMENT;
    // Public Instance Methods
         #  public boolean action(Event evt, Object what);
        1.1  public synchronized void add(PopupMenu popup);

18.20 java.awt.Event (JDK 1.0)

This class contains public instance variables that describe some kind of GUI event. In Java 1.1, this class has been superseded by `AWTEvent` and the `java.awt.event` package.

The class contains a large number of constants. Some of the constants specify the event type and are values for the `id` variable. Other constants are values for keys, like the function keys, that do not have ASCII (or Latin-1) values, and are set on the `key` field. Other constants are mask values that are ORed into the `modifiers` field to describe the state of the modifier keys on the keyboard. The `target` field is very important--it is the object for which the event occurred. The `when` field specifies when the event occurred. The `x` and `y` fields specify the mouse coordinates at which it occurred. Finally, the `arg` field is a value specific to the type of the event. Not all fields have valid values for all types of events.

```
public class Event extends Object implements Serializable {
    // Public Constructors
            public Event(Object target, long when, int id, int x, int y, int key, int 
modifiers, Object arg);
            public Event(Object target, long when, int id, int x, int y, int key, int 
modifiers);
            public Event(Object target, int id, Object arg);
    // Event Type Constants
            public static final int ACTION_EVENT;
            public static final int GOT_FOCUS, LOST_FOCUS;
            public static final int KEY_ACTION, KEY_ACTION_RELEASE;
            public static final int KEY_PRESS, KEY_RELEASE;

18.2 java.awt.AWTEvent (JDK 1.1)

This abstract class serves as the root event type for all AWT events in Java 1.1 and supersedes the Event class which was used in Java 1.0.

Each AWTEvent has a source object, as all EventObject objects do. You can query the source of an event with the inherited getSource() method. The AWTEvent class adds an event type, or "id," for every AWT event. Use getID() to query the type of the event. Subclasses of AWTEvent define various constants for this type field.

The various _MASK constants defined by this class allow Component.enableEvents() to be called by applets and custom components that want to receive various event types without having to register an EventListener object to receive them.

```
public abstract class AWTEvent extends EventObject {
    // Public Constructors
            public AWTEvent(Event event);
            public AWTEvent(Object source, int id);
    // Constants
            public static final long ACTION_EVENT_MASK;
            public static final long ADJUSTMENT_EVENT_MASK;
            public static final long COMPONENT_EVENT_MASK;
            public static final long CONTAINER_EVENT_MASK;
            public static final long FOCUS_EVENT_MASK;

20. The java.awt.event Package

Contents:

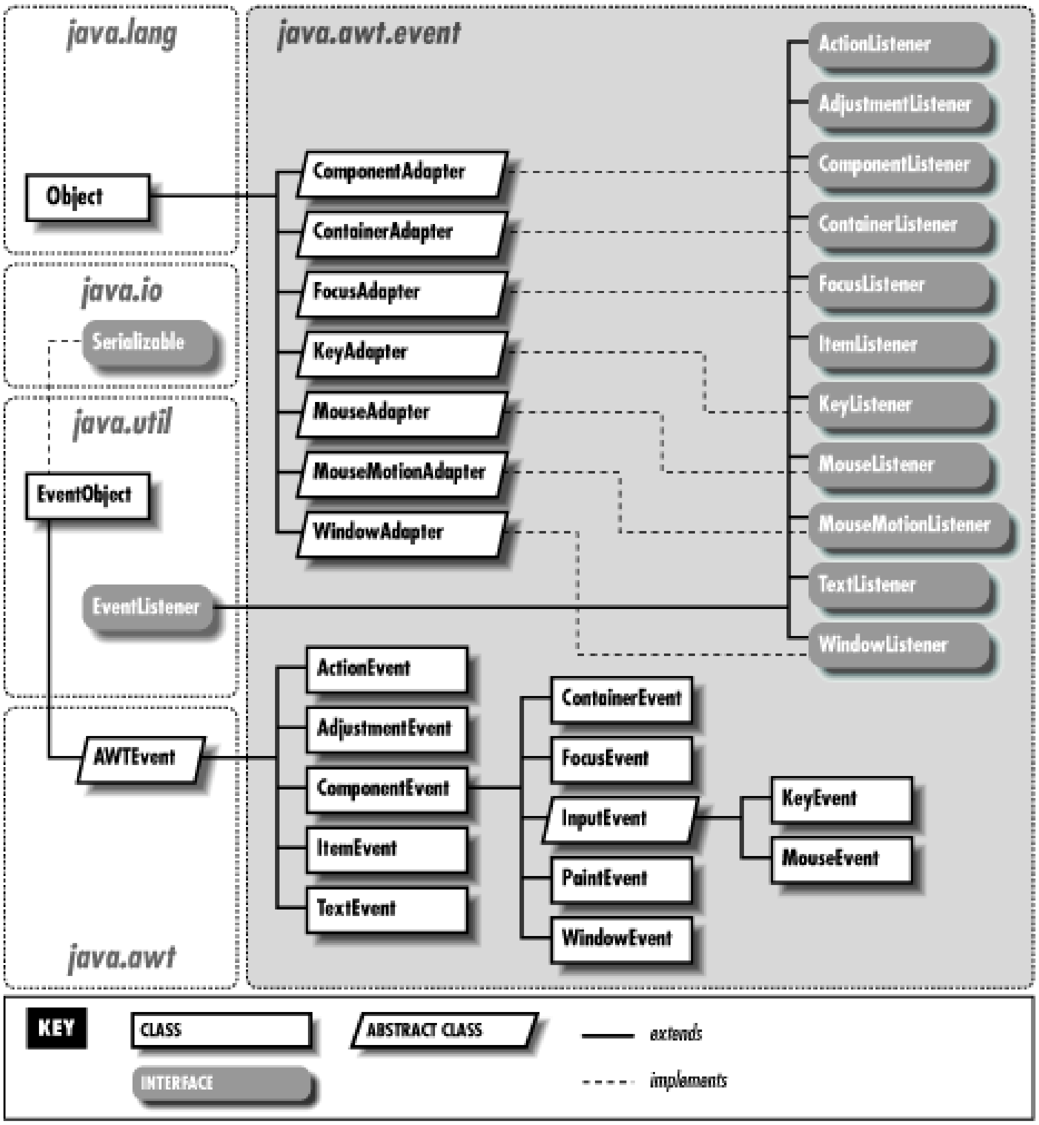
This package defines classes and interfaces used for event handling in the AWT. This package, and all of its classes and interfaces, are new in Java 1.1.

The members of this package fall into three categories:

- Events. The classes with names ending in "Event" represent specific types of events, generated by the AWT or by one of the AWT components.
- Listeners. The interfaces in this package are all "event listeners"; their names end with "Listener." These interfaces define the methods that must be implemented by any object that wants to be notified when a particular event occurs. Note that there is a `Listener` interface for each `Event` class.
- Adapters. Each of the classes with a name ending in "Adapter" provides a no-op implementation for an event listener interface that defines more than one method. When you are only interested in a single method of an event listener interface, it is easier to subclass an `Adapter` class than to implement all of the methods of the corresponding `Listener` interface.

Figure 20.1 shows the class hierarchy for this package. See Chapter 7, *Events*, for more information on events and event handling.

Figure 20.1: The java.awt.event package



20.1 java.awt.event.ActionEvent (JDK 1.1)

An object of this class represents a high-level "action" event generated by an AWT component. Instead of representing a direct user event, such as a mouse or keyboard event, ActionEvent represents some sort of action performed by the user on an AWT component.

The getID() method returns the type of action that has occurred. For AWT-generated action events, this type is always ActionEvent.ACTION_PERFORMED; custom components can generate action events of other types.

The getActionCommand() method returns a String that serves as a kind of name for the action that the event represents. The Button and MenuItem components have a setActionCommand() method that allows the programmer to specify an "action command" string to be included with any action events generated by those components. It is this value that is returned by the getActionCommand() method. When more than one Button or other component notifies the same ActionListener, you can use getActionCommand() to help determine the appropriate response to the event. This is generally a better technique than using the source object returned by getSource(). If no action command string is explicitly set, getActionCommand returns the label of the Button or MenuItem. Note, however, that internationalized programs should not rely on these labels to be constant.

Finally, getModifiers() returns a value that indicates what keyboard modifiers were in effect when the action event was triggered. Use the various _MASK constants, along with the & operator to decode this value.

```
public class ActionEvent extends AWTEvent {
    // Public Constructors
            public ActionEvent(Object source, int id, String command);
            public ActionEvent(Object source, int id, String command, int modifiers);
    // Constants
            public static final int ACTION_FIRST;
            public static final int ACTION_LAST;
            public static final int ACTION_PERFORMED;
            public static final int ALT_MASK;
            public static final int CTRL_MASK;
            public static final int META_MASK;
            public static final int SHIFT_MASK;
    // Public Instance Methods
            public String getActionCommand();
            public int getModifiers();
            public String paramString();  // Overrides AWTEvent
}
```

Hierarchy:

Object->EventObject(Serializable)->AWTEvent->ActionEvent

Passed To:

ActionListener.actionPerformed(), AWTEventMulticaster.actionPerformed(), Button.processActionEvent(), List.processActionEvent(), MenuItem.processActionEvent(), TextField.processActionEvent()

20.2 java.awt.event.ActionListener (JDK 1.1)

This interface defines the method that an object must implement to "listen" for action events on AWT components. When an `ActionEvent` occurs, an AWT component notifies its registered `ActionListener` objects by invoking their `actionPerformed()` methods.

```
public abstract interface ActionListener extends EventListener {
    // Public Instance Methods
            public abstract void actionPerformed(ActionEvent e);
}
```

18.56 java.awt.SystemColor (JDK 1.1)

Instances of the `SystemColor` class represent colors used in the system desktop. You can use these colors to produce applications and custom components that fit well in the desktop color scheme. On platforms that allow the desktop colors to be modified dynamically, the actual color represented by these symbolic system colors may be dynamically updated.

The `SystemColor` class does not have a constructor, but it defines constant `SystemColor` objects that represent each of the symbolic colors used by the system desktop.

If you need to compare a `SystemColor` object to a regular `Color` object, use the `getRGB()` method of both objects and compare the resulting values.

```
public final class SystemColor extends Color implements Serializable {
    // No Constructor
    // Color Constants
            public static final SystemColor activeCaption, activeCaptionBorder, 
activeCaptionText;
            public static final SystemColor control, controlDkShadow, 
controlHighlight;
            public static final SystemColor controlLtHighlight, controlShadow, 
controlText;
            public static final SystemColor desktop;
            public static final SystemColor inactiveCaption, inactiveCaptionBorder, 
inactiveCaptionText;
            public static final SystemColor info, infoText;
            public static final SystemColor menu, menuText;
            public static final SystemColor scrollbar;
            public static final SystemColor text, textHighlight, textHighlightText;
            public static final SystemColor textInactiveText, textText;
            public static final SystemColor window, windowBorder, windowText;
    // Color Index Constants
            public static final int ACTIVE_CAPTION, ACTIVE_CAPTION_BORDER, 
ACTIVE_CAPTION_TEXT;
            public static final int CONTROL, CONTROL_DK_SHADOW, CONTROL_HIGHLIGHT;
            public static final int CONTROL_LT_HIGHLIGHT, CONTROL_SHADOW, 
CONTROL_TEXT;
            public static final int DESKTOP;
            public static final int INACTIVE_CAPTION, INACTIVE_CAPTION_BORDER, 
INACTIVE_CAPTION_TEXT;
            public static final int INFO, INFO_TEXT;
            public static final int MENU, MENU_TEXT;
            public static final int NUM_COLORS;
            public static final int SCROLLBAR;
            public static final int TEXT, TEXT_HIGHLIGHT, TEXT_HIGHLIGHT_TEXT;
            public static final int TEXT_INACTIVE_TEXT, TEXT_TEXT;
            public static final int WINDOW, WINDOW_BORDER, WINDOW_TEXT;
    // Public Instance Methods

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

25.61 java.lang.Thread (JDK 1.0)

This class encapsulates all the information about a single thread of control running on the Java interpreter. To create a thread, you must pass a `Runnable` object (i.e., an object that implements the `Runnable` interface by defining a `run()` method) to the `Thread` constructor, or you must subclass `Thread` so that it defines its own `run()` method.

The `run()` method of the `Thread` or of the specified `Runnable` object is the "body" of the thread. It begins executing when the `start()` method of the `Thread` object is called. The thread runs until the `run()` method returns or until the `stop()` method of its `Thread` object is called. The static methods of this class operate on the currently running thread. The instance methods may be called from one thread to operate on a different thread.

`start()` starts a thread running. `stop()` stops it by throwing a `ThreadDeath` error. `suspend()` temporarily halts a thread. `resume()` allows it to resume. `sleep()` makes the current thread stop for a specified amount of time. `yield()` makes the current thread give up control to any other threads of equal priority that are waiting to run. `join()` waits for a thread to die. `interrupt()` wakes up a waiting or sleeping thread (with an `InterruptedException`) or sets an "interrupted" flag on a non-sleeping thread. A thread can test its own "interrupted" flag with `interrupted()` or can test the flag of another thread with `isInterrupted()`. The `Object` `wait()` method makes the current thread block until the object's `notify()` method is called by another thread.

```
public class Thread extends Object implements Runnable {
    // Public Constructors
            public Thread();
            public Thread(Runnable target);
            public Thread(ThreadGroup group, Runnable target);
            public Thread(String name);
            public Thread(ThreadGroup group, String name);
            public Thread(Runnable target, String name);
            public Thread(ThreadGroup group, Runnable target, String name);
    // Constants
            public static final int MAX_PRIORITY;
            public static final int MIN_PRIORITY;
            public static final int NORM_PRIORITY;
    // Class Methods
            public static int activeCount();
            public static native Thread currentThread();
            public static void dumpStack();
            public static int enumerate(Thread[] tarray);
            public static boolean interrupted();
            public static native void sleep(long millis) throws InterruptedException;
            public static void sleep(long millis, int nanos) throws
InterruptedException;
```

```
            public static native void yield();
    // Public Instance Methods
            public void checkAccess();
            public native int countStackFrames();

25.63 java.lang.ThreadGroup (JDK 1.0)

This class defines a group of threads and allows operations on the group as a whole. A `ThreadGroup` may contain `Thread` objects, as well as "child" `ThreadGroup` objects. All `ThreadGroup` objects are created as children of some other `ThreadGroup`, and thus there is a parent/child hierarchy of `ThreadGroup` objects.

Some programs may find it convenient to define their own `ThreadGroup`, but generally thread groups are only used by system-level applications.

```
public class ThreadGroup extends Object {
    // Public Constructors
            public ThreadGroup(String name);
            public ThreadGroup(ThreadGroup parent, String name);
    // Public Instance Methods
            public int activeCount();
            public int activeGroupCount();
        1.1public boolean allowThreadSuspension(boolean b);
            public final void checkAccess();
            public final void destroy();
            public int enumerate(Thread[] list);
            public int enumerate(Thread[] list, boolean recurse);
            public int enumerate(ThreadGroup[] list);
            public int enumerate(ThreadGroup[] list, boolean recurse);
            public final int getMaxPriority();
            public final String getName();
            public final ThreadGroup getParent();
            public final boolean isDaemon();
        1.1public synchronized boolean isDestroyed();
            public void list();
            public final boolean parentOf(ThreadGroup g);
            public final void resume();
            public final void setDaemon(boolean daemon);
            public final void setMaxPriority(int pri);
            public final void stop();
            public final void suspend();
            public String toString();  // Overrides Object
            public void uncaughtException(Thread t, Throwable e);
}
```

30.9 java.util.GregorianCalendar (JDK 1.1)

This concrete subclass of `Calendar` implements the "standard" solar calendar with years numbered from the birth of Christ, which is used in most locales throughout the world. You do not typically use this class directly, but instead obtain a `Calendar` object suitable for the default locale by calling `Calendar.getInstance()`. See `Calendar` for details on working with `Calendar` objects.

There is a discontinuity in the Gregorian calendar that represents the historical switch from the Julian calendar to the Gregorian calendar. By default `GregorianCalendar` assumes that this switch occurs on October 15, 1582. Most programs need not be concerned with this.

```
public class GregorianCalendar extends Calendar {
    // Public Constructors
            public GregorianCalendar();
            public GregorianCalendar(TimeZone zone);
            public GregorianCalendar(Locale aLocale);
            public GregorianCalendar(TimeZone zone, Locale aLocale);
            public GregorianCalendar(int year, int month, int date);
            public GregorianCalendar(int year, int month, int date, int hour, int
minute);
            public GregorianCalendar(int year, int month, int date, int hour, int
minute, int second);
    // Constants
            public static final int AD;
            public static final int BC;
    // Public Instance Methods

30.2 java.util.Calendar (JDK 1.1)

This abstract class defines methods used to perform date and time arithmetic. It also includes methods that convert dates and times to and from the machine-usable millisecond format used by the `Date` class and units like minutes, hours, days, weeks, months, and years that are more useful to humans.

As an abstract class, `Calendar` cannot be directly instantiated. Instead, it provides static `getInstance()` methods that return instances of a `Calendar` subclass suitable for use in a specified or default locale with a specified or default time zone.

`Calendar` defines a number of useful constants. Some of these are values that represent days of the week and months of the year. Other constants, such as `HOUR` and `DAY_OF_WEEK`, represent various fields of date and time information. These field constants are passed to a number of `Calendar` methods, such as `get()` and `set()`, in order to indicate what particular date or time field is of interest.

`setTime()` and the various `set()` methods set the date represented by a `Calendar` object. The `add()` method adds (or subtracts) values to a calendar field, incrementing the next larger field when the field "rolls over." `roll()` does the same, without modifying any but the specified field. `before()` and `after()` compare two `Calendar` objects.

Many of the methods of the `Calendar` class are replacements for methods of Date that have been deprecated in Java 1.1. While the `Calendar` class is used to convert a time value into its various hour, day, month, and other fields, it is not intended to present those fields into a form suitable for display to the end user. That function is performed by the `DateFormat` class in the `java.text` package, which handles internationalization issues.

See also `Date`, `DateFormat`, and `TimeZone`.

```
public abstract class Calendar extends Object implements Serializable, Cloneable {
    // Protected Constructors
            protected Calendar();
            protected Calendar(TimeZone zone, Locale aLocale);
    // Constants

18.13 java.awt.Choice (JDK 1.0)

This class represents an "option menu" or "dropdown list." The `addItem()` method adds an item with the specified label to a `Choice` menu. `getSelectedIndex()` returns the numerical position of the selected item in the menu, and `getSelectedItem()` returns the label of the selected item.

```
public class Choice extends Component implements ItemSelectable {
    // Public Constructor
            public Choice();
    // Public Instance Methods
        1.1 public synchronized void add(String item);
            public synchronized void addItem(String item);
        1.1 public synchronized void addItemListener(ItemListener l);  // From 
ItemSelectable
            public void addNotify();  // Overrides Component
        #   public int countItems();
            public String getItem(int index);
        1.1 public int getItemCount();
            public int getSelectedIndex();
            public synchronized String getSelectedItem();
        1.1 public synchronized Object[] getSelectedObjects();  // From 
ItemSelectable
        1.1 public synchronized void insert(String item, int index);
        1.1 public synchronized void remove(String item);
        1.1 public synchronized void remove(int position);
        1.1 public synchronized void removeAll();
        1.1 public synchronized void removeItemListener(ItemListener l);  // From 
ItemSelectable
            public synchronized void select(int pos);
            public synchronized void select(String str);

18.16 java.awt.Container (JDK 1.0)

This class implements a component that can contain other components. You cannot instantiate `Container` directly, but must use one of its subclasses, such as `Panel`, `Frame`, or `Dialog`. Once a `Container` is created, you may set its `LayoutManager` with `setLayout()`, add components to it with `add()`, and remove them with `remove()`. `getComponents()` returns an array of the components contained in a `Container`. `locate()` determines within which contained component a specified point falls. `list()` produces helpful debugging output.

```
public abstract class Container extends Component {
    // Protected Constructor
        1.1  protected Container();
    // Public Instance Methods
             public Component add(Component comp);
             public Component add(String name, Component comp);
             public Component add(Component comp, int index);

18.38 java.awt.List (JDK 1.0)

This class is a `Component` that graphically displays a list of strings. The list is scrollable if necessary. The constructor takes optional arguments that specify the number of visible rows in the list and whether selection of more than one item is allowed. The various instance methods allow strings to be added and removed from the `List`, and allow the selected item or items to be queried.

```
public class List extends Component implements ItemSelectable {
    // Public Constructors
            public List();
        1.1  public List(int rows);
            public List(int rows, boolean multipleMode);
    // Public Instance Methods
        1.1  public void add(String item);
        1.1  public synchronized void add(String item, int index);
        1.1  public synchronized void addActionListener(ActionListener l);
            public void addItem(String item);
            public synchronized void addItem(String item, int index);

18.52 java.awt.Rectangle (JDK 1.0)

This class defines a rectangle as the X and Y coordinate of its upper-left corner and a width and height. The instance methods perform various tests and transformations on the rectangle. The `x`, `y`, `width`, and `height` variables are public and may thus be manipulated directly. `Rectangle` objects are used in several places in the `java.awt` package to specify clipping rectangles and bounding boxes.

```
public class Rectangle extends Object implements Shape, Serializable {
    // Public Constructors
            public Rectangle();
        1.1  public Rectangle(Rectangle r);
            public Rectangle(int x, int y, int width, int height);

18.44 java.awt.MenuItem (JDK 1.0)

This class encapsulates a menu item with a specified textual label. A `MenuItem` can be added to a menu pane with the `Menu.add()` method. The `disable()` method makes an item non-selectable; you might use it to "gray-out" a menu item when the command it represents is not valid in the current context. The `enable()` method makes an item selectable again. In Java 1.1, use `setActionCommand()` to specify an identifying string that is included in `ActionEvent` events generated by the menu item.

```
public class MenuItem extends MenuComponent {
    // Public Constructors
        1.1  public MenuItem();
            public MenuItem(String label);
        1.1  public MenuItem(String label, MenuShortcut s);
    // Public Instance Methods
        1.1  public synchronized void addActionListener(ActionListener l);
            public void addNotify();
        1.1  public void deleteShortcut();
        #   public synchronized void disable();
        #   public synchronized void enable();
        #   public void enable(boolean b);
        1.1  public String getActionCommand();
            public String getLabel();
        1.1  public MenuShortcut getShortcut();
            public boolean isEnabled();
            public String paramString();  // Overrides MenuComponent
        1.1  public synchronized void removeActionListener(ActionListener l);
        1.1  public void setActionCommand(String command);
        1.1  public synchronized void setEnabled(boolean b);
            public synchronized void setLabel(String label);
        1.1  public void setShortcut(MenuShortcut s);
    // Protected Instance Methods

```

Passed To:

```
Toolkit.createTextField()
```

18.5 java.awt.Adjustable (JDK 1.1)

This interface defines the methods that should be implemented by an object that maintains a user-adjustable numeric value. This value has a specified minimum and maximum value, and it may be incremented or decremented either a unit at a time or a block at a time. An `Adjustable` object generates an `AdjustmentEvent` when it is adjusted, and it maintains a list of `AdjustmentListener` objects interested in being notified when such an event occurs.

This interface abstracts the essential functionality of the `Scrollbar` component.

```
public abstract interface Adjustable {
    // Constants
            public static final int HORIZONTAL;
            public static final int VERTICAL;
    // Public Instance Methods
            public abstract void addAdjustmentListener(AdjustmentListener l);
            public abstract int getBlockIncrement();
            public abstract int getMaximum();
            public abstract int getMinimum();
            public abstract int getOrientation();
            public abstract int getUnitIncrement();
            public abstract int getValue();
            public abstract int getVisibleAmount();
            public abstract void removeAdjustmentListener(AdjustmentListener l);
            public abstract void setBlockIncrement(int b);
            public abstract void setMaximum(int max);
            public abstract void setMinimum(int min);
            public abstract void setUnitIncrement(int u);
            public abstract void setValue(int v);
            public abstract void setVisibleAmount(int v);
}
```

21.5 java.awt.image.FilteredImageSource (JDK 1.0)

This class is an ImageProducer that produces image data filtered from some other ImageProducer. A FilteredImageSource is created with a specified ImageProducer and a specified ImageFilter. For example, an applet might use the following code to download and crop an image:

```
Image full_image = getImage(getDocumentBase(), "images/1.gif");
ImageFilter cropper = new CropImageFilter(10, 10, 100, 100);
ImageProducer prod = new FilteredImageSource(full_image.getSource(), cropper);
Image cropped_image = createImage(prod);
```

The methods of this class are the standard ImageProducer methods that you can invoke to add and remove ImageConsumer objects.

```
public class FilteredImageSource extends Object implements ImageProducer {
    // Public Constructor
            public FilteredImageSource(ImageProducer orig, ImageFilter imgf);
    // Public Instance Methods
            public synchronized void addConsumer(ImageConsumer ic);  // From 
ImageProducer
            public synchronized boolean isConsumer(ImageConsumer ic);  // From 
ImageProducer
            public synchronized void removeConsumer(ImageConsumer ic);  // From 
ImageProducer
            public void requestTopDownLeftRightResend(ImageConsumer ic);  // From 
ImageProducer
            public void startProduction(ImageConsumer ic);  // From ImageProducer
}
```

21.9 java.awt.image.ImageProducer (JDK 1.0)

This interface defines the methods that any class that produces image data must define to enable communication with `ImageConsumer` classes. An `ImageConsumer` registers itself as interested in a producer's image by calling the `addConsumer()` method.

Most applications never need to use or implement this interface.

```
public abstract interface ImageProducer {
    // Public Instance Methods
            public abstract void addConsumer(ImageConsumer ic);
            public abstract boolean isConsumer(ImageConsumer ic);
            public abstract void removeConsumer(ImageConsumer ic);
            public abstract void requestTopDownLeftRightResend(ImageConsumer ic);
            public abstract void startProduction(ImageConsumer ic);
}
```

Implemented By:

`FilteredImageSource, MemoryImageSource`

Passed To:

`Component.createImage(), ComponentPeer.createImage(), FilteredImageSource(), ImageFilter.resendTopDownLeftRight(), PixelGrabber(), Toolkit.createImage()`

Returned By:

`Image.getSource()`

21.11 java.awt.image.MemoryImageSource (JDK 1.0)

This class is an `ImageProducer` that produces an image from data stored in memory. The various constructors specify image data, color model, array offset, scan line length, and properties in slightly different ways. The instance methods implement the standard `ImageProducer` interface that allows an `ImageConsumer` object to register interest in the image.

```
public class MemoryImageSource extends Object implements ImageProducer {
    // Public Constructors
            public MemoryImageSource(int w, int h, ColorModel cm, byte[] pix, int 
off, int scan);
            public MemoryImageSource(int w, int h, ColorModel cm, byte[] pix, int 
off, int scan, Hashtable props);
            public MemoryImageSource(int w, int h, ColorModel cm, int[] pix, int off, 
int scan);
            public MemoryImageSource(int w, int h, ColorModel cm, int[] pix, int off, 
int scan, Hashtable props);
            public MemoryImageSource(int w, int h, int[] pix, int off, int scan);
            public MemoryImageSource(int w, int h, int[] pix, int off, int scan, 
Hashtable props);
    // Public Instance Methods
            public synchronized void addConsumer(ImageConsumer ic);  // From 
ImageProducer
            public synchronized boolean isConsumer(ImageConsumer ic);  // From 
ImageProducer
        1.1  public void newPixels();
        1.1  public synchronized void newPixels(int x, int y, int w, int h);
        1.1  public synchronized void newPixels(int x, int y, int w, int h, boolean 
framenotify);
        1.1  public synchronized void newPixels(byte[] newpix, ColorModel newmodel, 
int offset, int scansize);
        1.1  public synchronized void newPixels(int[] newpix, ColorModel newmodel, 
int offset, int scansize);
            public synchronized void removeConsumer(ImageConsumer ic);  // From 
ImageProducer
            public void requestTopDownLeftRightResend(ImageConsumer ic);  // From 
ImageProducer
        1.1  public synchronized void setAnimated(boolean animated);
        1.1  public synchronized void setFullBufferUpdates(boolean fullbuffers);
            public void startProduction(ImageConsumer ic);  // From ImageProducer
}
```

30.26 java.util.Vector (JDK 1.0)

This class implements an array of objects that grows in size as necessary. It is useful when you need to keep track of a number of objects but do not know in advance how many there will be. There are a number of methods for storing objects in and removing objects from the `Vector`. Other methods look up the object at specified positions in the `Vector`, or search for specified objects within the `Vector`. `elements()` returns an `Enumeration` of the objects stored in the `Vector`. `size()` returns the number of objects currently stored in the `Vector`. `capacity()` returns the number of elements that may be stored before the vector's internal storage must be reallocated.

```
public class Vector extends Object implements Cloneable, Serializable {
    // Public Constructors
            public Vector(int initialCapacity, int capacityIncrement);
            public Vector(int initialCapacity);
            public Vector();
    // Protected Instance Variables
            protected int capacityIncrement;
            protected int elementCount;
            protected Object[] elementData;
    // Public Instance Methods
            public final synchronized void addElement(Object obj);
            public final int capacity();
            public synchronized Object clone();  // Overrides Object
            public final boolean contains(Object elem);
            public final synchronized void copyInto(Object[] anArray);
            public final synchronized Object elementAt(int index);
            public final synchronized Enumeration elements();
            public final synchronized void ensureCapacity(int minCapacity);
            public final synchronized Object firstElement();
            public final int indexOf(Object elem);
            public final synchronized int indexOf(Object elem, int index);
            public final synchronized void insertElementAt(Object obj, int index);
            public final boolean isEmpty();
            public final synchronized Object lastElement();
            public final int lastIndexOf(Object elem);
            public final synchronized int lastIndexOf(Object elem, int index);
            public final synchronized void removeAllElements();
            public final synchronized boolean removeElement(Object obj);
            public final synchronized void removeElementAt(int index);
            public final synchronized void setElementAt(Object obj, int index);
            public final synchronized void setSize(int newSize);
            public final int size();
            public final synchronized String toString();  // Overrides Object
            public final synchronized void trimToSize();
}
```

Toolkit.createMenuBar()

18.53 java.awt.ScrollPane (JDK 1.1)

This `Container` class creates horizontal and vertical scrollbars surrounding a "viewport" and allows a single child component to be displayed and scrolled within this viewport. Typically the child of the `ScrollPane` is larger than the `ScrollPane` itself, so scrollbars allow the user to select the currently visible portion.

When you call the `ScrollPane()` constructor, you may optionally specify a scrollbar display policy, which should be one of the three constants defined by this class. If you do not specify a policy, `ScrollPane` uses the `SCROLLBARS_AS_NEEDED` policy.

A program can programmatically scroll the child within the viewport by calling `setScrollPosition()`. `getHAdjustable()` and `getVAdjustable()` return the horizontal and vertical `Adjustable` objects that control scrolling (typically these are not actually instances of `Scrollbar`). You can use these `Adjustable` objects to specify the unit and block increment values for the scrollbars. You can also directly set the `Adjustable` value, as an alternative to `setScrollPosition()`, but should not set other values of the `Adjustable` objects.

Use `setSize()` to set the size of the `ScrollPane` container. You may want to take the size of the scrollbars into account when computing the overall container size--use `getHScrollbarHeight()` and `getVScrollbarWidth()` to obtain these values.

`ScrollPane` overrides the `printComponents()` method of `Container` so that when a `ScrollPane` is printed, the entire child component is printed, rather than only the currently visible portion.

```
public class ScrollPane extends Container {
    // Public Constructors
            public ScrollPane();
            public ScrollPane(int scrollbarDisplayPolicy);
    // Constants
            public static final int SCROLLBARS_ALWAYS;

Toolkit.createMenu()

18.10 java.awt.Checkbox (JDK 1.0)

This class represents a GUI checkbox with a textual label. The `Checkbox` maintains a `boolean` state--whether it is checked or not. The checkbox may optionally be part of a `CheckboxGroup` which enforces "radio button" behavior.

```
public class Checkbox extends Component implements ItemSelectable {
    // Public Constructors
            public Checkbox();
            public Checkbox(String label);
        1.1 public Checkbox(String label, boolean state);
        1.1 public Checkbox(String label, boolean state, CheckboxGroup group);
            public Checkbox(String label, CheckboxGroup group, boolean state);
    // Public Instance Methods
        1.1 public synchronized void addItemListener(ItemListener l);  // From 
ItemSelectable
            public void addNotify();  // Overrides Component
            public CheckboxGroup getCheckboxGroup();
            public String getLabel();
        1.1 public Object[] getSelectedObjects();  // From ItemSelectable
            public boolean getState();
        1.1 public synchronized void removeItemListener(ItemListener l);  // From 
ItemSelectable
            public void setCheckboxGroup(CheckboxGroup g);
            public synchronized void setLabel(String label);
            public void setState(boolean state);
    // Protected Instance Methods
            protected String paramString();  // Overrides Component
        1.1 protected void processEvent(AWTEvent e);  // Overrides Component
        1.1 protected void processItemEvent(ItemEvent e);
}
```

Passed To:

`Toolkit.createCheckboxMenuItem()`

18.34 java.awt.ItemSelectable (JDK 1.1)

This interface abstracts the functionality of an AWT component that presents one or more items to the user and allows the user to select zero or more of them. It is implemented by several components in the AWT.

`getSelectedObjects()` returns an array of selected objects, or `null`, if none are selected. `addItemListener()` and `removeItemListener()` are standard methods for adding and removing `ItemListener` objects to be notified when an item is selected.

```
public abstract interface ItemSelectable {
    // Public Instance Methods
            public abstract void addItemListener(ItemListener l);
            public abstract Object[] getSelectedObjects();
            public abstract void removeItemListener(ItemListener l);
}
```

Implemented By:

`Checkbox, CheckboxMenuItem, Choice, List`

Passed To:

`ItemEvent()`

Returned By:

`ItemEvent.getItemSelectable()`

18.6 java.awt.BorderLayout (JDK 1.0)

This class implements the `LayoutManager` interface to lay out `Component` objects in a `Container`. The `BorderLayout` arranges components that have been added to their `Container` (using the `Container.add()` method) with the names "North," "South," "East," "West," and "Center." These named components are arranged along the edges and in the center of the container. The `hgap` and `vgap` arguments to the `BorderLayout` constructor specify the desired horizontal and vertical spacing between adjacent components.

Note that applications should never call the `LayoutManager` methods of this class directly; the `Container` for which the `BorderLayout` is registered does this.

```
public class BorderLayout extends Object implements LayoutManager2, Serializable {
    // Public Constructors
            public BorderLayout();
            public BorderLayout(int hgap, int vgap);
    // Constants
        1.1 public static final String CENTER;
        1.1 public static final String EAST;
        1.1 public static final String NORTH;
        1.1 public static final String SOUTH;
        1.1 public static final String WEST;
    // Public Instance Methods

18.9 java.awt.CardLayout (JDK 1.0)

This class is a `LayoutManager` that makes each of the components it manages as large as the container and ensures that only one is visible at a time. The standard `LayoutManager` methods are called by the `Container` object, and should not be called directly by applet or application code. `first()`, `last()`, `next()`, `previous()`, and `show()` make a particular `Component` in the `Container` visible. The names with which the components are added to the container are used only by the `show()` method.

```
public class CardLayout extends Object implements LayoutManager2, Serializable {
    // Public Constructors
            public CardLayout();
            public CardLayout(int hgap, int vgap);
    // Public Instance Methods
        1.1 public void addLayoutComponent(Component comp, Object constraints);  // 
From LayoutManager2
          # public void addLayoutComponent(String name, Component comp);  // From 
LayoutManager
            public void first(Container parent);
        1.1 public int getHgap();
        1.1 public float getLayoutAlignmentX(Container parent);  // From 
LayoutManager2
        1.1 public float getLayoutAlignmentY(Container parent);  // From

java.awt.Canvas (JDK 1.0) | BOOK INDEX | java.awt.Checkbox (JDK 1.0)

18.23 java.awt.FlowLayout (JDK 1.0)

This class implements the `LayoutManager` interface to lay out `Component` objects in a `Container`. `FlowLayout` arranges components in a container like words on a page: from left to right and top to bottom. It fits as many components as it can in a row before moving on to the next row. The constructor allows you to specify one of three constants as an alignment value for the rows, and also allows you to specify horizontal spacing between components and vertical spacing between rows.

Note that applications should never call the `LayoutManager` methods of this class directly; the `Container` for which the `FlowLayout` is registered does this.

```
public class FlowLayout extends Object implements LayoutManager, Serializable {
    // Public Constructors
            public FlowLayout();
            public FlowLayout(int align);
            public FlowLayout(int align, int hgap, int vgap);
    // Constants
            public static final int CENTER;
            public static final int LEFT;
            public static final int RIGHT;
    // Public Instance Methods
            public void addLayoutComponent(String name, Component comp);  // From 
LayoutManager
        1.1  public int getAlignment();
        1.1  public int getHgap();
        1.1  public int getVgap();
            public void layoutContainer(Container target);  // From LayoutManager
            public Dimension minimumLayoutSize(Container target);  // From 
LayoutManager
            public Dimension preferredLayoutSize(Container target);  // From 
LayoutManager
            public void removeLayoutComponent(Component comp);  // From LayoutManager
        1.1  public void setAlignment(int align);
        1.1  public void setHgap(int hgap);
        1.1  public void setVgap(int vgap);
            public String toString();  // Overrides Object
}
```

18.29 java.awt.GridBagLayout (JDK 1.0)

This class implements the `LayoutManager` interface to lay out `Component` objects in a `Container`. It is the most complicated and most powerful `LayoutManager` in the `java.awt` package. It divides the container into a grid of rows and columns (which need not have the same width and height) and places the components into this grid, adjusting the size of the grid cells as necessary to ensure that components do not overlap. Each component controls how it is positioned within this grid by specifying a number of variables (or "constraints") in a `GridBagConstraints` object. Do not confuse this class with the much simpler `GridLayout` which arranges components in a grid of equally sized cells.

Use `setConstraints()` to specify a `GridBagConstraints` object for each of the components in the container. Or, in Java 1.1, specify the `GridBagConstraints` object when adding the component to the container with `add()`. The variables in this object specify the position of the component in the grid, the number of horizontal and vertical grid cells that the component occupies, and also control other important aspects of component layout. See `GridBagConstraints` for more information on these "constraint" variables. `setConstraints()` makes a copy of the constraints object, so you may reuse a single object in your code.

Note that applications should never call the `LayoutManager` methods of this class directly; the `Container` for which the `GridBagLayout` is registered does this.

```
public class GridBagLayout extends Object implements LayoutManager2, Serializable {
    // Public Constructor
            public GridBagLayout();
    // Constants
            protected static final int MAXGRIDSIZE;
            protected static final int MINSIZE;
            protected static final int PREFERREDSIZE;
    // Public Instance Variables
            public double[] columnWeights;
            public int[] columnWidths;
            public int[] rowHeights;
            public double[] rowWeights;
    // Protected Instance Variables
            protected Hashtable comptable;
            protected GridBagConstraints defaultConstraints;
            protected GridBagLayoutInfo layoutInfo;
    // Public Instance Methods
            public void addLayoutComponent(String name, Component comp);  // From
LayoutManager
        1.1  public void addLayoutComponent(Component comp, Object constraints);  //
From LayoutManager2
            public GridBagConstraints getConstraints(Component comp);
        1.1  public float getLayoutAlignmentX(Container parent);  // From
LayoutManager2
        1.1  public float getLayoutAlignmentY(Container parent);  // From
LayoutManager2
            public int[][] getLayoutDimensions();
            public Point getLayoutOrigin();
            public double[][] getLayoutWeights();
        1.1  public void invalidateLayout(Container target);  // From LayoutManager2
            public void layoutContainer(Container parent);  // From LayoutManager
            public Point location(int x, int y);
        1.1  public Dimension maximumLayoutSize(Container target);  // From

```

PREVIOUS | HOME | NEXT
java.awt.GridBagConstraints (JDK 1.0) | BOOK INDEX | java.awt.GridLayout (JDK 1.0)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18.30 java.awt.GridLayout (JDK 1.0)

This class implements the `LayoutManager` interface to lay out `Component` objects in a `Container`. It divides the `Container` into a specified number of rows and columns and arranges the components in those rows and columns, left-to-right and top-to-bottom. If either the number of rows or the number of columns is set to zero, its value is computed from the other dimension and the total number of components. Do not confuse this class with the more flexible and complicated `GridBagLayout`.

Note that applications should never call the `LayoutManager` methods of this class directly; the `Container` for which the `GridLayout` is registered does this.

```
public class GridLayout extends Object implements LayoutManager, Serializable {
    // Public Constructors
        1.1  public GridLayout();
            public GridLayout(int rows, int cols);
            public GridLayout(int rows, int cols, int hgap, int vgap);
    // Public Instance Methods
            public void addLayoutComponent(String name, Component comp);  // From 
LayoutManager
        1.1  public int getColumns();
        1.1  public int getHgap();
        1.1  public int getRows();
        1.1  public int getVgap();
            public void layoutContainer(Container parent);  // From LayoutManager
            public Dimension minimumLayoutSize(Container parent);  // From 
LayoutManager
            public Dimension preferredLayoutSize(Container parent);  // From 
LayoutManager
            public void removeLayoutComponent(Component comp);  // From LayoutManager
        1.1  public void setColumns(int cols);
        1.1  public void setHgap(int hgap);
        1.1  public void setRows(int rows);
        1.1  public void setVgap(int vgap);
            public String toString();  // Overrides Object
}
```

18.36 java.awt.LayoutManager (JDK 1.0)

This interface defines the methods necessary for a class to be able to arrange `Component` objects within a `Container` object. Most programs use one of the existing classes that implements this interface: `BorderLayout`, `CardLayout`, `FlowLayout`, `GridBagConstraints`, `GridBagLayout`, or `GridLayout`.

To define a new class that lays out components, you must implement each of the methods defined by this interface. `addLayoutComponent()` is called when a component is added to the container. `removeLayoutComponent()` is called when a component is removed. `layoutContainer()` should perform the actual positioning of components by setting the size and position of each component in the specified container. `minimumLayoutSize()` should return the minimum container width and height that the `LayoutManager` needs in order to lay out its components. `preferredLayoutSize()` should return the optimal container width and height for the `LayoutManager` to lay out its components.

In Java 1.1, layout managers should implement the `LayoutManager2` interface, which is an extension of this one. Note that a Java applet or application never directly calls any of these `LayoutManager` methods--the `Container` object for which the `LayoutManager` is registered does that.

```
public abstract interface LayoutManager {
    // Public Instance Methods
            public abstract void addLayoutComponent(String name, Component comp);
            public abstract void layoutContainer(Container parent);
            public abstract Dimension minimumLayoutSize(Container parent);
            public abstract Dimension preferredLayoutSize(Container parent);
            public abstract void removeLayoutComponent(Component comp);
}
```

java.awt.Label (JDK 1.0) | BOOK INDEX | java.awt.LayoutManager2 (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18.37 java.awt.LayoutManager2 (JDK 1.1)

This interface is an extension of the `LayoutManager` interface. It defines additional layout management methods for layout managers that perform constraint-based layout. `GridBagLayout` is an example of a constraint-based layout manager--each component added to the layout is associated with a `GridBagConstraints` object that specifies the "constraints" on how the component is to be laid out.

Java programs do not directly invoke the methods of this interface--they are used by the `Container` object for which the layout manager is registered.

```
public abstract interface LayoutManager2 extends LayoutManager {
    // Public Instance Methods
            public abstract void addLayoutComponent(Component comp, Object 
constraints);
            public abstract float getLayoutAlignmentX(Container target);
            public abstract float getLayoutAlignmentY(Container target);
            public abstract void invalidateLayout(Container target);
            public abstract Dimension maximumLayoutSize(Container target);
}
```

Implemented By:

BorderLayout, CardLayout, GridBagLayout

18.8 java.awt.Canvas (JDK 1.0)

This class is a `Component` that does no default drawing or event handling on its own. You can subclass it to display any kind of drawing or image, and to handle any kind of user input event. `Canvas` inherits the event handling methods of its superclass. In Java 1.1, you can also subclass `Component` directly to create a "lightweight component," instead of having to subclass `Canvas`.

```
public class Canvas extends Component {
    // Public Constructor
        1.1 public Canvas();
    // Public Instance Methods
            public void addNotify();  // Overrides Component
            public void paint(Graphics g);  // Overrides Component
}
```

Hierarchy:

```
Object->Component(ImageObserver, MenuContainer, Serializable)->Canvas
```

Passed To:

```
Toolkit.createCanvas()
```

18.18 java.awt.Dialog (JDK 1.0)

This class represents a dialog box window. A `Dialog` may be modal so that it blocks user input to all other windows until dismissed, may optionally have a title, and may be resizable. A `Dialog` object is a `Container` and `Component` objects can be added to it in the normal way with the `add()` method. The default `LayoutManager` for `Dialog` is `BorderLayout`. You may specify a different `LayoutManager` object with `setLayout()`. Call the `pack()` method of `Window` to initiate layout management of the dialog and set its initial size appropriately. Call `show()` to pop a dialog up, and `hide()` to pop it down. For modal dialogs, `show()` blocks until the dialog is dismissed. Event handling continues while `show()` is blocked, using a new event dispatcher thread. In Java 1.0, `show()` is inherited from `Window`. Call the `Window.dispose()` method when the `Dialog` is no longer needed so that its window system resources may be reused.

```
public class Dialog extends Window {
    // Public Constructors
        1.1  public Dialog(Frame parent);
            public Dialog(Frame parent, boolean modal);
        1.1  public Dialog(Frame parent, String title);
            public Dialog(Frame parent, String title, boolean modal);
    // Public Instance Methods
            public void addNotify();  // Overrides Window
            public String getTitle();
            public boolean isModal();
            public boolean isResizable();
        1.1  public void setModal(boolean b);
            public synchronized void setResizable(boolean resizable);
            public synchronized void setTitle(String title);
        1.1  public void show();  // Overrides Window
    // Protected Instance Methods
            protected String paramString();  // Overrides Container
}
```

Hierarchy:

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18.22 java.awt.FileDialog (JDK 1.0)

This class represents a file selection dialog box. The constants `LOAD` and `SAVE` are values of an optional constructor argument that specifies whether the dialog should be an **Open File** dialog or a **Save As** dialog. You may specify a `FilenameFilter` object to control which files are displayed in the dialog.

The inherited `show()` method pops the dialog up. For dialogs of this type, `show()` blocks, not returning until the user has selected a file and dismissed the dialog (which pops down automatically--you don't have to call `hide()`). Once `show()` has returned, use `getFile()` to get the name of the file the user selected.

```
public class FileDialog extends Dialog {
    // Public Constructors
        1.1  public FileDialog(Frame parent);
            public FileDialog(Frame parent, String title);
            public FileDialog(Frame parent, String title, int mode);
    // Constants
            public static final int LOAD;
            public static final int SAVE;
    // Public Instance Methods
            public void addNotify();  // Overrides Dialog
            public String getDirectory();
            public String getFile();
            public FilenameFilter getFilenameFilter();
            public int getMode();
            public synchronized void setDirectory(String dir);
            public synchronized void setFile(String file);
            public synchronized void setFilenameFilter(FilenameFilter filter);
        1.1  public void setMode(int mode);
    // Protected Instance Methods
            protected String paramString();  // Overrides Dialog
}
```

Hierarchy:

```
Object->Component(ImageObserver, MenuContainer, Serializable)-> Container-
>Window->Dialog->FileDialog
```

Passed To:

`Toolkit.createFileDialog()`

18.26 java.awt.Frame (JDK 1.0)

This class represents an optionally resizable top-level application window with a titlebar and other platform-dependent window decorations. `setTitle()` specifies a title, `setMenuBar()` specifies a menu bar, `setCursor()` specifies a cursor, and `setIconImage()` specifies an icon for the window. Call the `pack()` method of `Window` to initiate layout management of the window and set its initial size appropriately. Call the `show()` method of `Window` to make a frame appear on the screen or to bring it to the front of the window stack. Call `hide()` to remove a frame from the screen. Call the `dispose()` method when the `Frame` is no longer needed so that it can release its window system resources for reuse.

The constants defined by this class specify various cursor types. In Java 1.1, these constants and the cursor methods of `Frame` are deprecated in favor of the `Cursor` class and cursor methods of `Component`.

```
public class Frame extends Window implements MenuContainer {
    // Public Constructors
            public Frame();
            public Frame(String title);
    // Constants
            public static final int CROSSHAIR_CURSOR;
            public static final int DEFAULT_CURSOR;
            public static final int E_RESIZE_CURSOR;

18.35 java.awt.Label (JDK 1.0)

This class is a `Component` that displays a single specified line of read-only text. The constant values specify the text alignment within the component and may be specified to the constructor or to `setAlignment()`.

```
public class Label extends Component {
    // Public Constructors
            public Label();
            public Label(String text);
            public Label(String text, int alignment);
    // Constants
            public static final int CENTER;
            public static final int LEFT;
            public static final int RIGHT;
    // Public Instance Methods
            public void addNotify();  // Overrides Component
            public int getAlignment();
            public String getText();
            public synchronized void setAlignment(int alignment);
            public synchronized void setText(String text);
    // Protected Instance Methods

Toolkit.createLabel()
```

18.46 java.awt.Panel (JDK 1.0)

This class is a Container that is itself contained within a container. Unlike Frame and Dialog, Panel is a container that does not create a separate window of its own. Panel is suitable for holding portions of a larger interface within a parent Frame or Dialog or within another Panel. (Note that Applet is a subclass of Panel, and thus applets are displayed in a Panel that is contained within a Web browser or applet viewer.) The default LayoutManager for a Panel is FlowLayout.

```
public class Panel extends Container {
    // Public Constructors
            public Panel();
        1.1  public Panel(LayoutManager layout);
    // Public Instance Methods
            public void addNotify();  // Overrides Container
}
```

18.49 java.awt.PopupMenu (JDK 1.1)

`PopupMenu` is a simple subclass of `Menu` that represents a popup menu rather than a pulldown menu. You create a `PopupMenu` just as you would create a `Menu` object. The main difference is that a popup menu must be "popped up" in response to a user event by calling its `show()` method.

Another difference is that, unlike a `Menu`, which can only appear within a `MenuBar` or another `Menu`, a `PopupMenu` can be associated with any component in a graphical user interface. A `PopupMenu` is associated with a component by calling the `add()` method of the component.

Popup menus are popped up by the user in different ways on different platforms. In order to hide this platform-dependency, the `MouseEvent` class defines the `isPopupTrigger()` method. If this method returns `true`, the specified `MouseEvent` represents the platform-specific popup menu trigger event, and you should use the `show()` method to pop your `PopupMenu` up. Note that the X and Y coordinates passed to `show()` should be in the coordinate system of the specified `Component`.

```
public class PopupMenu extends Menu {
    // Public Constructors
            public PopupMenu();
            public PopupMenu(String label);
    // Public Instance Methods
            public synchronized void addNotify();  // Overrides Menu
            public void show(Component origin, int x, int y);
}
```

`Toolkit.createTextArea()`

18.61 java.awt.Window (JDK 1.0)

This class represents a top-level window with no borders or menu bar. `Window` is a `Container` with `BorderLayout` as its default layout manager. `Window` is rarely used directly; its subclasses `Frame` and `Dialog` are more commonly useful.

`show()` (which overrides `Component.show()`) makes a `Window` visible and brings it to the front of other windows. `toFront()` brings a window to the front, and `toBack()` buries a window beneath others. `pack()` is an important method that initiates layout management for the window, and sets the window size to match the preferred size of the components contained within the window. `getToolkit()` returns the `Toolkit()` in use for this window. Call `dispose()` when a `Window` is no longer needed to free its window system resources.

```
public class Window extends Container {
    // Public Constructor
            public Window(Frame parent);
    // Public Instance Methods
            public void addNotify();  // Overrides Container
        1.1  public synchronized void addWindowListener(WindowListener l);
            public void dispose();

30.15 java.util.Observable (JDK 1.0)

This class is the superclass of all "observable" objects to be used in an object-oriented model/view paradigm. The class methods allow you to add and delete `Observer` objects to and from an `Observable`'s list, and to notify all of the `Observer` objects on the list. `Observer` objects are "notified" by invoking their `update()` method. `Observable` also maintains an internal "changed" flag, which may be set and cleared by the `Observable`, and which may be queried with `hasChanged()` by any interested observer.

```
public class Observable extends Object {
    // Public Constructor
        1.1public Observable();
    // Public Instance Methods
            public synchronized void addObserver(Observer o);
            public synchronized int countObservers();
            public synchronized void deleteObserver(Observer o);
            public synchronized void deleteObservers();
            public synchronized boolean hasChanged();
            public void notifyObservers();
            public void notifyObservers(Object arg);
    // Protected Instance Methods
            protected synchronized void clearChanged();

18.48 java.awt.Polygon (JDK 1.0)

This class defines a polygon as an array of points. The points of the polygon may be specified by the constructor, or with the `addPoint()` method. `getBoundingBox()` returns the smallest `Rectangle` that contains the polygon, and `inside()` tests whether a specified point is within the `Polygon`. Note that the arrays of X and Y points and the number of points in the polygon (not necessarily the same as the array size) are defined as public variables. `Polygon` objects are used when drawing polygons with the `Graphics.drawPolygon()` and `Graphics.fillPolygon()` methods.

```
public class Polygon extends Object implements Shape, Serializable {
    // Public Constructors
            public Polygon();
            public Polygon(int[] xpoints, int[] ypoints, int npoints);
    // Public Instance Variables
            public int npoints;
            public int[] xpoints;
            public int[] ypoints;
    // Protected Instance Variables
        1.1  protected Rectangle bounds;
    // Public Instance Methods
            public void addPoint(int x, int y);
        1.1  public boolean contains(Point p);
        1.1  public boolean contains(int x, int y);
        #   public Rectangle getBoundingBox();
        1.1  public Rectangle getBounds();  // From Shape
        #   public boolean inside(int x, int y);
        1.1  public void translate(int deltaX, int deltaY);
}

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

23.4 java.beans.Customizer (JDK 1.1)

The `Customizer` interface specifies the methods that must be defined by any class designed to customize a Java bean. In addition to implementing this interface, a customizer class must be a subclass of `java.awt.Component`, and it must have a constructor that takes no arguments, so that it can be instantiated by an application builder.

Customizer classes are typically used by a complex Java bean to allow the user to easily configure the bean, and to provide an alternative to a simple list of properties and their values. If a customizer class is defined for a Java bean, it must be associated with the bean through a `BeanDescriptor` object returned by a `BeanInfo` class for the bean. Note that while a `Customizer` class is created by the author of a bean, that class is only instantiated and used by application builders and similar tools.

After a `Customizer` class is instantiated, its `setObject()` method is invoked once to specify the bean object that it is to customize. The `addPropertyChangeListener()` and `removePropertyChangeListener()` methods may be called to register and de-register `PropertyChangeListener` objects. The `Customizer` should send a `PropertyChangeEvent` to all registered listeners any time it changes a property of the bean it is customizing.

```
public abstract interface Customizer {
    // Public Instance Methods
            public abstract void addPropertyChangeListener(PropertyChangeListener 
listener);
            public abstract void removePropertyChangeListener(PropertyChangeListener 
listener);
            public abstract void setObject(Object bean);
}
```

23.14 java.beans.PropertyChangeSupport (JDK 1.1)

The `PropertyChangeSupport` class is a convenience class that maintains a list of registered `PropertyChangeListener` objects and provides the `firePropertyChange()` method for sending a `PropertyChangeEvent` object to all registered listeners. Because there are some tricky thread synchronization issues involved in doing this correctly, it is recommended that all Java beans that support "bound" properties either extend this class, or, more commonly, create an instance of this class to which they can delegate the task of maintaining the list of listeners.

```
public class PropertyChangeSupport extends Object implements Serializable {
    // Public Constructor
            public PropertyChangeSupport(Object sourceBean);
    // Public Instance Methods
            public synchronized void addPropertyChangeListener(PropertyChangeListener 
listener);
            public void firePropertyChange(String propertyName, Object oldValue, 
Object newValue);
            public synchronized void 
removePropertyChangeListener(PropertyChangeListener listener);
}
```

23.16 java.beans.PropertyEditor (JDK 1.1)

The PropertyEditor interface defines the methods that must be implemented by a Java beans property editor intended for use within an application builder or similar tool. PropertyEditor is a complex interface because it defines methods to support several different ways of displaying property values to the user, and it also defines methods to support several different ways of allowing the user to edit the property value.

For a property of type *x*, the author of a Java bean typically implements a property editor of class *x*Editor. While the editor is implemented by the bean author, it is usually only instantiated or used by application builders or similar tools (or by a Customizer class for a Bean).

In addition to implementing the PropertyEditor interface, a property editor must have a constructor that expects no arguments, so that it can be easily instantiated by an application builder. Also, it must accept registration and deregistration of PropertyChangeListener objects, and it must send a PropertyChangeEvent to all registered listeners when it changes the value of the property being edited.

The PropertyEditorSupport class is a trivial implementation of PropertyEditor, suitable for subclassing, or for supporting a list of PropertyChangeListener objects.

```
public abstract interface PropertyEditor {
    // Public Instance Methods
            public abstract void addPropertyChangeListener(PropertyChangeListener
listener);
            public abstract String getAsText();
            public abstract Component getCustomEditor();
            public abstract String getJavaInitializationString();
            public abstract String[] getTags();
            public abstract Object getValue();
            public abstract boolean isPaintable();
            public abstract void paintValue(Graphics gfx, Rectangle box);
            public abstract void removePropertyChangeListener(PropertyChangeListener
listener);
            public abstract void setAsText(String text) throws
IllegalArgumentException;
            public abstract void setValue(Object value);
            public abstract boolean supportsCustomEditor();
}
```

Implemented By:

PropertyEditorSupport

Returned By:

PropertyEditorManager.findEditor()

23.18 java.beans.PropertyEditorSupport (JDK 1.1)

The `PropertyEditorSupport` class is a trivial implementation of the `PropertyEditor` interface. It provides "no-op" default implementations of most methods, so that you can can define simple `PropertyEditor` subclasses that only override a few required methods.

In addition, `PropertyEditorSupport` defines working versions of `addPropertyChangeListener()` and `removePropertyChangeListener()`, along with a `firePropertyChange()` method that sends a `PropertyChangeEvent` to all registered listeners. `PropertyEditor` classes may choose to instantiate a `PropertyEditorSupport` object simply to handle the job of managing the list of listeners. When used in this way, the `PropertyEditorSupport` object should be instantiated with a source object specified, so that that source object can be used in the `PropertyChangeEvent` objects that are sent.

```
public class PropertyEditorSupport extends Object implements PropertyEditor {
    // Protected Constructors
            protected PropertyEditorSupport();
            protected PropertyEditorSupport(Object source);
    // Public Instance Methods
            public synchronized void addPropertyChangeListener(PropertyChangeListener
            public synchronized void addPropertyChangeListener'u'listener);  // From
PropertyEditor
            public void firePropertyChange();
            public String getAsText();  // From PropertyEditor
            public Component getCustomEditor();  // From PropertyEditor
            public String getJavaInitializationString();  // From PropertyEditor
            public String[] getTags();  // From PropertyEditor
            public Object getValue();  // From PropertyEditor
            public boolean isPaintable();  // From PropertyEditor
            public void paintValue(Graphics gfx, Rectangle box);  // From
PropertyEditor
            public synchronized void
removePropertyChangeListener(PropertyChangeListener
            public synchronized void removePropertyChangeListener'u'listener);  //
From PropertyEditor
            public void setAsText(String text) throws IllegalArgumentException;  //
From PropertyEditor
            public void setValue(Object value);  // From PropertyEditor
            public boolean supportsCustomEditor();  // From PropertyEditor
}
```

18.58 java.awt.TextComponent (JDK 1.0)

This class is the superclass of the `TextArea` and `TextField` components. It cannot be instantiated itself, but provides methods that are common to these two component types. `setEditable()` specifies whether the text in the text component is editable or not. `getText()` returns the text in the component, and `setText()` specifies text to be displayed. `getSelectedText()` returns the currently selected text in the text component, and `getSelectionStart()` and `getSelectionEnd()` return the extents of the selected region of text. `select()` and `selectAll()` select some or all of the text displayed in the text component.

See also `TextField` and `TextArea`.

```
public class TextComponent extends Component {
    // No Constructor
    // Protected Instance Variables
        1.1  protected transient TextListener textListener;
    // Public Instance Methods
        1.1  public void addTextListener(TextListener l);
        1.1  public int getCaretPosition();
            public synchronized String getSelectedText();
            public synchronized int getSelectionEnd();
            public synchronized int getSelectionStart();
            public synchronized String getText();
            public boolean isEditable();
            public void removeNotify();  // Overrides Component
        1.1  public void removeTextListener(TextListener l);
            public synchronized void select(int selectionStart, int selectionEnd);
            public synchronized void selectAll();
        1.1  public void setCaretPosition(int position);
            public synchronized void setEditable(boolean b);
        1.1  public synchronized void setSelectionEnd(int selectionEnd);
        1.1  public synchronized void setSelectionStart(int selectionStart);
            public synchronized void setText(String t);
    // Protected Instance Methods
            protected String paramString();  // Overrides Component
        1.1  protected void processEvent(AWTEvent e);  // Overrides Component
        1.1  protected void processTextEvent(TextEvent e);
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

23.22 java.beans.VetoableChangeSupport (JDK 1.1)

`VetoableChangeSupport` is a convenience class that maintains a list of registered `VetoableChangeListener` objects and provides a `fireVetoableChange()` method for sending a `PropertyChangeEvent` to all registered listeners. If any of the registered listeners veto the proposed change, `fireVetoableChange()` send out another `PropertyChangeEvent` notifying previously notified listeners that the property has changed back to its original value.

Because of the extra complexity of correctly handling vetoable changes, and because of some tricky thread synchronization issues involved in maintaining the list of listeners, it is recommended that all Java beans that support "constrained" events create a `VetoableChangeSupport` object to which they can delegate the tasks of maintaining the list of listeners and of firing events.

```
public class VetoableChangeSupport extends Object implements Serializable {
    // Public Constructor
            public VetoableChangeSupport(Object sourceBean);
    // Public Instance Methods
            public synchronized void addVetoableChangeListener(VetoableChangeListener 
listener);
            public void fireVetoableChange(String propertyName, Object oldValue, 
Object newValue)
            public void fireVetoableChange'u'throws PropertyVetoException;
            public synchronized void 
removeVetoableChangeListener(VetoableChangeListener listener);
}
```

20.3 java.awt.event.AdjustmentEvent (JDK 1.1)

An event of this type indicates that an adjustment has been made to an `Adjustable` object--usually, this means that the user has interacted with a `Scrollbar` component.

The `getValue()` method returns the new value of the `Adjustable` object. This is usually the most important piece of information stored in the event. `getAdjustable()` returns the `Adjustable` object that was the source of the event. It is a convenient alternative to the inherited `getSource()` method.

The `getID()` method returns the type of an `AdjustmentEvent`. The standard AWT components only generate adjustment events of type `AdjustmentEvent.ADJUSTMENT_VALUE_CHANGED`. There are several types of adjustments that can be made to an `Adjustable` object, however, and the `getAdjustmentType()` method returns one of five constants to indicate which type has occurred. `UNIT_INCREMENT` indicates that the `Adjustable` value has been incremented by one unit, as in a scroll-line-down operation. `UNIT_DECREMENT` indicates the opposite: scroll-line-up. `BLOCK_INCREMENT` and `BLOCK_DECREMENT` indicate that the `Adjustable` object has been incremented or decremented by multiple units, as in a scroll-page-down or scroll-page-up operation. Finally, the `TRACK` constant indicates that the `Adjustable` value has been set to an absolute value unrelated to its previous value, as when the user drags a scrollbar to a new position.

```
public class AdjustmentEvent extends AWTEvent {
    // Public Constructor
            public AdjustmentEvent(Adjustable source, int id, int type, int value);
    // Constants
            public static final int ADJUSTMENT_FIRST;
            public static final int ADJUSTMENT_LAST;
            public static final int ADJUSTMENT_VALUE_CHANGED;
            public static final int BLOCK_DECREMENT;
            public static final int BLOCK_INCREMENT;
            public static final int TRACK;
            public static final int UNIT_DECREMENT;
            public static final int UNIT_INCREMENT;
    // Public Instance Methods

20.4 java.awt.event.AdjustmentListener (JDK 1.1)

This interface defines the method that an object must implement to "listen" for adjustment events on AWT components. When an `AdjustmentEvent` occurs, an AWT component notifies its registered `AdjustmentListener` objects by invoking their `adjustmentValueChanged()` methods.

```
public abstract interface AdjustmentListener extends EventListener {
    // Public Instance Methods
            public abstract void adjustmentValueChanged(AdjustmentEvent e);
}
```

Implemented By:

`AWTEventMulticaster`

Passed To:

`Adjustable.addAdjustmentListener(), Adjustable.removeAdjustmentListener(), AWTEventMulticaster.add(), AWTEventMulticaster.remove(), Scrollbar.addAdjustmentListener(), Scrollbar.removeAdjustmentListener()`

Returned By:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove()`

31. The java.util.zip Package

Contents:

The `java.util.zip` package contains classes for data compression and decompression. It is new in Java 1.1. Figure 31.1 shows the class hierarchy of the package.

The `Deflater` and `Inflater` classes perform data compression and decompression. `DeflaterOutputStream` and `InflaterInputStream` apply that functionality to byte streams; the subclasses of these streams implement both the GZIP and ZIP compression formats. The `Adler32` and `CRC32` classes implement the `Checksum` interface and compute the checksums required for data compression.

Figure 31.1: The java.util.zip package

[Graphic: Figure 31-1]

31.1 java.util.zip.Adler32 (JDK 1.1)

This class implements the `Checksum` interface and computes a checksum on a stream of data using the Adler-32 algorithm. This algorithm is significantly faster than the CRC-32 algorithm and is almost as reliable.

The `CheckedInputStream` and `CheckedOutputStream` classes provide a higher-level interface to computing checksums on streams of data.

```
public class Adler32 extends Object implements Checksum {
    // Default Constructor: public Adler32()
    // Public Instance Methods
            public long getValue();  // From Checksum
            public void reset();  // From Checksum
            public void update(int b);  // From Checksum
            public native void update(byte[] b, int off, int len);  // From Checksum
            public void update(byte[] b);
}
```

30.3 java.util.Date (JDK 1.0)

This class represents dates and times. It lets you work with them in a system-independent way. You can create a `Date` by specifying the number of milliseconds from the epoch (midnight GMT, January 1st, 1970), or by specifying the year, month, date, and optionally, the hour, minute, and second. Years are specified as the number of years since 1900. If you call the `Date` constructor with no arguments, the `Date` is initialized to the current time and date. The instance methods of the class allow you to get and set the various date and time fields, to compare dates and times, and to convert dates to and from string representations.

In Java 1.1, many of the date methods have been deprecated in favor of the methods of the `Calendar` class.

```
public class Date extends Object implements Serializable, Cloneable {
    // Public Constructors
            public Date();
            public Date(long date);
        #   public Date(int year, int month, int date);
        #   public Date(int year, int month, int date, int hrs, int min);
        #   public Date(int year, int month, int date, int hrs, int min, int sec);
        #   public Date(String s);
    // Class Methods
        #   public static long UTC(int year, int month, int date, int hrs, int min, 
int sec);
        #   public static long parse(String s);
    // Public Instance Methods
            public boolean after(Date when);
            public boolean before(Date when);
            public boolean equals(Object obj);  // Overrides Object
        #   public int getDate();
        #   public int getDay();
        #   public int getHours();
        #   public int getMinutes();
        #   public int getMonth();
        #   public int getSeconds();
            public long getTime();
        #   public int getTimezoneOffset();
        #   public int getYear();
            public int hashCode();  // Overrides Object
        #   public void setDate(int date);
        #   public void setHours(int hours);
        #   public void setMinutes(int minutes);
        #   public void setMonth(int month);
        #   public void setSeconds(int seconds);
            public void setTime(long time);
        #   public void setYear(int year);
        #   public String toGMTString();
        #   public String toLocaleString();
            public String toString();  // Overrides Object
}
```

20.14 java.awt.event.InputEvent (JDK 1.1)

This abstract class serves as the superclass for the raw user input event types `MouseEvent` and `KeyEvent`.

Use the inherited `getComponent()` to determine in which component the event occurred. Use `getWhen()` to obtain a timestamp for the event. Use `getModifiers()` to determine which keyboard modifier keys or mouse buttons were down when the event occurred. You can decode the `getModifiers()` return value using the various `_MASK` constants defined by this class. The class also defines four convenience methods for determining the state of keyboard modifiers.

In Java 1.1, input events are delivered to the appropriate listener objects before they are delivered to the AWT components themselves. If a listener calls the `consume()` method of the event, the event is not passed on to the component. For example, if a listener registered on a `Button` "consumes" a mouse click, it prevents the button itself from responding to that event. You can use `isConsumed()` to test whether some other listener object has already consumed the event.

```
public abstract class InputEvent extends ComponentEvent {
    // No Constructor
    // Constants
            public static final int ALT_MASK;
            public static final int BUTTON1_MASK;
            public static final int BUTTON2_MASK;
            public static final int BUTTON3_MASK;
            public static final int CTRL_MASK;
            public static final int META_MASK;
            public static final int SHIFT_MASK;
    // Public Instance Methods
            public void consume();  // Overrides AWTEvent
            public int getModifiers();
            public long getWhen();
            public boolean isAltDown();
            public boolean isConsumed();  // Overrides AWTEvent
            public boolean isControlDown();
            public boolean isMetaDown();

29.7 java.text.DateFormat (JDK 1.1)

This class formats and parses dates and times in a locale-specific way. As an abstract class, it cannot be instantiated directly, but it provides a number of static methods that return instances of a concrete subclass which you can use to format dates in a variety of ways. The `getDateInstance()` methods return a `DateFormat` object suitable for formatting dates in either the default locale or a specified locale. A formatting style may also optionally be specified--the constants `FULL`, `LONG`, `MEDIUM`, `SHORT`, and `DEFAULT` specify this style. Similarly, the `getTimeInstance()` methods return a `DateFormat` object that formats and parses times, and the `getDateTimeInstance()` methods return a `DateFormat` object that formats both dates and times. These methods also optionally take a format style constant and a `Locale`. Finally, `getInstance()` returns a default `DateFormat` object that formats both dates and times in the `SHORT` format.

Once you have created a `DateFormat` object, you can use the `setCalendar()` and `setTimeZone()` methods if you want to format the date using a calendar or time zone other than the default.

The various `format()` methods convert `java.util.Date` objects to strings, using whatever format is encapsulated in the `DateFormat` object. The `parse()` and `parseObject()` methods perform the reverse operation--they parse a string formatted according to the rules of the `DateFormat` object and convert it into a `Date` object.

The `DEFAULT`, `FULL`, `MEDIUM`, `LONG`, and `SHORT` constants are used to specify how verbose or compact the formatted date or time should be. The remaining constants, which all end with `_FIELD`, specify various fields of formatted dates and times and are used with the `FieldPosition` object that is optionally passed to `format()`.

```
public abstract class DateFormat extends Format implements Cloneable {
    // Protected Constructor
            protected DateFormat();
    // Format Style Constants
            public static final int DEFAULT;
            public static final int FULL;
            public static final int LONG;
            public static final int MEDIUM;
            public static final int SHORT;
    // Date and Time Field Constants
            public static final int ERA_FIELD;

18.28 java.awt.GridBagConstraints (JDK 1.0)

This class encapsulates the instance variables that tell a `GridBagLayout` how to position a given `Component` within its `Container`.

`gridx`, `gridy`

> These fields specify the grid position of the component. The `RELATIVE` constant specifies a position to the right or below the previous component.

`gridwidth`, `gridheight`

> These fields specify the height and width of the component in grid cells. The constant `REMAINDER` specifies that the component is the last one and should get all remaining cells.

`fill`

> This field specifies which dimensions of a component should grow when the space available for it is larger than its default size. Legal values are the constants `NONE`, `BOTH`, `HORIZONTAL`, and `VERTICAL`.

`ipadx`, `ipady`

> These fields specify internal padding to add on each side of the component in each dimension. They increase the size of the component beyond its default minimum size.

`insets`

> This `Insets` object specifies margins to appear on all sides of the component.

`anchor`

> This field specifies how the component should be displayed within its grid cells when it is smaller than those cells. The `CENTER` constant and the compass-point constants are legal values.

`weightx`, `weighty`

> These fields specify how extra space in the container should be distributed among its components in the X and Y dimensions. Larger weights specify that a component should receive a proportionally larger amount of extra space. A

zero weight specifies that the component should not receive any extra space. These weights specify the resizing behavior of the component and its container.

See also `GridBagLayout`.

```
public class GridBagConstraints extends Object implements Cloneable, Serializable {
    // Public Constructor
            public GridBagConstraints();
    // Constants
            public static final int BOTH;
            public static final int CENTER;
            public static final int EAST;
            public static final int HORIZONTAL;

30. The java.util Package

Contents:

The `java.util` package defines a number of useful classes. This package should not be considered a "utility" package separate from the rest of the language; in fact, Java depends directly on several of the classes in this package. Figure 30.1 shows the class hierarchy of this package.

Figure 30.1: The java.util package

[Graphic: Figure 30-1]

The `Hashtable` class is one of the most useful in the package--it implements a hashtable or associative array. It allows arbitrary objects to be stored and retrieved by arbitrary keys. The `Properties` subclass of `Hashtable` is used to store the Java system properties list.

`Vector` is another extremely useful class. It implements an array of objects that grows as needed when objects are added.

The `Enumeration` interface provides a simple and consistent way to loop through all the elements contained within some kind of object or data structure.

The Date class represents a date and time, using a millisecond representation. In Java 1.1, the Calendar class manipulates dates using more familiar units such as months, days, hours, and minutes. The TimeZone class is also used in conjunction with dates.

In Java 1.1, ResourceBundle and its subclasses, ListResourceBundle and PropertyResourceBundle, represent a "bundle" of localized resources that are read in by an internationalized program at runtime.

The remaining classes are also useful. BitSet implements an arbitrary-size array of bits. Random generates and returns pseudo-random numbers in a variety of forms. StringTokenizer parses a string into tokens. Stack implements a last-in-first-out stack on which objects may be pushed, and from which they may be popped. And the Observer interface and Observable class provide infrastructure for implementing the object-oriented model-view paradigm in Java.

30.1 java.util.BitSet (JDK 1.0)

This class defines an arbitrarily large set of bits. Instance methods allow you to set, clear, and query individual bits in the set, and also to perform bitwise boolean arithmetic on the bits in BitSet objects. This class can be used as an extremely compact array of boolean values, although reading and writing those values is slower than normal array access.

```
public final class BitSet extends Object implements Cloneable, Serializable {
    // Public Constructors
            public BitSet();
            public BitSet(int nbits);
    // Public Instance Methods
            public void and(BitSet set);
            public void clear(int bit);
            public Object clone();  // Overrides Object
            public boolean equals(Object obj);  // Overrides Object
            public boolean get(int bit);
            public int hashCode();  // Overrides Object
            public void or(BitSet set);
            public void set(int bit);
            public int size();
            public String toString();  // Overrides Object
            public void xor(BitSet set);
}
```

24.42 java.io.ObjectOutputStream (JDK 1.1)

The `ObjectOutputStream` is used to serialize objects, arrays, and other values to a stream. The `writeObject()` method serializes an object or array, and various other methods are used to write primitive data values to the stream. Note that only objects that implement the `Serializable` interface or the `Externalizable` interface can be serialized.

The `defaultWriteObject()` may only be called from the `writeObject()` method of a `Serializable` object. It allows an object to perform additional processing before or after serializing itself.

The remaining methods of `ObjectOutputStream` are miscellaneous stream manipulation methods and protected methods for use by subclasses that want to customize its serialization behavior.

```
public class ObjectOutputStream extends OutputStream implements ObjectOutput {
    // Public Constructor
            public ObjectOutputStream(OutputStream out) throws IOException;
    // Public Instance Methods
            public void close() throws IOException;  // Overrides OutputStream

AWTEventMulticaster.save(), AWTEventMulticaster.saveInternal()

25.58 java.lang.StringBuffer (JDK 1.0)

This class represents a string of characters. It differs from the `String` class in that its contents may be modified. A `StringBuffer` object grows in length as necessary. The string stored in a `StringBuffer` object may be modified in place with the `setCharAt()`, `append()`, and `insert()` methods.

After a string is processed in a `StringBuffer` object, it may be efficiently converted to a `String` object for subsequent use. The `StringBuffer.toString()` method does not copy the internal array of characters; instead it shares that array with the new `String` object, and makes a new copy for itself only when further modifications are made to the `StringBuffer` object.

```
public final class StringBuffer extends Object implements Serializable {
    // Public Constructors
            public StringBuffer();
            public StringBuffer(int length);
            public StringBuffer(String str);
    // Public Instance Methods
            public synchronized StringBuffer append(Object obj);
            public synchronized StringBuffer append(String str);
            public synchronized StringBuffer append(char[] str);
            public synchronized StringBuffer append(char[] str, int offset, int len);
            public StringBuffer append(boolean b);
            public synchronized StringBuffer append(char c);
            public StringBuffer append(int i);
            public StringBuffer append(long l);
            public StringBuffer append(float f);
            public StringBuffer append(double d);
            public int capacity();
            public synchronized char charAt(int index);
            public synchronized void ensureCapacity(int minimumCapacity);
            public synchronized void getChars(int srcBegin, int srcEnd, char[] dst, 
int dstBegin);
            public synchronized StringBuffer insert(int offset, Object obj);
            public synchronized StringBuffer insert(int offset, String str);
            public synchronized StringBuffer insert(int offset, char[] str);
            public StringBuffer insert(int offset, boolean b);
            public synchronized StringBuffer insert(int offset, char c);
            public StringBuffer insert(int offset, int i);
            public StringBuffer insert(int offset, long l);
            public StringBuffer insert(int offset, float f);
            public StringBuffer insert(int offset, double d);
            public int length();
            public synchronized StringBuffer reverse();
            public synchronized void setCharAt(int index, char ch);

29.9 java.text.DecimalFormat (JDK 1.1)

This is the concrete `Format` class used by `NumberFormat` for all locales that use base 10 numbers. Most applications do not need to use this class directly--they can use the static methods of `NumberFormat` to obtain a default `NumberFormat` object for a desired locale, and may then perform minor locale-independent customizations on that object.

Applications that require highly-customized number formatting and parsing may create custom `DecimalFormat` objects by passing a suitable pattern to the `DecimalFormat()` constructor method. The `applyPattern()` method can be used to change this pattern. A pattern consists of a string of characters from the following table. For example: "$#,##0.00;($#,##0.00)".

Character	Meaning
#	A digit; zeros show as absent
0	A digit; zeros show as 0
.	The locale-specific decimal separator
,	The locale-specific grouping separator
-	The locale-specific negative prefix
%	Show value as a percentage
;	Separates positive number format (on left) from optional negative number format (on right)
'	Quote a reserved character, so it appears literally in the output
other	Appears literally in output

A `DecimalFormatSymbols` object may be optionally specified when creating a `DecimalFormat` object. If one is not specified, a `DecimalFormatSymbols` object suitable for the default locale is used.

```
public class DecimalFormat extends NumberFormat {
    // Public Constructors
            public DecimalFormat();
            public DecimalFormat(String pattern);
            public DecimalFormat(String pattern, DecimalFormatSymbols symbols);
    // Public Instance Methods
            public void applyLocalizedPattern(String pattern);
            public void applyPattern(String pattern);
            public Object clone();  // Overrides NumberFormat
            public boolean equals(Object obj);  // Overrides NumberFormat
            public StringBuffer format(double number, StringBuffer result,
FieldPosition fieldPosition);  // Defines NumberFormat
            public StringBuffer format(long number, StringBuffer result,
FieldPosition fieldPosition);  // Defines NumberFormat
            public DecimalFormatSymbols getDecimalFormatSymbols();
            public int getGroupingSize();
            public int getMultiplier();
            public String getNegativePrefix();
            public String getNegativeSuffix();
            public String getPositivePrefix();
            public String getPositiveSuffix();
            public int hashCode();  // Overrides NumberFormat
            public boolean isDecimalSeparatorAlwaysShown();
            public Number parse(String text, ParsePosition status);  // Defines
NumberFormat
            public void setDecimalFormatSymbols(DecimalFormatSymbols newSymbols);
            public void setDecimalSeparatorAlwaysShown(boolean newValue);
            public void setGroupingSize(int newValue);
            public void setMultiplier(int newValue);
            public void setNegativePrefix(String newValue);
            public void setNegativeSuffix(String newValue);
            public void setPositivePrefix(String newValue);
            public void setPositiveSuffix(String newValue);
            public String toLocalizedPattern();
            public String toPattern();
}

29.18 java.text.SimpleDateFormat (JDK 1.1)

This is the concrete `Format` subclass used by `DateFormat` to handle formatting and parsing of dates. Most applications should not use this class directly--instead, they should obtain a localized `DateFormat` object by calling one of the static methods of `DateFormat`.

`SimpleDateFormat` formats dates and times according to a pattern, which specifies the positions of the various fields of the date, and a `DateFormatSymbols` object, which specifies important auxiliary data, such as the names of months. Applications that require highly customized date or time formatting can create a custom `SimpleDateFormat` object by specifying the desired pattern. This creates a `SimpleDateFormat` object that uses the `DateFormatSymbols` object for the default locale. You may also specify a locale explicitly to use the `DateFormatSymbols` object for that locale. Or, you can even provide an explicit `DateFormatSymbols` object of your own, if you need to format dates and times for an unsupported locale.

You can use the `applyPattern()` method of a `SimpleDateFormat` to change the formatting pattern used by the object. The syntax of this pattern is described in the following table. Any characters in the format string that do not appear in this table appear literally in the formatted date.

Field	**Full Form**	**Short Form**
Year	`yyyy` (4 digits)	`yy` (2 digits)
Month	`MMM` (name)	`MM` (2 digits), `M` (1 or 2 digits)
Day of week	`EEEE`	`EE`
Day of month	`dd` (2 digits)	`d` (1 or 2 digits)
Hour (1-12)	`hh` (2 digits)	`h` (1 or 2 digits)
Hour (0-23)	`HH` (2 digits)	`H` (1 or 2 digits)
Hour (0-11)	`KK`	`K`
Hour (1-24)	`kk`	`k`
Minute	`mm`	
Second	`ss`	
Millisecond	`SSS`	
AM/PM	`a`	
Time zone	`zzzz`	`zz`
Day of week in month	`F` (e.g., 3rd Thursday)	
Day in year	`DDD` (3 digits)	`D` (1, 2, or 3 digits)
Week in year	`ww`	
Era (e.g., BC/AD)	G	

```
public class SimpleDateFormat extends DateFormat {
    // Public Constructors
            public SimpleDateFormat();
            public SimpleDateFormat(String pattern);
            public SimpleDateFormat(String pattern, Locale loc);
            public SimpleDateFormat(String pattern, DateFormatSymbols formatData);
    // Public Instance Methods
            public void applyLocalizedPattern(String pattern);
            public void applyPattern(String pattern);
            public Object clone();  // Overrides DateFormat
            public boolean equals(Object obj);  // Overrides DateFormat

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

29.3 java.text.ChoiceFormat (JDK 1.1)

This class is a subclass of `Format` that converts a number to a `String` in a way that is reminiscent of a `switch` statement or an enumerated type. Each `ChoiceFormat` object has an array of doubles known as its "limits" and an array of strings known as its "formats." When the `format()` method is called to format a number *x*, the `ChoiceFormat` finds an index *i* such that:

```
limits[i] <= x < limits[i+1]
```

If *x* is less than the first element of the array, the first element is used, and if it is greater than the last, the last element is used. Once the index *i* has been determined, it is used as the index into the array of strings, and the indexed string is returned as the result of the `format()` method.

A `ChoiceFormat` object may also be created by encoding its "limits" and "formats" into a single string known as its "pattern." A typical pattern looks like the one that follows, used to return the singular or plural form of a word, based on the numeric value passed to the `format()` method:

```
ChoiceFormat cf = new ChoiceFormat("0#errors|1#error|2#errors");
```

A `ChoiceFormat` object created in this way returns the string "errors" when it formats the number 0, or any number greater than or equal to 2. It returns "error" when it formats the number 1. In the syntax shown here, note the pound sign (#) used to separate the limit number from the string that corresponds to that case and the vertical bar (`|`) used to separate the individual cases. You can use the `applyPattern()` method to change the pattern used by a `ChoiceFormat` object; use `toPattern()` to query the pattern it uses.

```
public class ChoiceFormat extends NumberFormat {
    // Public Constructors
            public ChoiceFormat(String newPattern);
            public ChoiceFormat(double[] limits, String[] formats);
    // Class Methods
            public static final double nextDouble(double d);
            public static double nextDouble(double d, boolean positive);
            public static final double previousDouble(double d);
    // Public Instance Methods
            public void applyPattern(String newPattern);
            public Object clone();  // Overrides NumberFormat
            public boolean equals(Object obj);  // Overrides NumberFormat
            public StringBuffer format(long number, StringBuffer toAppendTo,
            FieldPosition status);  // Defines NumberFormat
            public StringBuffer format(double number, StringBuffer toAppendTo,
            FieldPosition status);  // Defines NumberFormat
            public Object[] getFormats();
            public double[] getLimits();
            public int hashCode();  // Overrides NumberFormat
            public Number parse(String text, ParsePosition status);  // Defines
NumberFormat
            public void setChoices(double[] limits, String[] formats);
            public String toPattern();
}
```

Hierarchy:

Object->Format(Serializable, Cloneable)->NumberFormat(Cloneable)->ChoiceFormat

29.13 java.text.MessageFormat (JDK 1.1)

This class formats and substitutes objects into specified positions in a message string (also known as the "pattern" string). It provides the closest Java equivalent to the `printf()` function of the C programming language.

If a message is to be displayed only a single time, the simplest way to use the `MessageFormat` class is through the static `format()` method which is passed a message or pattern string and an array of argument objects to be formatted and substituted into the string. If the message is to be displayed several times, it makes more sense to create a `MessageFormat` object, supplying the pattern string, and then to call the `format()` instance method of this object, supplying the array of objects to be formatted into the message.

The message or pattern string used by the `MessageFormat` should contain digits enclosed in curly braces to indicate where each argument should be substituted. The sequence "`{0}`" indicates that the first object should be converted to a string (if necessary) and inserted at that point, while the sequence "`{3}`" indicates that the fourth object should be inserted, for example. If the object to be inserted is not a string, `MessageFormat` checks to see if it is a `Date` or a subclass of `Number`. If so, it uses a default `DateFormat` or `NumberFormat` object to convert the value to a string. If not, it simply invokes the object's `toString()` method to convert it.

A digit within curly braces in a pattern string may be optionally followed by a comma, and one of the words "date", "time", "number", or "choice", to indicate that the corresponding argument should be formatted as a date, time, number, or choice before being substituted into the pattern string. Any of these keywords may additionally be followed by a comma and additional pattern information to be used in formatting the date, time, number, or choice. (See `SimpleDateFormat`, `DecimalFormat`, and `ChoiceFormat` for more information.)

You can use the `setLocale()` method to specify a non-default `Locale` that the `MessageFormat` should use when obtaining `DateFormat` and `NumberFormat` objects to format dates, time, and numbers inserted into the pattern.

You can change the `Format` object used at a particular position in the pattern with the `setFormat()` method. You can set a new pattern for the `MessageFormat` object by calling `applyPattern()`, and you can obtain a string that represents the current formatting pattern by calling `toPattern()`.

`MessageFormat` also supports a `parse()` method that can parse an array of objects out of a specified string, according to the specified pattern.

```
public class MessageFormat extends Format {
    // Public Constructor
            public MessageFormat(String pattern);
    // Class Methods
            public static String format(String pattern, Object[] arguments);
    // Public Instance Methods
```

```
            public void applyPattern(String newPattern);
            public Object clone();  // Overrides Format
            public boolean equals(Object obj);  // Overrides Object
            public final StringBuffer format(Object[] source, StringBuffer result, 
FieldPosition ignore);
            public final StringBuffer format(Object source, StringBuffer result, 
FieldPosition ignore);  // Defines Format
            public Format[] getFormats();
            public Locale getLocale();
            public int hashCode();  // Overrides Object
            public Object[] parse(String source, ParsePosition status);
            public Object[] parse(String source) throws ParseException;
            public Object parseObject(String text, ParsePosition status);  // Defines 
Format
            public void setFormat(int variable, Format newFormat);
            public void setFormats(Format[] newFormats);
            public void setLocale(Locale theLocale);
            public String toPattern();
}

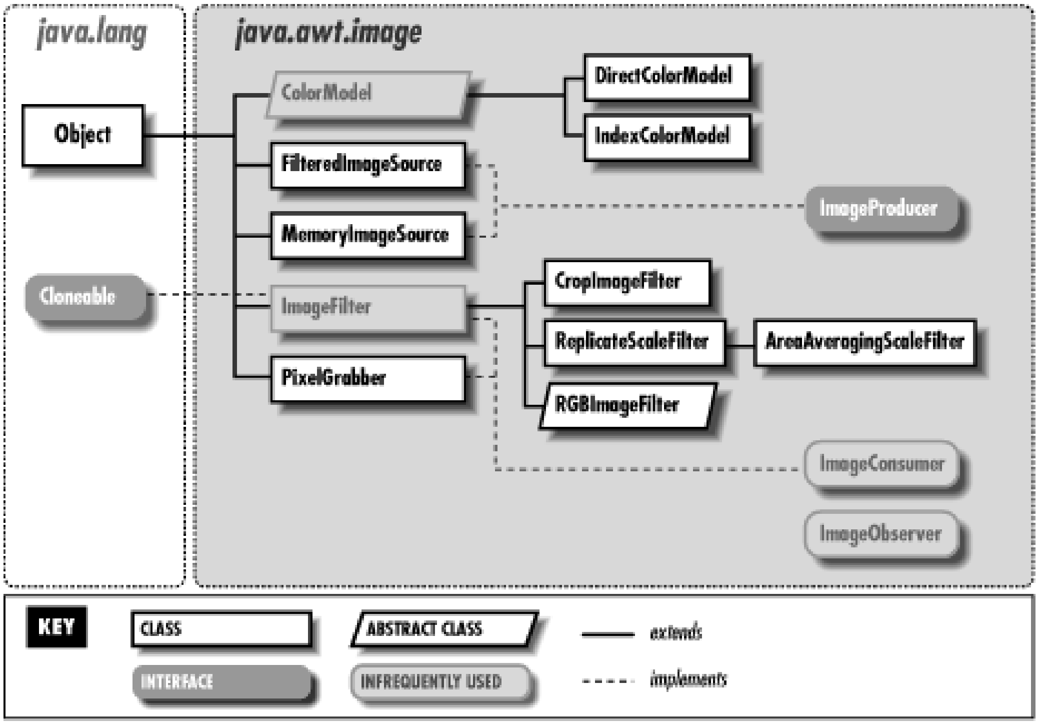
21. The java.awt.image Package

Contents:

The `java.awt.image` package is, by any standard, a confusing one. The purpose of the package is to support image processing, and the classes in the package provide a powerful infrastructure for that purpose. (see Figure 21.1.) Most of the classes are part of the infrastructure, however, and are not normally used by ordinary applications that have only simple image manipulation requirements.

To understand this package, it is first important to note that the `Image` class itself is part of the `java.awt` package, not the `java.awt.image` package. Furthermore, the `java.awt.image` classes are not the source of images; they simply serve to manipulate images that come from somewhere else. The `Applet.getImage()` method is perhaps the most common method for obtaining an image in Java--it downloads the image from a specified URL. In a stand-alone application, the `URL.getContent()` method can be used to obtain an `ImageProducer` object, which can then be passed to the `Component.createImage()` method to obtain an `Image` object.

Figure 21.1: The java.awt.image package



The ImageProducer interface is one you'll encounter frequently in java.awt.image. It represents an image source. If you've created an Image object with Applet.getImage(), you can obtain the ImageProducer for that Image (which has not been downloaded yet) with Image.getSource(). Conversely, given an ImageProducer object, you can create an Image from it with the createImage() method of any Component (such as an Applet). Once you have an ImageProducer object, you can manipulate it with the other java.awt.image classes.

FilteredImageSource is the most important class for image manipulation. It is itself a type of ImageProducer that, when created, applies a specified ImageFilter object to some other specified ImageProducer object. The FilteredImageSource thus configured can be used as an ImageProducer to display a filtered image. CropImageFilter is a predefined type of ImageFilter that you can use to extract a specified rectangle out of a larger image.

RGBImageFilter is another subclass of ImageFilter that makes it easy to filter the colors of an image. To do so, you must subclass RGBImageFilter and provide the definition of a single simple method that manipulates the image colors. In order to manipulate image colors, you will probably need to be familiar with the ColorModel class and its two subclasses, DirectColorModel and IndexColorModel. An instance of ColorModel or of one of its subclasses converts a pixel value to the red, green, and blue components of the color it represents.

Finally, two other classes in the java.awt.image package are worth noting. MemoryImageSource is a type of ImageProducer that generates an image from an array of bytes or integers in memory. PixelGrabber does the reverse--it captures pixels from an ImageProducer and stores them into an array. You can use these classes separately or together to perform your own custom image manipulation.

21.1 java.awt.image.AreaAveragingScaleFilter (JDK 1.1)

This class implements an ImageFilter that scales an image to a specified pixel size. It uses a scaling algorithm that averages adjacent pixel values when shrinking an image, which produces relatively smooth scaled images. Its superclass, ReplicateScaleFilter, implements a faster, less smooth scaling algorithm.

The methods of this class are ImageConsumer methods intended for communication between the image filter and the FilteredImageSource that uses it. Applications do not usually call these methods directly.

The easiest way to use this filter is to call `Image.getScaledInstance()`, specifying an appropriate hint constant.

```
public class AreaAveragingScaleFilter extends ReplicateScaleFilter {
    // Public Constructor
            public AreaAveragingScaleFilter(int width, int height);
    // Public Instance Methods
            public void setHints(int hints);  // Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model,
byte[] pixels, int off, int scansize);
            public void setPixels'u'// Overrides ReplicateScaleFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model, int[]
pixels, int off, int scansize);
            public void setPixels'u'// Overrides ReplicateScaleFilter
}
```

Hierarchy:

26. The java.lang.reflect Package

Contents:

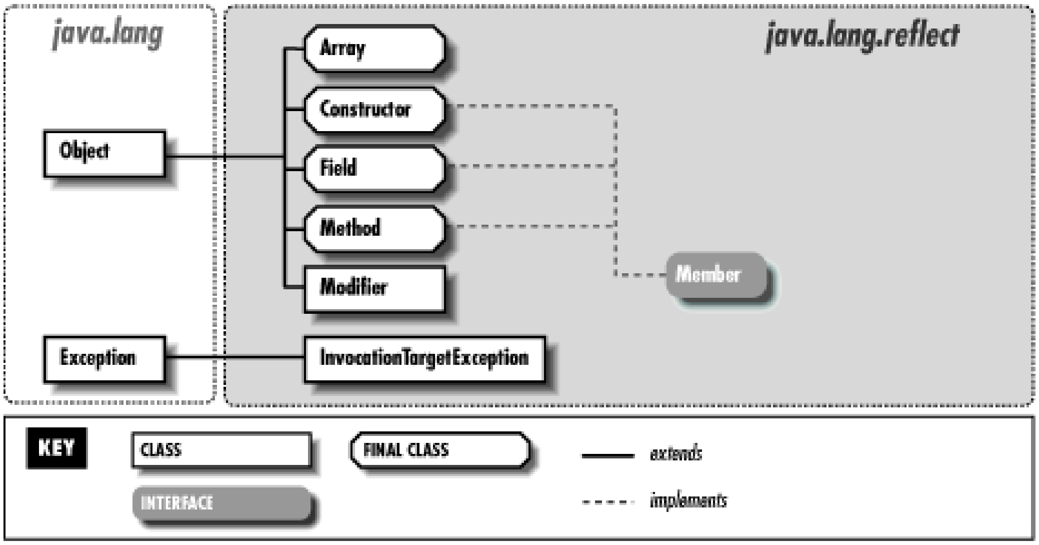
The `java.lang.reflect` package contains the classes and interfaces that, along with `java.lang.Class`, comprise the Java Reflection API. This package is new in Java 1.1. Figure 26.1 shows the class hierarchy.

The `Constructor`, `Field`, and `Method` classes represent constructors, fields, and methods of a class. Because these types all represent members of a class, they each implement the `Member` interface, which defines a simple set of methods that can be invoked for any class member. These classes allow information about the class members to be obtained, and allow methods and constructors to be invoked and fields to be queried and set.

Class member modifiers are represented as integers that specify a number of bit flags. The `Modifier` class defines static methods that are useful in interpreting the meanings of these flags. The `Array` class defines static methods for creating arrays and reading and writing array elements.

See Chapter 12, *Reflection* for examples of using these classes.

Figure 26.1: The java.lang.reflect package



26.1 java.lang.reflect.Array (JDK 1.1)

This class contains methods that allow you to set and query the values of array elements, to determine the length of an array, and to create new instances of arrays. Note that the `Array` class is used for manipulating array values, not array types; Java data types, including array types, are represented by `java.lang.Class`. Since the `Array` class represents a Java value, unlike the `Field`, `Method`, and `Constructor` classes which represent class members, the `Array` class is significantly different (despite some surface similarities) from those other classes in this package. Most notably, all the methods of `Array` are static and apply to all array values, rather than applying only to a specific field, method, or constructor.

The `get()` method returns the value of the specified element of the specified array as an `Object`. If the array elements are of a primitive type, the value is converted to a wrapper object before being returned. You can also use `getInteger()` and related methods to query array elements and return them as specific primitive types. The `set()` method and its primitive type variants perform the opposite operation. Also, the `getLength()` method returns the length of the array.

The `newInstance()` methods create new arrays. One version of this method is passed the number of elements in the array and the type of those elements. The other version of this method creates multidimensional arrays. Besides just specifying the component type of the array, it is passed an array of numbers. The length of this array specifies the number of dimensions for the array to be created, and the values of each array element specify the size of each dimension of the created array.

```

java.lang.Void (JDK 1.1) | BOOK INDEX | java.lang.reflect.Constructor (JDK 1.1)

25.60 java.lang.System (JDK 1.0)

This class defines methods that provide a platform-independent interface to system functions. All of the methods and variables of this class are static. The class may not be instantiated.

`getProperty()` looks up a named property on the system properties list, returning the optionally specified default value if no property definition was found. `getProperties()` returns the entire properties list. `setProperties()` sets a `Properties` object on the properties list.

The `in`, `out`, and `err` variables are the system standard input, output, and error streams. `arraycopy()` copies an array or a portion of an array into a destination array. `currentTimeMillis()` returns the current time in milliseconds since midnight GMT on January 1, 1970.

`exit()`, `gc()`, `load()`, `loadLibrary()`, and `runFinalization()` invoke the methods of the same name in the `Runtime` object. See `Runtime` for details.

```
public final class System extends Object {
    // No Constructor
    // Constants
            public static final PrintStream err;
            public static final InputStream in;
            public static final PrintStream out;
    // Class Methods
            public static native void arraycopy(Object src, int src_position, Object
dst, int dst_position, int length);
            public static native long currentTimeMillis();
            public static void exit(int status);
            public static void gc();
            public static Properties getProperties();
            public static String getProperty(String key);
            public static String getProperty(String key, String def);
            public static SecurityManager getSecurityManager();
        #   public static String getenv(String name);
        1.1public static native int identityHashCode(Object x);
            public static void load(String filename);
            public static void loadLibrary(String libname);
            public static void runFinalization();
        1.1public static void runFinalizersOnExit(boolean value);
        1.1public static void setErr(PrintStream err);
        1.1public static void setIn(InputStream in);
        1.1public static void setOut(PrintStream out);
            public static void setProperties(Properties props);
            public static void setSecurityManager(SecurityManager s);
}

23.6 java.beans.FeatureDescriptor (JDK 1.1)

The `FeatureDescriptor` class is the base class for `MethodDescriptor` and `PropertyDescriptor`, as well as other classes used by the JavaBeans introspection mechanism. It provides basic information about a feature (method, property, event, etc.) of a bean. Typically, the methods that begin with `get` and `is` are used by application builders or other tools to query the features of a bean. The `set` methods, on the other hand, may be used by bean authors to define information about the bean.

`setName()` specifies the locale-independent, programmatic name of the feature. `setDisplayName()` specifies a localized, human-readable name. `setShortDescription()` specifies a short localized string (about 40 characters) that describes the feature. Both the short description and the localized name default to the value of the programmatic name. `setExpert()` and `setHidden()` allow you to indicate that the feature is for use only by experts, or for use only by the builder tool, and should be hidden from users of the builder. Finally, the `setValue()` method allows you to associate an arbitrary named value with the feature.

```
public class FeatureDescriptor extends Object {
    // Public Constructor
            public FeatureDescriptor();
    // Public Instance Methods
            public Enumeration attributeNames();
            public String getDisplayName();
            public String getName();
            public String getShortDescription();
            public Object getValue(String attributeName);
            public boolean isExpert();
            public boolean isHidden();
            public void setDisplayName(String displayName);
            public void setExpert(boolean expert);
            public void setHidden(boolean hidden);
            public void setName(String name);
            public void setShortDescription(String text);
            public void setValue(String attributeName, Object value);
}
```

java.io.Serializable (JDK 1.1)
java.io.StreamCorruptedException (JDK 1.1)
java.io.StreamTokenizer (JDK 1.0)
java.io.StringBufferInputStream (JDK 1.0; Deprecated.)
java.io.StringReader (JDK 1.1)
java.io.StringWriter (JDK 1.1)
java.io.SyncFailedException (JDK 1.1)
java.io.UnsupportedEncodingException (JDK 1.1)
java.io.UTFDataFormatException (JDK 1.0)
java.io.WriteAbortedException (JDK 1.1)
java.io.Writer (JDK 1.1)

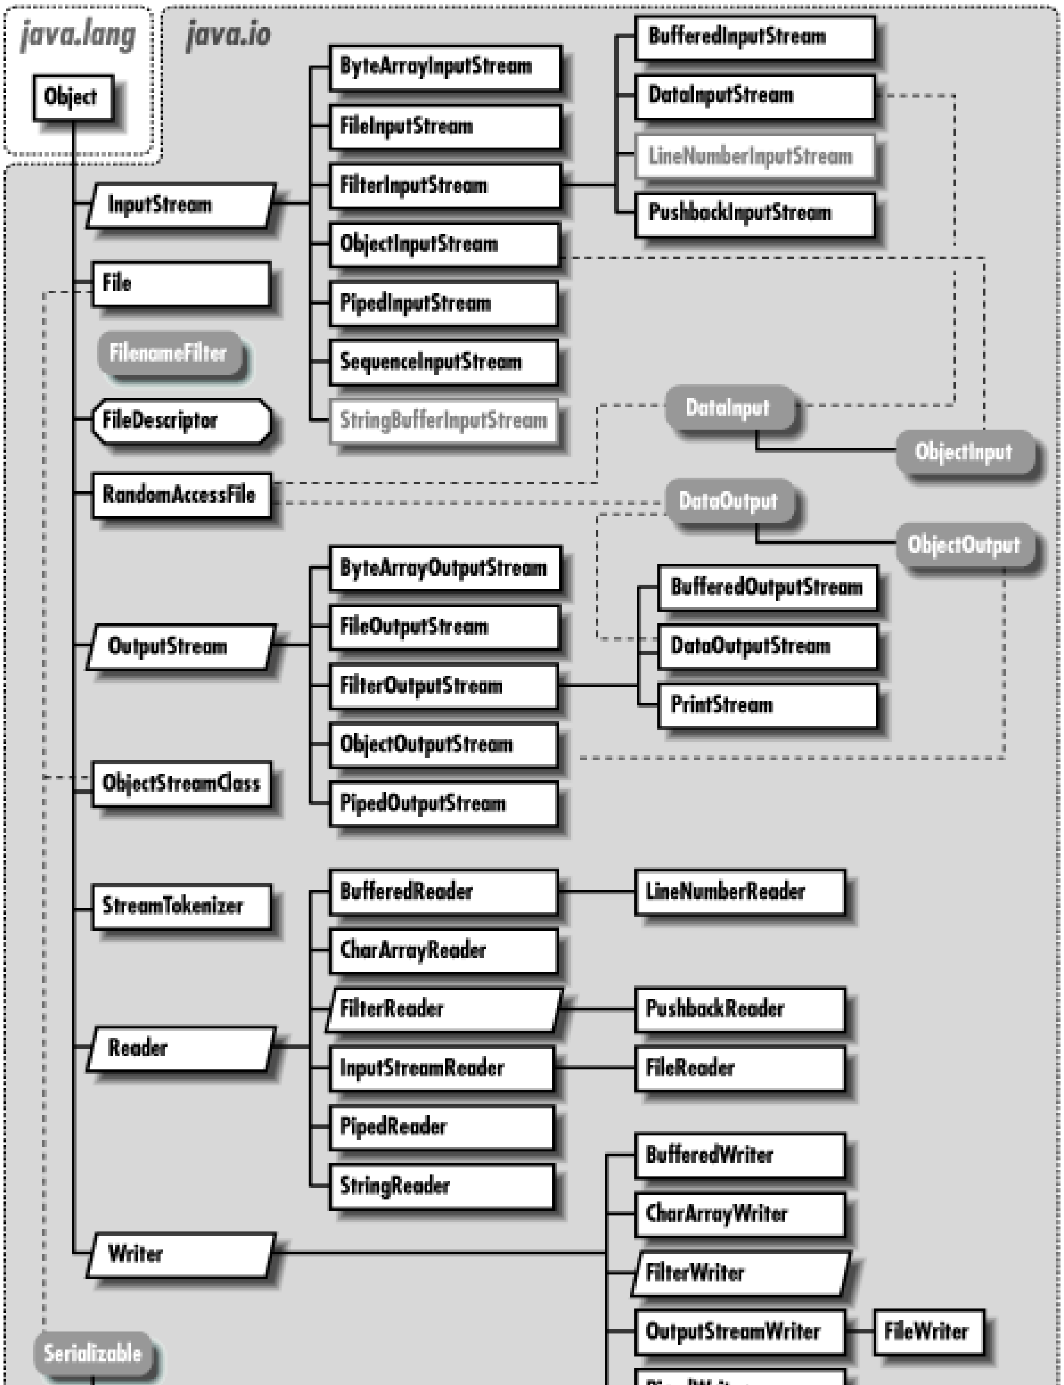
The `java.io` package contains a relatively large number of classes, but, as you can see from Figure 24.1 and Figure 24.2, the classes form a fairly structured hierarchy. Most of the package consists of byte streams--subclasses of `InputStream` or `OutputStream`--and (in Java 1.1) character streams--subclasses of `Reader` or `Writer`. Each of these stream types has a very specific purpose, and despite its size, `java.io` is a straightforward package to understand and to use.

Before we consider the stream classes in the package, we'll consider the important non-stream classes. `File` represents a file or directory name in a system independent way, and provides methods for listing directories, querying file attributes, and for renaming and deleting files. `FilenameFilter` is an interface that defines a method that accepts or rejects specified filenames. It is used by the `java.awt.FileDialog` dialog box and by the `File` class to specify what types of files should be included in directory listings. `RandomAccessFile` allows you to read or write from or to arbitrary locations of a file. Often, though, you'll prefer sequential access to a file and should use one of the stream classes.

`InputStream` and `OutputStream` are abstract classes that define methods for reading and writing bytes. Their subclasses allow bytes to be read from and written to a variety of sources and sinks. `FileInputStream` and `FileOutputStream` read from and write to files. `ByteArrayInputStream` and `ByteArrayOutputStream` read from and write to an array of bytes in memory. `PipedInputStream` reads bytes from a `PipedOutputStream`, and `PipedOutputStream` writes bytes to a `PipedInputStream`. These classes work together to implement a "pipe" for communication between threads.

`FilterInputStream` and `FilterOutputStream` are special--they filter input and output bytes. When a `FilterInputStream` is created, an `InputStream` is specified for it to filter. When you call the `read()` method of a `FilterInputStream`, it calls the `read()` method of its specified stream, processes the bytes it reads somehow, and then returns the filtered bytes. Similarly, you specify an `OutputStream` to be filtered when you create a `FilterOutputStream`. Calling the `write()` method of a `FilterOutputStream` causes it to process your bytes in some way and then pass those filtered bytes to the `write()` method of its `OutputStream`.

Figure 24.1: The java.io package



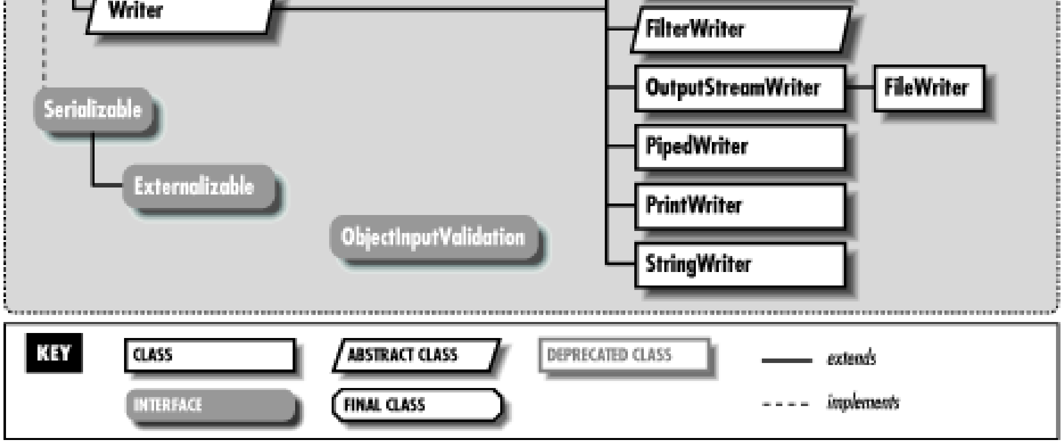


Figure 24.2: The exception classes of the java.io package

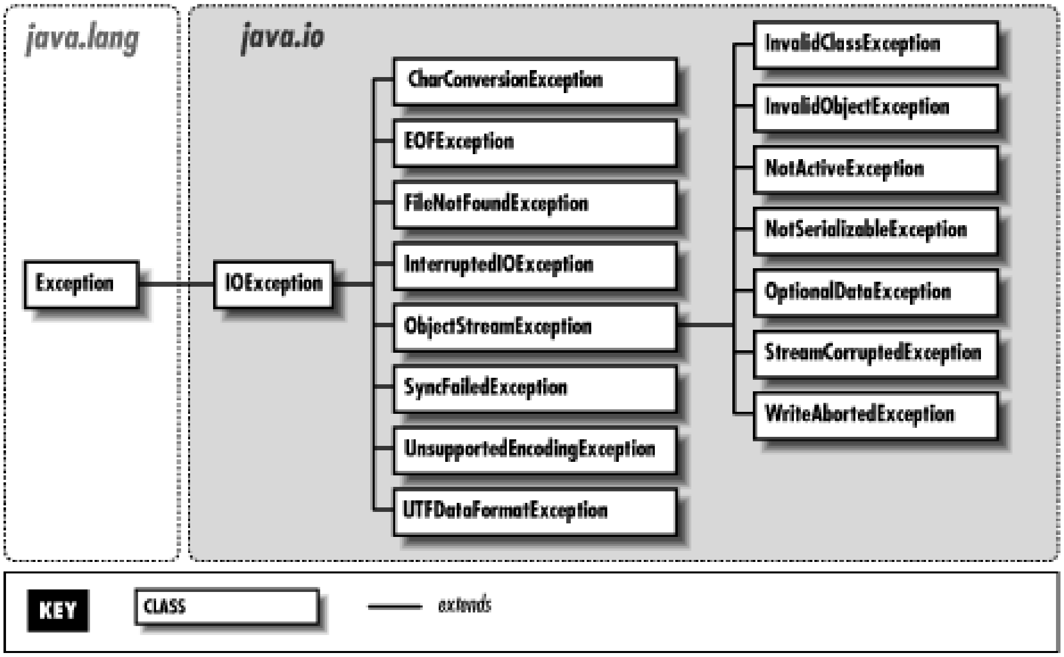

`FilterInputStream` and `FilterOutputStream` do not perform any filtering themselves; this is done by their subclasses. `BufferedInputStream` and `BufferedOutputStream` provide input and output buffering and can increase I/O efficiency. `DataInputStream` reads raw bytes from a stream and interprets them in various binary formats. It has various methods to read primitive Java data types in their standard binary formats. `DataOutputStream` allows you to write Java primitive data types in binary format.

In Java 1.1, the byte streams just described are complemented by an analogous set of character input and output streams. `Reader` is the superclass of all character input streams, and `Writer` is the superclass of all character output streams. These character streams supersede the byte streams for all textual I/O. They are more efficient than the byte streams, and they correctly handle the conversion between local encodings and Unicode text, making them invaluable for internationalized programs. Most of the `Reader` and `Writer` streams have obvious byte stream analogs. `BufferedReader` is a commonly used stream. It provides buffering for efficiency, and also has a `readLine()` method to read one line of text at a time. `PrintWriter` is another very common stream--its methods allow output of a textual representation of any primitive Java type or of any object (via the object's `toString()` method). See Chapter 11, *Internationalization* for a discussion of the use of character streams in internationalized programs.

The `ObjectInputStream` and `ObjectOutputStream` classes are special. These byte stream classes are new in Java 1.1 and are part of the Object Serialization API. See Chapter 9, *Object Serialization* for further details.

24.1 java.io.BufferedInputStream (JDK 1.0)

This class is a `FilterInputStream` that provides input data buffering--efficiency is increased by reading in large amounts of data and storing them in an internal buffer. When data is requested, it is usually available from the buffer. Thus, most calls to read data do not have to make a call to actually read data from a disk, network, or other slow source. Create a `BufferedInputStream` by specifying the `InputStream` that is to have buffering applied in the call to the constructor. See also `BufferedReader`.

```
public class BufferedInputStream extends FilterInputStream {
    // Public Constructors
            public BufferedInputStream(InputStream in);
            public BufferedInputStream(InputStream in, int size);
    // Protected Instance Variables
            protected byte[] buf;
            protected int count;
            protected int marklimit;
            protected int markpos;
            protected int pos;
    // Public Instance Methods
            public synchronized int available() throws IOException;  // Overrides 
FilterInputStream
            public synchronized void mark(int readlimit);  // Overrides 
FilterInputStream
            public boolean markSupported();  // Overrides FilterInputStream
            public synchronized int read() throws IOException;  // Overrides 
FilterInputStream
            public synchronized int read(byte[] b, int off, int len) throws 
IOException;  // Overrides FilterInputStream
            public synchronized void reset() throws IOException;  // Overrides 
FilterInputStream
            public synchronized long skip(long n) throws IOException;  // Overrides 
FilterInputStream
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.5 java.io.ByteArrayInputStream (JDK 1.0)

This class is a subclass of `InputStream` in which input data come from a specified array of `byte` values. This is useful when you want to read data in memory as if it were coming from a file or pipe or socket. Note that the specified array of bytes is not copied when a `ByteArrayInputStream` is created. See also `CharArrayReader`.

```
public class ByteArrayInputStream extends InputStream {
    // Public Constructors
            public ByteArrayInputStream(byte[] buf);
            public ByteArrayInputStream(byte[] buf, int offset, int length);
    // Protected Instance Variables
            protected byte[] buf;
            protected int count;
        1.1  protected int mark;
            protected int pos;
    // Public Instance Methods
            public synchronized int available();  // Overrides InputStream
        1.1  public void mark(int markpos);  // Overrides InputStream
        1.1  public boolean markSupported();  // Overrides InputStream
            public synchronized int read();  // Defines InputStream
            public synchronized int read(byte[] b, int off, int len);  // Overrides
InputStream
            public synchronized void reset();  // Overrides InputStream
            public synchronized long skip(long n);  // Overrides InputStream
}
```

Hierarchy:

Object->InputStream->ByteArrayInputStream

24.18 java.io.FileInputStream (JDK 1.0)

This class is a subclass of `InputStream` that reads bytes from a file specified by name or by a `File` or `FileDescriptor` object. `read()` reads a byte or array of bytes from the file. It returns -1 when the end of file has been reached. To read binary data, you typically use this class in conjunction with a `BufferedInputStream` and `DataInputStream`. To read text, you typically use it with an `InputStreamReader` and `BufferedReader`. Call `close()` to close the file when input is no longer needed.

```
public class FileInputStream extends InputStream {
    // Public Constructors
            public FileInputStream(String name) throws FileNotFoundException;
            public FileInputStream(File file) throws FileNotFoundException;
            public FileInputStream(FileDescriptor fdObj);
    // Public Instance Methods
            public native int available() throws IOException;  // Overrides 
InputStream
            public native void close() throws IOException;  // Overrides InputStream
            public final FileDescriptor getFD() throws IOException;
            public native int read() throws IOException;  // Defines InputStream
            public int read(byte[] b) throws IOException;  // Overrides InputStream
            public int read(byte[] b, int off, int len) throws IOException;  // 
Overrides InputStream
            public native long skip(long n) throws IOException;  // Overrides 
InputStream
    // Protected Instance Methods
            protected void finalize() throws IOException;  // Overrides Object
}
```

Hierarchy:

Object->InputStream->FileInputStream

24.24 java.io.FilterInputStream (JDK 1.0)

This class provides method definitions required to filter data obtained from the `InputStream` specified when the `FilterInputStream` is created. It must be subclassed to perform some sort of filtering operation, and may not be instantiated directly. See the subclasses `BufferedInputStream`, `DataInputStream`, and `PushbackInputStream`.

```
public class FilterInputStream extends InputStream {
    // Protected Constructor
            protected FilterInputStream(InputStream in);
    // Protected Instance Variables
            protected InputStream in;
    // Public Instance Methods
            public int available() throws IOException;  // Overrides InputStream
            public void close() throws IOException;  // Overrides InputStream
            public synchronized void mark(int readlimit);  // Overrides InputStream
            public boolean markSupported();  // Overrides InputStream
            public int read() throws IOException;  // Defines InputStream
            public int read(byte[] b) throws IOException;  // Overrides InputStream
            public int read(byte[] b, int off, int len) throws IOException;  // 
Overrides InputStream
            public synchronized void reset() throws IOException;  // Overrides 
InputStream
            public long skip(long n) throws IOException;  // Overrides InputStream
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.28 java.io.InputStream (JDK 1.0)

This abstract class is the superclass of all input streams. It defines the basic input methods that all input stream classes provide.

`read()` reads a single byte or an array or subarray of bytes. It returns the byte read, or the number of bytes read, or -1 if the end-of-file has been reached. `skip()` skips a specified number of bytes of input. `available()` returns the number of bytes that can be read without blocking. `close()` closes the input stream and frees up any system resources associated with it. The stream should not be used after `close()` has been called.

If `markSupported()` returns `true` for a given `InputStream`, that stream supports `mark()` and `reset()` methods. `mark()` marks the current position in the input stream so that `reset()` can return to that position as long as no more than the specified number of bytes have been read between the `mark()` and `reset()`. See also `Reader`.

```
public abstract class InputStream extends Object {
    // Default Constructor: public InputStream()
    // Public Instance Methods
            public int available() throws IOException;
            public void close() throws IOException;
            public synchronized void mark(int readlimit);
            public boolean markSupported();
            public abstract int read() throws IOException;
            public int read(byte[] b) throws IOException;
            public int read(byte[] b, int off, int len) throws IOException;
            public synchronized void reset() throws IOException;
            public long skip(long n) throws IOException;
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.34 java.io.LineNumberInputStream (JDK 1.0; Deprecated.)

This class is a `FilterInputStream` that keeps track of the number of lines of data that have been read. `getLineNumber()` returns the current line number. `setLineNumber()` sets the line number of the current line. Subsequent lines are numbered starting from that number.

This class is deprecated in Java 1.1 because it does not properly convert bytes to characters. Use `LineNumberReader` instead.

```
public class LineNumberInputStream extends FilterInputStream {
    // Public Constructor
            public LineNumberInputStream(InputStream in);
    // Public Instance Methods
            public int available() throws IOException;  // Overrides 
FilterInputStream
            public int getLineNumber();
            public void mark(int readlimit);  // Overrides FilterInputStream
            public int read() throws IOException;  // Overrides FilterInputStream
            public int read(byte[] b, int off, int len) throws IOException;  // 
Overrides FilterInputStream
            public void reset() throws IOException;  // Overrides FilterInputStream
            public void setLineNumber(int lineNumber);
            public long skip(long n) throws IOException;  // Overrides 
FilterInputStream
}
```

Hierarchy:

Object->InputStream->FilterInputStream->LineNumberInputStream

24.38 java.io.ObjectInput (JDK 1.1)

This interface extends the `DataInput` interface and adds methods for deserializing objects and reading bytes and arrays of bytes.

```
public abstract interface ObjectInput extends DataInput {
    // Public Instance Methods
            public abstract int available() throws IOException;
            public abstract void close() throws IOException;
            public abstract int read() throws IOException;
            public abstract int read(byte[] b) throws IOException;
            public abstract int read(byte[] b, int off, int len) throws IOException;
            public abstract Object readObject() throws ClassNotFoundException, 
IOException;
            public abstract long skip(long n) throws IOException;
}
```

Implemented By:

ObjectInputStream

Passed To:

Externalizable.readExternal()

24.39 java.io.ObjectInputStream (JDK 1.1)

`ObjectInputStream` is used to deserialize objects, arrays, and other values from a stream that was previously created with an `ObjectOutputStream`. The `readObject()` method deserializes objects and arrays (which should then be cast to the appropriate type); various other methods are used to read primitive data values from the stream. Note that only objects that implement the `Serializable` interface or the `Externalizable` interface can be serialized and deserialized.

The `defaultReadObject()` method may only be called from the `readObject()` method of an object that is currently being deserialized. It allows an object to perform additional processing after deserializing itself. The `registerValidation()` method may also only be called from the `readObject()` method of an object being deserialized. It registers an `ObjectInputValidation` object (typically the object being deserialized) to be notified when a complete tree of objects has been deserialized and the original call to the `readObject()` method of the `ObjectInputStream` is about to return to its caller.

The remaining methods include miscellaneous stream manipulation methods and several protected methods for use by subclasses that want to customize the deserialization behavior of `ObjectInputStream`.

```
public class ObjectInputStream extends InputStream implements ObjectInput {
    // Public Constructor
            public ObjectInputStream(InputStream in) throws IOException,
StreamCorruptedException;
    // Public Instance Methods
            public int available() throws IOException;  // Overrides InputStream
            public void close() throws IOException;  // Overrides InputStream
            public final void defaultReadObject() throws IOException,

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.48 java.io.PipedInputStream (JDK 1.0)

This class is an `InputStream` that implements one-half of a pipe, and is useful for communication between threads. A `PipedInputStream` must be connected to a `PipedOutputStream` object, which may be specified when the `PipedInputStream` is created or with the `connect()` method. Data read from a `PipedInputStream` object are received from the `PipedOutputStream` to which it is connected.

See `InputStream` for information on the low-level methods for reading data from a `PipedInputStream`. A `FilterInputStream` may be used to provide a higher-level interface for reading data from a `PipedInputStream`.

```
public class PipedInputStream extends InputStream {
    // Public Constructors
            public PipedInputStream(PipedOutputStream src) throws IOException;
            public PipedInputStream();
    // Constants
        1.1  protected static final int PIPE_SIZE;
    // Protected Instance Variables
        1.1  protected byte[] buffer;
        1.1  protected int in;
        1.1  protected int out;
    // Public Instance Methods
            public synchronized int available() throws IOException;  // Overrides 
InputStream
            public void close() throws IOException;  // Overrides InputStream
            public void connect(PipedOutputStream src) throws IOException;
            public synchronized int read() throws IOException;  // Defines 
InputStream
            public synchronized int read(byte[] b, int off, int len) throws 
IOException;  // Overrides InputStream
    // Protected Instance Methods
        1.1  protected synchronized void receive(int b) throws IOException;
}
```

Hierarchy:

Object->InputStream->PipedInputStream

Passed To:

PipedOutputStream(), PipedOutputStream.connect()

PREVIOUS | HOME | NEXT

java.io.OutputStreamWriter (JDK 1.1) | BOOK INDEX | java.io.PipedOutputStream (JDK 1.0)

24.54 java.io.PushbackInputStream (JDK 1.0)

This class is a `FilterInputStream` that implements a one-byte pushback buffer or, in Java 1.1, a pushback buffer of a specified length. The `unread()` methods "push" bytes back into the stream--these bytes are the first ones read by the next call to a `read()` method. This class is sometimes useful when writing parsers.

See also `PushbackReader`.

```
public class PushbackInputStream extends FilterInputStream {
    // Public Constructors
        1.1  public PushbackInputStream(InputStream in, int size);
            public PushbackInputStream(InputStream in);
    // Protected Instance Variables
        1.1  protected byte[] buf;
        1.1  protected int pos;
    // Public Instance Methods
            public int available() throws IOException;  // Overrides 
FilterInputStream
            public boolean markSupported();  // Overrides FilterInputStream
            public int read() throws IOException;  // Overrides FilterInputStream
            public int read(byte[] b, int off, int len) throws IOException;  // 
Overrides FilterInputStream
            public void unread(int b) throws IOException;
        1.1  public void unread(byte[] b, int off, int len) throws IOException;
        1.1  public void unread(byte[] b) throws IOException;
}
```

Hierarchy:

Object->InputStream->FilterInputStream->PushbackInputStream

24.58 java.io.SequenceInputStream (JDK 1.0)

This class provides a way of seamlessly concatenating the data from two or more input streams. It provides an `InputStream` interface to a sequence of `InputStream` objects. Data are read from the streams in the order in which the streams are specified. When the end of one stream is reached, data are automatically read from the next stream. This class might be useful, for example, when implementing an "include file" facility for a parser of some sort.

```
public class SequenceInputStream extends InputStream {
    // Public Constructors
            public SequenceInputStream(Enumeration e);
            public SequenceInputStream(InputStream s1, InputStream s2);
    // Public Instance Methods
        1.1  public int available() throws IOException;  // Overrides InputStream
            public void close() throws IOException;  // Overrides InputStream
            public int read() throws IOException;  // Defines InputStream
            public int read(byte[] buf, int pos, int len) throws IOException;  //
Overrides InputStream
}
```

Hierarchy:

Object->InputStream->SequenceInputStream

24.62 java.io.StringBufferInputStream (JDK 1.0; Deprecated.)

This class is a subclass of `InputStream` in which input bytes come from the characters of a specified `String` object.

This class does not correctly convert the characters of a `StringBuffer` into bytes, and is deprecated in Java 1.1. Use `StringReader` instead to correctly convert characters into bytes, or use `ByteArrayInputStream` to read bytes from an array of bytes.

```
public class StringBufferInputStream extends InputStream {
    // Public Constructor
            public StringBufferInputStream(String s);
    // Protected Instance Variables
            protected String buffer;
            protected int count;
            protected int pos;
    // Public Instance Methods
            public synchronized int available();  // Overrides InputStream
            public synchronized int read();  // Defines InputStream

InputStream
            public synchronized void reset();  // Overrides InputStream
            public synchronized long skip(long n);  // Overrides InputStream
}
```

Hierarchy:

Object->InputStream->StringBufferInputStream

23.23 java.beans.Visibility (JDK 1.1)

This interface is intended to be implemented by advanced beans that may run either with or without a GUI (graphical user interface) present. The methods it defines allow a bean to specify whether it requires a GUI and allows the environment to notify the bean whether a GUI is available.

If a bean absolutely requires a GUI, it should return `true` from `needsGui()`. If a bean is running without a GUI, it should return `true` from `avoidingGui()`. If no GUI is available, the bean may be notified through a call to `dontUseGui()`, and if a GUI is available, the bean may be notified through a call to `okToUseGui()`.

```
public abstract interface Visibility {
    // Public Instance Methods
            public abstract boolean avoidingGui();
            public abstract void dontUseGui();
            public abstract boolean needsGui();
            public abstract void okToUseGui();
}
```

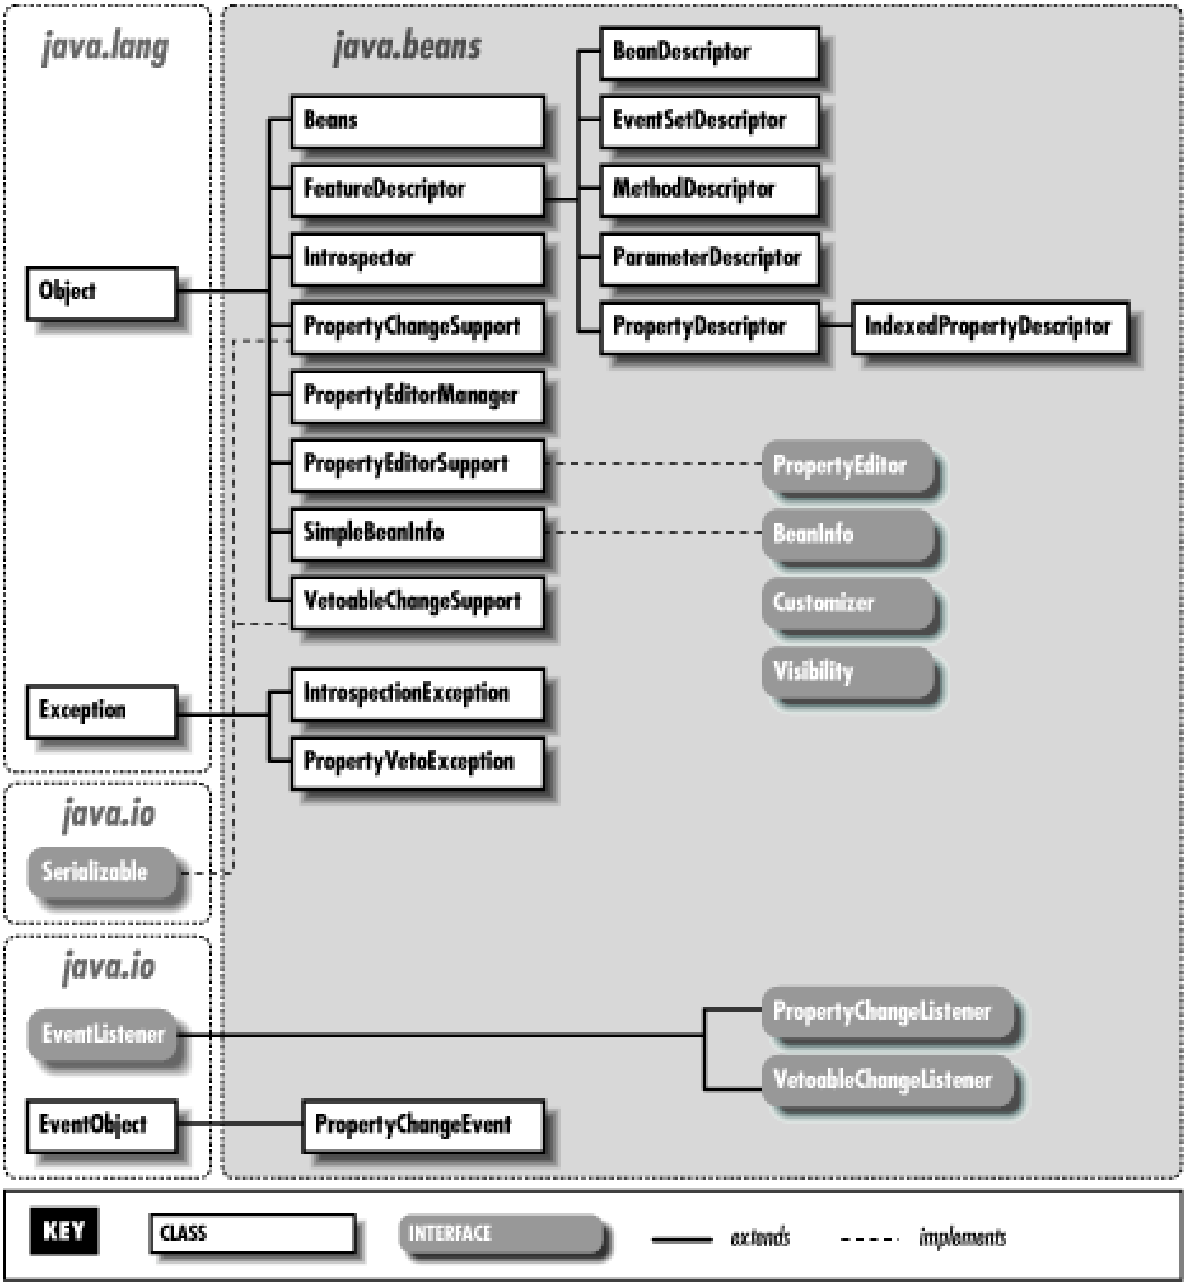
23. The java.beans Package

Contents:

The `java.beans` package contains the classes and interfaces that constitute the JavaBeans API. It is new in Java 1.1. Figure 23.1 shows the class hierarchy for this package.

The classes and interfaces in this package are useful to programmers who are developing "beanbox" tools to manipulate beans, and to programmers who are writing their own beans. Programmers who are building applications using beans do not have to be familiar with java.beans. See Chapter 10, *Java Beans* for more details on writing custom beans.

Figure 23.1: The java.beans package



23.1 java.beans.BeanDescriptor (JDK 1.1)

A BeanDescriptor object is a type of FeatureDescriptor that describes a Java bean. The BeanInfo class for a Java bean optionally creates and initializes a BeanDescriptor object to describe the bean. Typically, only application builders and similar tools use the BeanDescriptor.

To create a BeanDescriptor, you must specify the class of the bean, and optionally, the class of a Customizer for the bean. You can use the methods of FeatureDescriptor to provide additional information about the bean.

```
public class BeanDescriptor extends FeatureDescriptor {
    // Public Constructors
            public BeanDescriptor(Class beanClass);
            public BeanDescriptor(Class beanClass, Class customizerClass);
    // Public Instance Methods
            public Class getBeanClass();
            public Class getCustomizerClass();
}
```

Hierarchy:

Object->FeatureDescriptor->BeanDescriptor

Returned By:

BeanInfo.getBeanDescriptor(), SimpleBeanInfo.getBeanDescriptor()

18.60 java.awt.Toolkit (JDK 1.0)

This abstract class defines methods that, when implemented, create platform-dependent "peers" for each of the `java.awt` `Component` types. Java supports its platform-independent GUI interface by implementing a subclass of `Toolkit` for each platform. Portable programs should never use these methods to create peers directly--they should use the `Component` classes themselves. A `Toolkit` object cannot be instantiated directly. `Component.getToolkit()` returns the `Toolkit` being used for a particular component.

The `Toolkit` class defines a few methods that you can use directly: the static method `getDefaultToolkit()` returns the default `Toolkit` that is in use. `getScreenSize()` returns the screen size in pixels, and `getScreenResolution()` returns the resolution in dots-per-inch. `getFontList()` returns the names of supported fonts. `sync()` flushes all pending graphics output, which can be useful for animation. In Java 1.1, `getPrintJob()`, `getSystemClipboard()`, and `getSystemEventQueue()` are also of interest.

```
public abstract class Toolkit extends Object {
    // Default Constructor: public Toolkit()
    // Class Methods
            public static synchronized Toolkit getDefaultToolkit();
        1.1  protected static Container getNativeContainer(Component c);
        1.1  public static String getProperty(String key, String defaultValue);
    // Public Instance Methods
        1.1  public abstract void beep();
            public abstract int checkImage(Image image, int width, int height, 
ImageObserver observer);
            public abstract Image createImage(ImageProducer producer);
        1.1  public Image createImage(byte[] imagedata);
        1.1  public abstract Image createImage(byte[] imagedata, int imageoffset, int 
imagelength);
            public abstract ColorModel getColorModel();
            public abstract String[] getFontList();
            public abstract FontMetrics getFontMetrics(Font font);
            public abstract Image getImage(String filename);
            public abstract Image getImage(URL url);
        1.1  public int getMenuShortcutKeyMask();
        1.1  public abstract PrintJob getPrintJob(Frame frame, String jobtitle, 
Properties props);
            public abstract int getScreenResolution();
            public abstract Dimension getScreenSize();
        1.1  public abstract Clipboard getSystemClipboard();
        1.1  public final EventQueue getSystemEventQueue();
            public abstract boolean prepareImage(Image image, int width, int height, 
ImageObserver observer);
            public abstract void sync();
    // Protected Instance Methods
            protected abstract ButtonPeer createButton(Button target);
            protected abstract CanvasPeer createCanvas(Canvas target);
            protected abstract CheckboxPeer createCheckbox(Checkbox target);
            protected abstract CheckboxMenuItemPeer
createCheckboxMenuItem(CheckboxMenuItem target);
            protected abstract ChoicePeer createChoice(Choice target);
        1.1  protected LightweightPeer createComponent(Component target);
            protected abstract DialogPeer createDialog(Dialog target);
            protected abstract FileDialogPeer createFileDialog(FileDialog target);
            protected abstract FramePeer createFrame(Frame target);
            protected abstract LabelPeer createLabel(Label target);
            protected abstract ListPeer createList(List target);
            protected abstract MenuPeer createMenu(Menu target);
            protected abstract MenuBarPeer createMenuBar(MenuBar target);
            protected abstract MenuItemPeer createMenuItem(MenuItem target);
            protected abstract PanelPeer createPanel(Panel target);
        1.1  protected abstract PopupMenuPeer createPopupMenu(PopupMenu target);
        1.1  protected abstract ScrollPanePeer createScrollPane(ScrollPane target);
            protected abstract ScrollbarPeer createScrollbar(Scrollbar target);
            protected abstract TextAreaPeer createTextArea(TextArea target);
            protected abstract TextFieldPeer createTextField(TextField target);
            protected abstract WindowPeer createWindow(Window target);
        1.1  protected abstract FontPeer getFontPeer(String name, int style);
        1.1  protected abstract EventQueue getSystemEventQueueImpl();
        1.1  protected void loadSystemColors(int[] systemColors);
}
```

31.7 java.util.zip.Deflater (JDK 1.1)

This class implements the general ZLIB data compression algorithm used by the *gzip* and *PKZip* compression programs. The constants defined by this class are used to specify the compression strategy to be used and the compression speed/strength trade-off level to be used. If you set the *nowrap* argument to the constructor to `true`, then the ZLIB header and checksum data are omitted from the compressed output, which is the format that both *gzip* and *PKZip* use.

The important methods of this class are `setInput()`, which specifies input data to be compressed, and `deflate()`, which compresses the data and returns the compressed output. The remaining methods exist so that `Deflater` can be used for stream-based compression, as it is in higher-level classes such as `GZIPOutputStream` and `ZipOutputStream`. These stream classes are sufficient in most cases. Most applications do not need to use `Deflater` directly.

The `Inflater` class uncompresses data compressed with a `Deflater` object.

```
public class Deflater extends Object {
    // Public Constructors
            public Deflater(int level, boolean nowrap);
            public Deflater(int level);
            public Deflater();
    // Constants
            public static final int BEST_COMPRESSION;
            public static final int BEST_SPEED;
            public static final int DEFAULT_COMPRESSION;
            public static final int DEFAULT_STRATEGY;
            public static final int DEFLATED;
            public static final int FILTERED;
            public static final int HUFFMAN_ONLY;
            public static final int NO_COMPRESSION;
    // Public Instance Methods
            public synchronized native int deflate(byte[] b, int off, int len);
            public int deflate(byte[] b);
            public synchronized native void end();
            public synchronized void finish();
            public synchronized boolean finished();
            public synchronized native int getAdler();
            public synchronized native int getTotalIn();
            public synchronized native int getTotalOut();
            public boolean needsInput();
            public synchronized native void reset();
            public synchronized native void setDictionary(byte[] b, int off, int 
len);
            public void setDictionary(byte[] b);
            public synchronized void setInput(byte[] b, int off, int len);
            public void setInput(byte[] b);
            public synchronized void setLevel(int Level);
            public synchronized void setStrategy(int strategy);
    // Protected Instance Methods
            protected void finalize();  // Overrides Object
}
```

28.7 java.net.DatagramSocketImpl (JDK 1.1)

This abstract class defines the methods necessary to implement communication through datagram and multicast sockets. System programmers may create subclasses of this class when they need to implement datagram or multicast sockets in a nonstandard network environment, such as behind a firewall or on a network that uses a nonstandard transport protocol.

Normal applications never need to use or subclass this class.

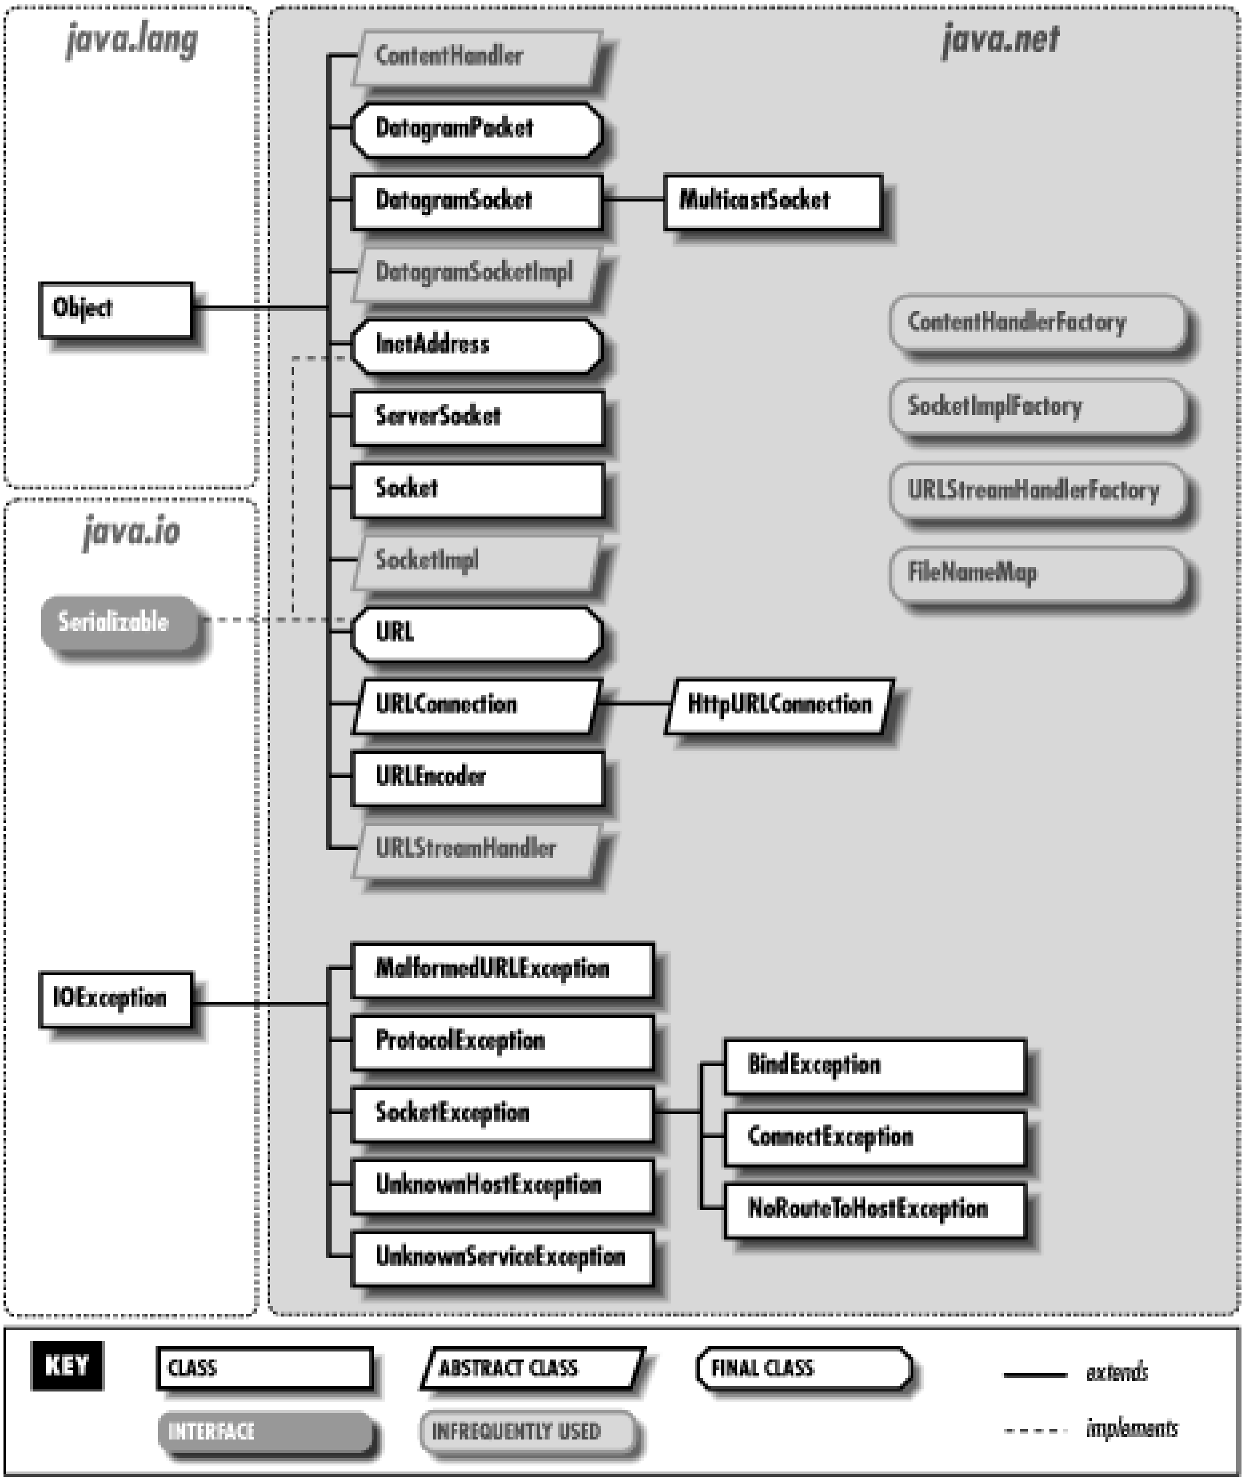
```
public abstract class DatagramSocketImpl extends Object {
    // Default Constructor: public DatagramSocketImpl()
    // Protected Instance Variables
            protected FileDescriptor fd;
            protected int localPort;
    // Protected Instance Methods
            protected abstract void bind(int lport, InetAddress laddr) throws 
SocketException;
            protected abstract void close();
            protected abstract void create() throws SocketException;
            protected FileDescriptor getFileDescriptor();
            protected int getLocalPort();
            protected abstract byte getTTL() throws IOException;
            protected abstract void join(InetAddress inetaddr) throws IOException;
            protected abstract void leave(InetAddress inetaddr) throws IOException;
            protected abstract int peek(InetAddress i) throws IOException;
            protected abstract void receive(DatagramPacket p) throws IOException;
            protected abstract void send(DatagramPacket p) throws IOException;
            protected abstract void setTTL(byte ttl) throws IOException;
}
```

28. The java.net Package

Contents:

The `java.net` package provides a powerful and flexible infrastructure for networking. Figure 28.1 shows the class hierarchy for this package. Many of the classes in this package are part of the networking infrastructure and are not used by normal applications; these complicated classes can make the package a difficult one to understand. In this overview we describe only the classes that an application might normally use.

Figure 28.1: The java.net package



The `URL` class represents an Internet Uniform Resource Locator. It provides a very simple interface to networking--the object referred to by the URL can be downloaded with a single call, or streams may be opened to read from or write to the object.

At a slightly more complex level, the `URLConnection` object may be obtained from a given `URL` object. The `URLConnection` class provides additional methods that allow you to work with URLs in more sophisticated ways.

If you want to do more than simply download an object referenced by a URL, you can do your own networking with the `Socket` class. This class allows you to connect to a specified port on a specified Internet host and read and write data using the `InputStream` and `OutputStream` classes of the `java.io` package. If you want to implement a server to accept connections from clients, you can use the related `ServerSocket` class. Both `Socket` and `ServerSocket` use the `InetAddress` address class, which represents an Internet address.

The `java.net` package allows you to do low-level networking with `DatagramPacket` objects which may be sent and received over the network through a `DatagramSocket` object. In Java 1.1, the package has been extended to include a `MulticastSocket` class that supports multicast networking.

28.1 java.net.BindException (JDK 1.1)

This exception signals that a socket could not be bound to a local address and port. This often means that the port is already in use.

```
public class BindException extends SocketException {
    // Public Constructors
            public BindException(String msg);
            public BindException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->SocketException->BindException

18.14 java.awt.Color (JDK 1.0)

The `Color` object describes a color. The `Color()` constructors describe a color as red, green, and blue components between 0 and 255, or as floating-point values between 0.0 and 1.0. The class method `Color.getHSBColor()` creates a color using the hue/saturation/brightness color model.

`brighter()` and `darker()` are useful methods to create shading effects. The `getColor()` methods look up a color name in the properties database and convert the resulting integer color value into a `Color` object. Two of these methods provide a default value to be used in case the specified color name is not found.

```
public class Color extends Object implements Serializable {
    // Public Constructors
            public Color(int r, int g, int b);
            public Color(int rgb);
            public Color(float r, float g, float b);
    // Constants
            public static final Color black;
            public static final Color blue;
            public static final Color cyan;
            public static final Color darkGray;
            public static final Color gray;
            public static final Color green;
            public static final Color lightGray;
            public static final Color magenta;
            public static final Color orange;
            public static final Color pink;
            public static final Color red;
            public static final Color white;
            public static final Color yellow;
    // Class Methods
            public static int HSBtoRGB(float hue, float saturation, float
brightness);
            public static float[] RGBtoHSB(int r, int g, int b, float[] hsbvals);
        1.1 public static Color decode(String nm) throws NumberFormatException;
            public static Color getColor(String nm);
            public static Color getColor(String nm, Color v);
            public static Color getColor(String nm, int v);
            public static Color getHSBColor(float h, float s, float b);
    // Public Instance Methods
```

```
            public Color brighter();
            public Color darker();
            public boolean equals(Object obj);  // Overrides Object
            public int getBlue();
            public int getGreen();
            public int getRGB();
            public int getRed();
            public int hashCode();  // Overrides Object
            public String toString();  // Overrides Object
}
```

java.awt.Choice (JDK 1.0) | BOOK INDEX | java.awt.Component (JDK 1.0)

18.24 java.awt.Font (JDK 1.0)

This class represents a font in a platform-independent way. The constructor accepts a font name, style, and point size. In Java 1.0, supported font names are: "TimesRoman," "Helvetica," "Courier," "Dialog," and "DialogInput." In Java 1.1, "Serif," "SansSerif," and "Monospaced" should be used in preference to the first three names. The style may be one of the constants `PLAIN`, `BOLD`, or `ITALIC`, or the sum `BOLD+ITALIC`.

The class method `getFont()` looks up the specified name in the system properties list and returns the font specified as the value of that property. It takes an optional `Font` default to use if the named font property is not found. This allows user customizability.

Use the `FontMetrics` class if you need to know how tall a font is or how wide a string drawn using that font will be.

```
public class Font extends Object implements Serializable {
    // Public Constructor
            public Font(String name, int style, int size);
    // Constants
            public static final int BOLD;
            public static final int ITALIC;
            public static final int PLAIN;
    // Protected Instance Variables
            protected String name;
            protected int size;
            protected int style;
    // Class Methods
        1.1  public static Font decode(String str);
            public static Font getFont(String nm);
            public static Font getFont(String nm, Font font);
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
            public String getFamily();
            public String getName();
        1.1  public FontPeer getPeer();
            public int getSize();
            public int getStyle();

Type Of:

`FontMetrics.font`

25.5 java.lang.Boolean (JDK 1.0)

This class provides an immutable object wrapper around the `boolean` primitive type. Note that the `TRUE` and `FALSE` constants are `Boolean` objects; they are not the same as the `true` and `false` `boolean` values. In Java 1.1, this class defines a `Class` constant that represents the `boolean` type.

`booleanValue()` returns the `boolean` value of a `Boolean` object. The class method `getBoolean()` retrieves the `boolean` value of a named property from the system property list. The class method `valueOf()` parses a string and returns the `Boolean` value it represents.

```
public final class Boolean extends Object implements Serializable {
    // Public Constructors
            public Boolean(boolean value);
            public Boolean(String s);
    // Constants
            public static final Boolean FALSE;
            public static final Boolean TRUE;
        1.1public static final Class TYPE;
    // Class Methods
            public static boolean getBoolean(String name);
            public static Boolean valueOf(String s);
    // Public Instance Methods
            public boolean booleanValue();
            public boolean equals(Object obj);  // Overrides Object
            public int hashCode();  // Overrides Object
            public String toString();  // Overrides Object
}
```

Returned By:

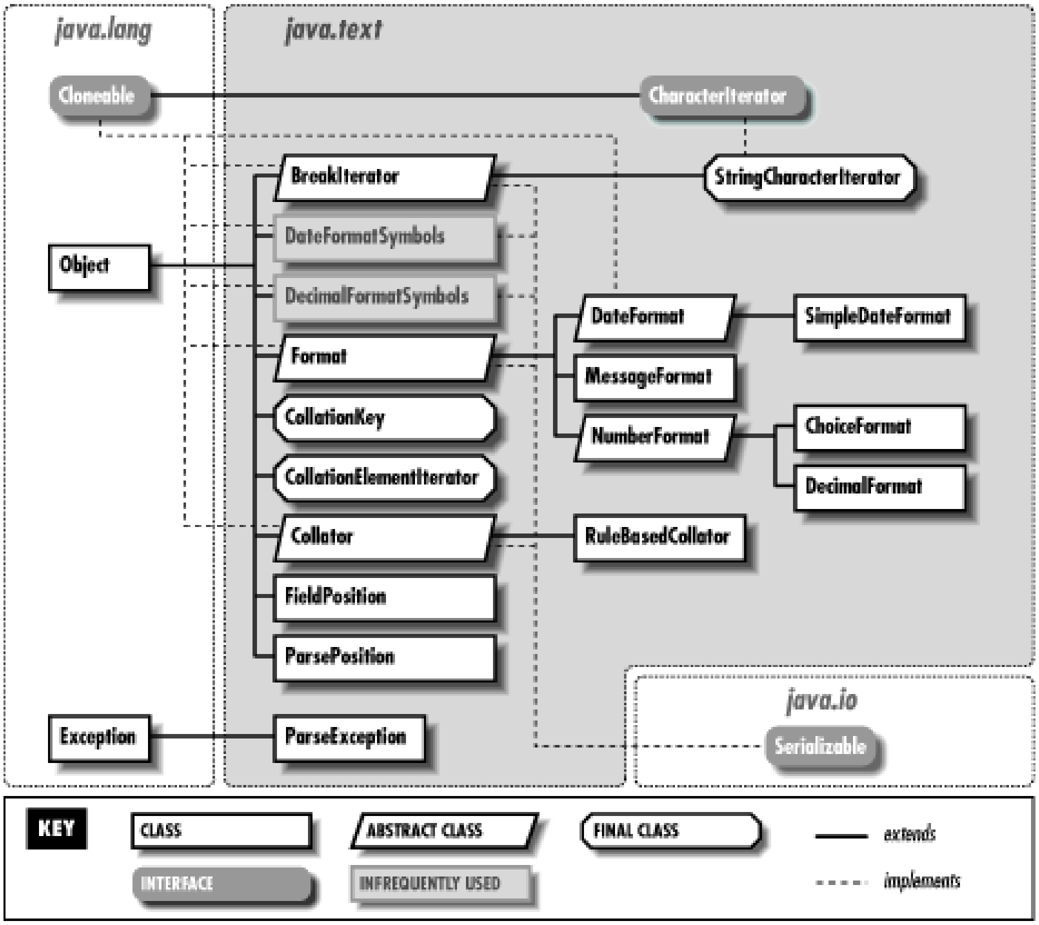
29. The java.text Package

Contents:

The `java.text` package consists of classes and interfaces that are useful for writing internationalized programs that handle local customs, such as date and time formatting and string alphabetization, correctly. This package is new in Java 1.1. Figure 29.1 shows its class hierarchy.

The `NumberFormat` class formats numbers, monetary quantities, and percentages as appropriate for the default or specified locale. `DateFormat` formats dates and times in a locale-specific way. The concrete `DecimalFormat` and `SimpleDateFormat` subclasses of these classes can be used for customized number, date, and time formatting. `MessageFormat` allows substitution of dynamic values, including formatted numbers and dates, into static message strings. `ChoiceFormat` formats a number using an enumerated set of string values. `Collator` compares strings according to the customary sorting order for a locale. `BreakIterator` scans text to find word, line, and sentence boundaries following locale-specfic rules.

Figure 29.1: The java.text package



29.1 java.text.BreakIterator (JDK 1.1)

This class is used to determine character, word, sentence, and line breaks in a block of text in a way that is independent of locale and text-encoding. As an abstract class, `BreakIterator` cannot be instantiated directly. Instead, you must use one of the class methods `getCharacterInstance()`, `getWordInstance()`, `getSentenceInstance()`, or `getLineInstance()` to return an instance of a nonabstract subclass of `BreakIterator`. These various "factory" methods return a `BreakIterator` object that is configured to locate the requested boundary types, and is localized to work for the optionally specified locale.

Once you have obtained an appropriate `BreakIterator` object, you use `setText()` to specify the text that it is to locate boundaries in. To locate boundaries in a Java `String` object, simply specify the string. To locate boundaries in text that uses some other encoding, you must specify a `CharacterIterator` object for that text so that the `BreakIterator` object can locate the individual characters of the text.

Having set the text to be searched, you can determine the character positions of characters, words, sentences, or line breaks with the `first()`, `last()`, `next()`, `previous()`, `current()`, and `following()` methods, which perform the obvious functions. Note that these methods do not return text itself, but merely the position of the appropriate word, sentence, or line break.

```
public abstract class BreakIterator extends Object implements Cloneable, Serializable
{
    // Protected Constructor
            protected BreakIterator();
    // Constants
            public static final int DONE;
    // Class Methods
            public static synchronized Locale[] getAvailableLocales();
            public static BreakIterator getCharacterInstance();
            public static BreakIterator getCharacterInstance(Locale where);
            public static BreakIterator getLineInstance();
            public static BreakIterator getLineInstance(Locale where);
            public static BreakIterator getSentenceInstance();
            public static BreakIterator getSentenceInstance(Locale where);
            public static BreakIterator getWordInstance();
            public static BreakIterator getWordInstance(Locale where);
    // Public Instance Methods
            public Object clone();  // Overrides Object
            public abstract int current();

24.2 java.io.BufferedOutputStream (JDK 1.0)

This class is a `FilterOutputStream` that provides output data buffering--output efficiency is increased by storing values to be written in a buffer and actually writing them out only when the buffer fills up or when the `flush()` method is called. Create a `BufferedOutputStream` by specifying the `OutputStream` that is to have buffering applied in the call to the constructor. See also `BufferedWriter`.

```
public class BufferedOutputStream extends FilterOutputStream {
    // Public Constructors
            public BufferedOutputStream(OutputStream out);
            public BufferedOutputStream(OutputStream out, int size);
    // Protected Instance Variables
            protected byte[] buf;
            protected int count;
    // Public Instance Methods
            public synchronized void flush() throws IOException;  // Overrides 
FilterOutputStream
            public synchronized void write(int b) throws IOException;  // Overrides 
FilterOutputStream
            public synchronized void write(byte[] b, int off, int len) throws 
IOException;  // Overrides FilterOutputStream
}
```

Hierarchy:

Object->OutputStream->FilterOutputStream->BufferedOutputStream

24.6 java.io.ByteArrayOutputStream (JDK 1.0)

This class is a subclass of `OutputStream` in which data that are written are stored in an internal `byte` array. The internal array grows as necessary, and can be retrieved with `toByteArray()` or `toString()`. The `reset()` method discards any data currently stored in the internal array and begins storing data from the beginning again. See also `CharArrayWriter`.

```
public class ByteArrayOutputStream extends OutputStream {
    // Public Constructors
            public ByteArrayOutputStream();
            public ByteArrayOutputStream(int size);
    // Protected Instance Variables
            protected byte[] buf;
            protected int count;
    // Public Instance Methods
            public synchronized void reset();
            public int size();
            public synchronized byte[] toByteArray();
            public String toString();  // Overrides Object
        1.1  public String toString(String enc) throws UnsupportedEncodingException;
        #   public String toString(int hibyte);
            public synchronized void write(int b);  // Defines OutputStream
            public synchronized void write(byte[] b, int off, int len);  // Overrides 
OutputStream
            public synchronized void writeTo(OutputStream out) throws IOException;
}
```

Hierarchy:

Object->OutputStream->ByteArrayOutputStream

24.7 java.io.CharArrayReader (JDK 1.1)

This class is a character input stream that uses a character array as the source of the characters it returns. You create a `CharArrayReader` by specifying the character array, or portion of an array, that it is to read from.

`CharArrayReader` defines the usual `Reader` methods, and supports the `mark()` and `reset()` methods.

Note that the character array you pass to the `CharArrayReader` is not copied by this class. This means that changes you make to the elements of the array after you create the input stream do affect the values read from the array.

`CharArrayReader()` is the character-array analog of `ByteArrayInputStream`, and is similar to `StringReader`.

```
public class CharArrayReader extends Reader {
    // Public Constructors
            public CharArrayReader(char[] buf);
            public CharArrayReader(char[] buf, int offset, int length);
    // Protected Instance Variables
            protected char[] buf;
            protected int count;
            protected int markedPos;
            protected int pos;
    // Public Instance Methods
            public void close();  // Defines Reader
            public void mark(int readAheadLimit) throws IOException;  // Overrides
Reader
            public boolean markSupported();  // Overrides Reader
            public int read() throws IOException;  // Overrides Reader
            public int read(char[] b, int off, int len) throws IOException;  //
Defines Reader
            public boolean ready() throws IOException;  // Overrides Reader
            public void reset() throws IOException;  // Overrides Reader
            public long skip(long n) throws IOException;  // Overrides Reader
}
```

Hierarchy:

Object->Reader->CharArrayReader

24.8 java.io.CharArrayWriter (JDK 1.1)

This class is a character output stream that uses an internal character array as the destination of characters written to it. When you create a `CharArrayWriter`, you may optionally specify an initial size for the character array, but you do not specify the character array itself--this array is managed internally by the `CharArrayWriter`, and grows as necessary to accommodate all the characters written to it. The `toString()` and `toCharArray()` methods return a copy of all characters written to the stream, either as a string or as an array of characters.

`CharArrayWriter` defines the standard `write()`, `flush()`, and `close()` methods that all `Writer` subclasses do. It also defines a few other useful methods. `size()` returns the number of characters that have been written to the stream. `reset()` resets the stream to its initial state, with an empty character array; this is more efficient than creating a new `CharArrayWriter`. Finally, `writeTo()` writes the contents of the internal character array to some other specified character stream.

`CharArrayWriter` is the character-stream analog of `ByteArrayOutputStream`, and is quite similar to `StringWriter`.

```
public class CharArrayWriter extends Writer {
    // Public Constructors
            public CharArrayWriter();
            public CharArrayWriter(int initialSize);
    // Protected Instance Variables
            protected char[] buf;
            protected int count;
    // Public Instance Methods
            public void close();  // Defines Writer
            public void flush();  // Defines Writer
            public void reset();
            public int size();
            public char[] toCharArray();
            public String toString();  // Overrides Object
            public void write(int c);  // Overrides Writer
            public void write(char[] c, int off, int len);  // Defines Writer
            public void write(String str, int off, int len);  // Overrides Writer
            public void writeTo(Writer out) throws IOException;
}
```

31.8 java.util.zip.DeflaterOutputStream (JDK 1.1)

This class is a subclass of `java.io.FilterOutputStream`; it "filters" a stream of data by compressing ("deflating") it and then writes the compressed data to another output stream. To create a `DeflaterOutputStream`, you must specify the stream that it is to write to, and also a `Deflater` object that is to perform the compression. You can set various options on the `Deflater` object to specify just what type of compression is to be performed. Once a `DeflaterOutputStream` is created, its `write()` and `close()` methods are the same as those of other output streams.

The `InflaterInputStream` class can be used to read data written with the `DeflaterOutputStream`.

Note that a `DeflaterOutputStream` writes raw compressed data; applications often prefer one of its subclasses, `GZIPOutputStream` or `ZipOutputStream`, which wraps the raw compressed data within a standard file format.

```
public class DeflaterOutputStream extends FilterOutputStream {
    // Public Constructors
            public DeflaterOutputStream(OutputStream out, Deflater def, int size);
            public DeflaterOutputStream(OutputStream out, Deflater def);
            public DeflaterOutputStream(OutputStream out);
    // Protected Instance Variables
            protected byte[] buf;
            protected Deflater def;
    // Public Instance Methods
            public void close() throws IOException;  // Overrides FilterOutputStream
            public void finish() throws IOException;
            public void write(int b) throws IOException;  // Overrides
FilterOutputStream
            public void write(byte[] b, int off, int len) throws IOException;  //
Overrides FilterOutputStream
    // Protected Instance Methods
            protected void deflate() throws IOException;
}
```

Hierarchy:

Object->OutputStream->FilterOutputStream->DeflaterOutputStream

Extended By:

GZIPOutputStream, ZipOutputStream

31.12 java.util.zip.InflaterInputStream (JDK 1.1)

This class is a subclass of `java.io.FilterInputStream`; it reads a specified stream of compressed input data (typically one that was written with `DeflaterOutputStream` or a subclass) and "filters" that data by uncompressing ("inflating") it. To create an `InflaterInputStream`, you must specify the input stream it is to read from, and also an `Inflater` object that is to perform the uncompresssion. Once an `InflaterInputStream` is created, the `read()` and `skip()` methods are the same as those of other input streams.

Note that the `InflaterInputStream` uncompresses raw data. Applications often prefer one of its subclasses, `GZIPInputStream` or `ZipInputStream`, which work with compressed data written in the standard *gzip* and *PKZip* file formats.

```
public class InflaterInputStream extends FilterInputStream {
    // Public Constructors
            public InflaterInputStream(InputStream in, Inflater inf, int size);
            public InflaterInputStream(InputStream in, Inflater inf);
            public InflaterInputStream(InputStream in);
    // Protected Instance Variables
            protected byte[] buf;
            protected Inflater inf;
            protected int len;
    // Public Instance Methods
            public int read() throws IOException;  // Overrides FilterInputStream
            public int read(byte[] b, int off, int len) throws IOException;  // 
Overrides FilterInputStream
            public long skip(long n) throws IOException;  // Overrides 
FilterInputStream
    // Protected Instance Methods
            protected void fill() throws IOException;
}
```

22. The java.awt.peer Package

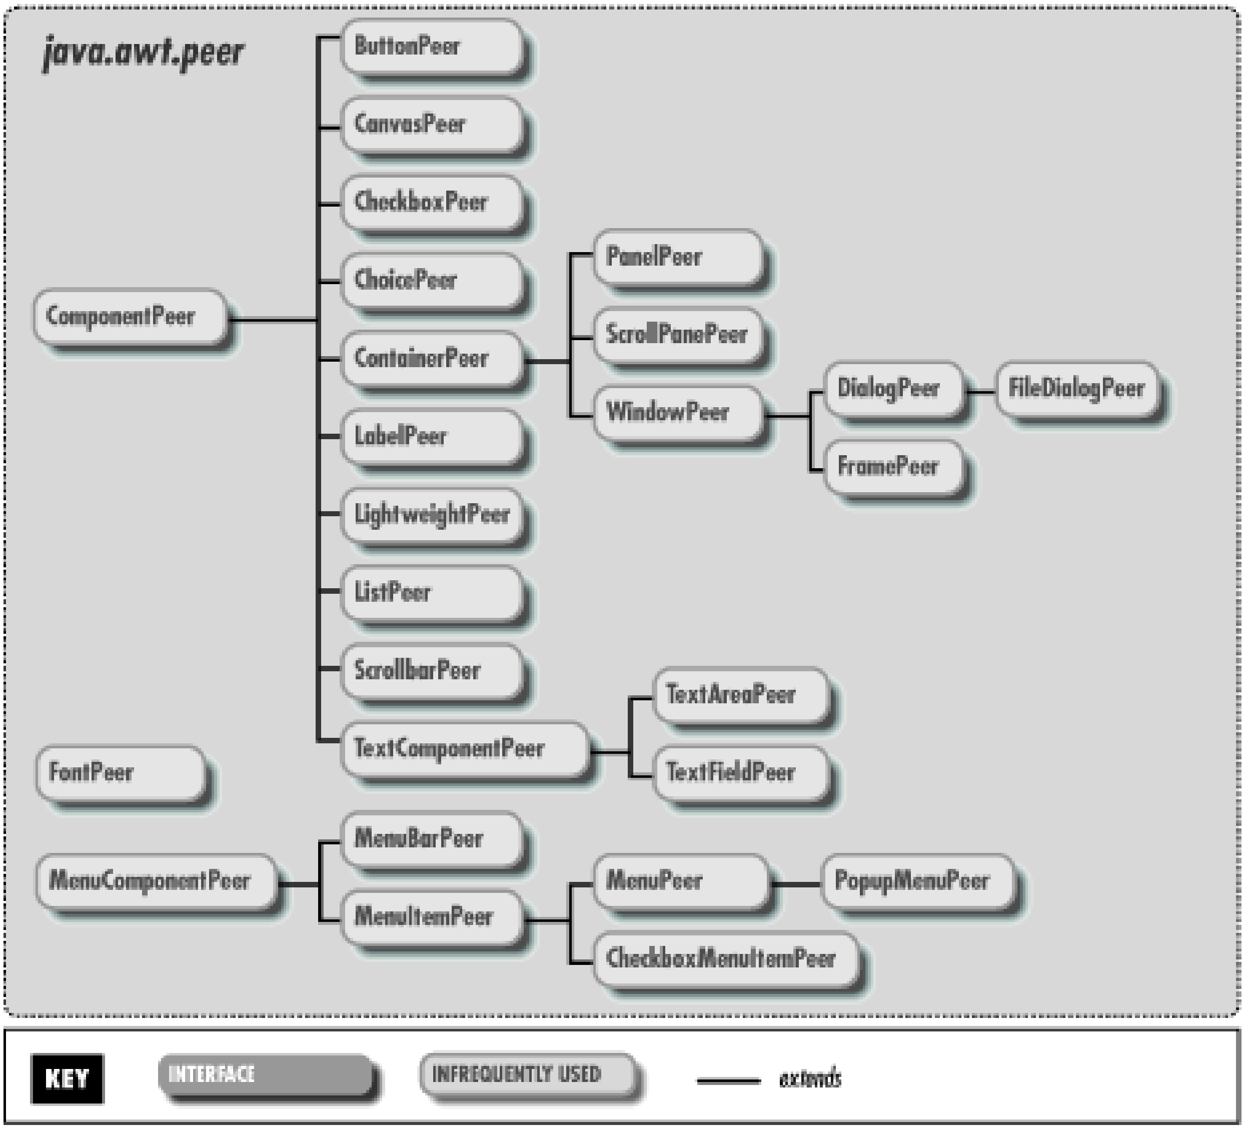
Contents:

The `java.awt.peer` package consists entirely of interface definitions. The hierarchy of these interfaces is shown in Figure 22.1. Each `java.awt.peer` interface corresponds to one of the `java.awt Component` or `MenuComponent` classes, and as you can see from the figure, the hierarchy of this package is identical to the hierarchy of those portions of the `java.awt` package.

The interfaces in this package define the methods that must be supported by the GUI components on a specific platform. Porting the `java.awt` GUI components to a new platform is a matter of implementing each of the methods in each of the interfaces in this package on top of the native GUI components of that platform. The `Toolkit` object in the `java.awt` package collects the implementations of these peer interfaces for a given platform. `Toolkit` contains methods that create instances of each of the interfaces in this package. Normal applications never need to instantiate these peers directly; instead they use the `java.awt Component` classes, which create peers as needed.

Because these peer interfaces are rarely used, and because the methods are quite similar to those of the corresponding `java.awt` component, there is no additional commentary for the individual interface definitions below.

Figure 22.1: The java.awt.peer package



22.1 java.awt.peer.ButtonPeer (JDK 1.0)

```
public abstract interface ButtonPeer extends ComponentPeer {
    // Public Instance Methods
            public abstract void setLabel(String label);
}
```

Returned By:

Toolkit.createButton()

24.30 java.io.InterruptedIOException (JDK 1.0)

An `IOException` that signals that an input or output operation was interrupted. The `bytesTransferred` variable contains the number of bytes read or written before the operation was interrupted.

```
public class InterruptedIOException extends IOException {
    // Public Constructors
            public InterruptedIOException();
            public InterruptedIOException(String s);
    // Public Instance Variables
            public int bytesTransferred;
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->InterruptedIOException

18.25 java.awt.FontMetrics (JDK 1.0)

This class represents font metrics for a specified `Font`. The methods allow you to determine the overall metrics for the font (ascent, descent, etc.), and also to compute the width of strings that are to be displayed in a particular font. You can obtain a `FontMetrics` object for a font with the `getFontMetrics()` method of `Component` or `Toolkit`.

```
public abstract class FontMetrics extends Object implements Serializable {
    // Protected Constructor
            protected FontMetrics(Font font);
    // Protected Instance Variables
            protected Font font;
    // Public Instance Methods
            public int bytesWidth(byte[] data, int off, int len);
            public int charWidth(int ch);
            public int charWidth(char ch);
            public int charsWidth(char[] data, int off, int len);
            public int getAscent();
            public int getDescent();
            public Font getFont();
            public int getHeight();
            public int getLeading();
            public int getMaxAdvance();
            public int getMaxAscent();
        #   public int getMaxDecent();
            public int getMaxDescent();
            public int[] getWidths();
            public int stringWidth(String str);
            public String toString();  // Overrides Object
}
```

Returned By:

`Component.getFontMetrics(), ComponentPeer.getFontMetrics(),` `Graphics.getFontMetrics(), Toolkit.getFontMetrics()`

25.6 java.lang.Byte (JDK 1.1)

This class provides an object wrapper around the `byte` primitive type. It defines useful constants for the minimum and maximum values that can be stored by the `byte` type, and also a `Class` object constant that represents the `byte` type. It also provides various methods for converting `Byte` values to and from strings and other numeric types.

Most of the static methods of this class are used to convert a `String` to a `Byte` object or a `byte` value: the four `parseByte()` and `valueOf()` methods parse a number from the specified string, using an optionally specified radix, and return it in one of these two forms. The `decode()` method parses a byte specified in base 10, base 8, or base 16 and returns it as a `Byte`. If the string begins with "0x" or "#", it is interpreted as a hexadecimal number. If it begins with "0", it is interpreted as an octal number. Otherwise, it is interpreted as a decimal number.

Note that this class has two different `toString()` methods. One is static and converts a `byte` primitive value to a String. The other is the usual `toString()` method that converts a `Byte` object to a string. Most of the remaining methods convert a `Byte` to various primitive numeric types.

```
public final class Byte extends Number {
    // Public Constructors
            public Byte(byte value);
            public Byte(String s) throws NumberFormatException;
    // Constants
            public static final byte MAX_VALUE;
            public static final byte MIN_VALUE;
            public static final Class TYPE;
    // Class Methods
            public static Byte decode(String nm) throws NumberFormatException;
            public static byte parseByte(String s) throws NumberFormatException;
            public static byte parseByte(String s, int radix) throws 
NumberFormatException;
            public static String toString(byte b);
            public static Byte valueOf(String s, int radix) throws 
NumberFormatException;
            public static Byte valueOf(String s) throws NumberFormatException;
    // Public Instance Methods
            public byte byteValue();  // Overrides Number
            public double doubleValue();  // Defines Number
            public boolean equals(Object obj);  // Overrides Object
            public float floatValue();  // Defines Number
            public int hashCode();  // Overrides Object
            public int intValue();  // Defines Number
            public long longValue();  // Defines Number
            public short shortValue();  // Overrides Number
            public String toString();  // Overrides Object
}
```

Hierarchy:

Object->Number(Serializable)->Byte

Returned By:

Byte.decode(), Byte.valueOf()

25.17 java.lang.Double (JDK 1.0)

This class provides an immutable object wrapper around the `double` primitive data type. `valueOf()` converts a string to a `Double`, `doubleValue()` returns the primitive `double` value of a `Double` object, and there are other methods for returning a `Double` value as a variety of other primitive types.

This class also provides some useful constants and static methods for testing `double` values. `MIN_VALUE` and `MAX_VALUE` are the smallest (closest to zero) and largest representable `double` values. `isInfinite()` in class method and instance method forms tests whether a `double` or a `Double` has an infinite value. Similarly, `isNaN()` tests whether a `double` or `Double` is not-a-number--this is a comparison that cannot be done directly because the `NaN` constant never tests equal to any other value, including itself. `doubleToLongBits()` and `longBitsToDouble()` allow you to manipulate the bit representation of a `double` directly.

```
public final class Double extends Number {
    // Public Constructors
            public Double(double value);
            public Double(String s) throws NumberFormatException;
    // Constants
            public static final double MAX_VALUE;
            public static final double MIN_VALUE;
            public static final double NEGATIVE_INFINITY;
            public static final double NaN;
            public static final double POSITIVE_INFINITY;
        1.1public static final Class TYPE;
    // Class Methods
            public static native long doubleToLongBits(double value);
            public static boolean isInfinite(double v);
            public static boolean isNaN(double v);
            public static native double longBitsToDouble(long bits);
            public static String toString(double d);

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

25.32 java.lang.Integer (JDK 1.0)

This class provides an immutable object wrapper around the `int` primitive data type. This class also contains useful minimum and maximum constants and useful conversion methods. `parseInt()` and `valueOf()` convert a string to an `int` or to an `Integer`, respectively. Each can take a radix argument to specify the base that the value is represented in. `decode()` also converts a `String` to an `Integer`. It assumes a hexadecimal number if the string begins with "0X" or "0x," or an octal number if the string begins with "0". Otherwise, a decimal number is assumed.

`toString()` converts in the other direction, and the `static` version takes a radix argument. `toBinaryString()`, `toOctalString()`, and `toHexString()` convert an `int` to a string using base 2, base 8, and base 16. These methods treat the integer as an unsigned value.

Other routines return the value of an `Integer` as various primitive types, and finally, the `getInteger()` methods return the integer value of a named property from the system property list or the specified default value.

```
public final class Integer extends Number {
    // Public Constructors
            public Integer(int value);
            public Integer(String s) throws NumberFormatException;

25.36 java.lang.Long (JDK 1.0)

This class provides an immutable object wrapper around the `long` primitive data type. This class also contains useful minimum and maximum constants and useful conversion methods. `parseLong()` and `valueOf()` convert a string to a `long` or to a `Long`, respectively. Each can take a radix argument to specify the base that the value is represented in. `toString()` converts in the other direction and may also take a radix argument. `toBinaryString()`, `toOctalString()`, and `toHexString()` convert a `long` to a string using base 2, base 8, and base 16. These methods treat the `long` as an unsigned value.

Other routines return the value of a `Long` as various primitive types, and finally, the `getLong()` methods return the `long` value of a named property or the value of the specified default.

```
public final class Long extends Number {
    // Public Constructors
            public Long(long value);
            public Long(String s) throws NumberFormatException;
    // Constants
            public static final long MAX_VALUE;
            public static final long MIN_VALUE;
        1.1public static final Class TYPE;
    // Class Methods
            public static Long getLong(String nm);
            public static Long getLong(String nm, long val);
            public static Long getLong(String nm, Long val);
            public static long parseLong(String s, int radix) throws
NumberFormatException;
            public static long parseLong(String s) throws NumberFormatException;
            public static String toBinaryString(long i);
            public static String toHexString(long i);
            public static String toOctalString(long i);
            public static String toString(long i, int radix);
            public static String toString(long i);
            public static Long valueOf(String s, int radix) throws
NumberFormatException;
            public static Long valueOf(String s) throws NumberFormatException;
    // Public Instance Methods

25.45 java.lang.Number (JDK 1.0)

This is an abstract class that is the superclass of `Byte`, `Short`, `Integer`, `Long`, `Float`, and `Double`. It defines the conversion functions that those types all implement.

```
public abstract class Number extends Object implements Serializable {
    // Default Constructor: public Number()
    // Public Instance Methods
        1.1public byte byteValue();
            public abstract double doubleValue();
            public abstract float floatValue();
            public abstract int intValue();
            public abstract long longValue();
        1.1public short shortValue();
}
```

Extended By:

BigDecimal, BigInteger, Byte, Double, Float, Integer, Long, Short

Returned By:

ChoiceFormat.parse(), DecimalFormat.parse(), NumberFormat.parse()

25.55 java.lang.Short (JDK 1.1)

This class provides an object wrapper around the `short` primitive type. It defines useful constants for the minimum and maximum values that can be stored by the `short` type, and also a `Class` object constant that represents the `short` type. It also provides various methods for converting `Short` values to and from strings and other numeric types.

Most of the static methods of this class are used to convert a `String` to a `Short` object or a `short` value: the four `parseShort()` and `valueOf()` methods parse a number from the specified string, using an optionally specified radix, and return it in one of these two forms. The `decode()` method parses a number specified in base 10, base 8, or base 16 and returns it as a `Short`. If the string begins with "0x" or "#", it is interpreted as a hexadecimal number, or if it begins with "0", it is interpreted as an octal number. Otherwise, it is interpreted as a decimal number.

Note that this class has two different `toString()` methods. One is static and converts a `short` primitive value to a String. The other is the usual `toString()` method that converts a `Short` object to a string. Most of the remaining methods convert a `Short` to various primitive numeric types.

```
public final class Short extends Number {
    // Public Constructors
            public Short(short value);
            public Short(String s) throws NumberFormatException;
    // Constants
            public static final short MAX_VALUE;
            public static final short MIN_VALUE;
            public static final Class TYPE;
    // Class Methods
            public static Short decode(String nm) throws NumberFormatException;
            public static short parseShort(String s) throws NumberFormatException;
            public static short parseShort(String s, int radix) throws 
NumberFormatException;
            public static String toString(short s);
            public static Short valueOf(String s, int radix) throws 
NumberFormatException;
            public static Short valueOf(String s) throws NumberFormatException;
    // Public Instance Methods
            public byte byteValue();  // Overrides Number
            public double doubleValue();  // Defines Number
            public boolean equals(Object obj);  // Overrides Object
            public float floatValue();  // Defines Number
            public int hashCode();  // Overrides Object
            public int intValue();  // Defines Number
            public long longValue();  // Defines Number
            public short shortValue();  // Overrides Number
            public String toString();  // Overrides Object
}
```

30.12 java.util.Locale (JDK 1.1)

The `Locale` class represents a locale: a political, geographical, or cultural region that typically has a distinct language and distinct customs and conventions for such things as formatting dates, times, and numbers.

The `Locale` class defines a number of constants that represent commonly used locales. `Locale` also defines a static `getDefault()` method that returns the default `Locale` object, which represents a locale value inherited from the host system. Furthermore, many locale-sensitive classes, such as `DateFormat`, provide `getAvailableLocales()` methods that return a list of supported `Locale` objects. If none of these methods for obtaining a `Locale` object is suitable, you can also explicitly create your own `Locale` object. To do this, you must specify a language code, a country code, and an optional variant string.

The `Locale` class does not implement any internationalization behavior itself; it merely serves as a locale identifier for those classes that can localize their behavior. Given a `Locale` object, you can invoke the various `getDisplay` methods to obtain a description of the locale suitable for display to a user. Note that these methods may themselves take a `Locale` argument so that the names of languages and countries can be localized as appropriate.

```
public final class Locale extends Object implements Cloneable, Serializable {
    // Public Constructors
            public Locale(String language, String country, String variant);
            public Locale(String language, String country);
    // Constants

21.13 java.awt.image.RGBImageFilter (JDK 1.0)

This abstract class is an `ImageFilter` that provides an easy way to implement filters that modify the colors of an image. To create a color filter that modifies the colors of an image, you should subclass `RGBImageFilter` and provide a definition of `filterRGB()` that converts the input pixel value (in the default RGB color model) to an output value. If the conversion does not depend on the location of the pixel, set the `canFilterIndexColorModel` variable to `true` so that the `RGBImageFilter` can save time by filtering the colormap of an image that uses an `IndexColorModel` instead of filtering each pixel of the image.

```
public abstract class RGBImageFilter extends ImageFilter {
    // Default Constructor: public RGBImageFilter()
    // Protected Instance Variables
            protected boolean canFilterIndexColorModel;
            protected ColorModel newmodel;
            protected ColorModel origmodel;
    // Public Instance Methods
            public IndexColorModel filterIndexColorModel(IndexColorModel icm);
            public abstract int filterRGB(int x, int y, int rgb);
            public void filterRGBPixels(int x, int y, int w, int h, int[] pixels, int 
off, int scansize);
            public void setColorModel(ColorModel model);  // Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model, 
            public void setPixels'u'byte[] pixels, int off, int scansize);  // 
Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model, 
            public void setPixels'u'int[] pixels, int off, int scansize);  // 
Overrides ImageFilter
            public void substituteColorModel(ColorModel oldcm, ColorModel newcm);
}
```

Hierarchy:

```
Object->ImageFilter(ImageConsumer, Cloneable)->RGBImageFilter
```

29.6 java.text.Collator (JDK 1.1)

This class is used to compare, order, and sort strings in a way that is appropriate for the default locale or some other specified locale. Because it is an abstract class, it cannot be instantiated directly. Instead, you must use the static `getInstance()` method to obtain an instance of a `Collator` subclass that is appropriate for the default or specified locale. You can use `getAvailableLocales()` to determine whether a `Collator` object is available for a desired locale.

Once an appropriate `Collator` object has been obtained, you can use the `compare()` method to compare strings. The possible return values of this method are -1, 0, and 1, which indicate, respectively, that the first string is collated before the second, that the two are equivalent for collation purposes, and that the first string is collated after the second. The `equals()` method is a convenient shortcut for testing two strings for collation equivalence.

When sorting an array of strings, each string in the array is typically compared more than once. Using the `compare()` method in this case is inefficient. A more efficient method for comparing strings multiple times is to use `getCollationKey()` for each string to create `CollationKey` objects. These objects can then be compared to each other more quickly than the strings themselves could be compared.

You can customize the way the `Collator` object performs comparisons by calling `setStrength()`. If you pass the constant `PRIMARY` to this method, the comparison only looks at primary differences in the strings--it compares letters but ignores accents and case differences. If you pass the constant `SECONDARY`, it ignores case differences but does not ignore accents. And if you pass `TERTIARY` (the default), the `Collator` object takes both accents and case differences into account in its comparison.

```
public abstract class Collator extends Object implements Cloneable, Serializable {
    // Protected Constructor
            protected Collator();
    // Constants
            public static final int CANONICAL_DECOMPOSITION;
            public static final int FULL_DECOMPOSITION;
            public static final int IDENTICAL;
            public static final int NO_DECOMPOSITION;
            public static final int PRIMARY;
            public static final int SECONDARY;
            public static final int TERTIARY;
    // Class Methods
            public static synchronized Locale[] getAvailableLocales();
            public static synchronized Collator getInstance();
            public static synchronized Collator getInstance(Locale desiredLocale);
    // Public Instance Methods
            public Object clone();  // Overrides Object
            public abstract int compare(String source, String target);
            public boolean equals(String source, String target);
            public boolean equals(Object that);  // Overrides Object
            public abstract CollationKey getCollationKey(String source);
            public synchronized int getDecomposition();
            public synchronized int getStrength();
            public abstract synchronized int hashCode();  // Overrides Object
            public synchronized void setDecomposition(int decompositionMode);
            public synchronized void setStrength(int newStrength);
}
```

Returned By:

Collator.getInstance()

24.16 java.io.File (JDK 1.0)

This class supports a platform-independent definition of file and directory names. It also provides methods to list the files in a directory, to check the existence, readability, writeability, type, size, and modification time of files and directories, to make new directories, to rename files and directories, and to delete files and directories. The constants defined by this class are the platform-dependent directory and path separator characters, available as a `String` or `char`.

`getName()` returns the name of the `File` with any directory names omitted. `getPath()` returns the full name of the file, including the directory name. `getParent()` returns the directory of the `File`. If the `File` is an absolute specification, then `getAbsolutePath()` returns the complete filename. Otherwise, if the `File` is a relative file specification, it returns the relative filename appended to the current working directory.

`isAbsolute()` tests whether the `File` is an absolute specification. `exists()`, `canWrite()`, `canRead()`, `isFile()`, and `isDirectory()` perform the obvious tests on the specified `File`. `length()` returns the length of the file. `lastModified()` returns the modification time of the file (which should be used for comparison with other file times only, and not interpreted as any particular time format).

`list()` returns the name of all entries in a directory that are not rejected by an optional `FilenameFilter`. `mkdir()` creates a directory. `mkdirs()` creates all the directories in a `File` specification. `renameTo()` renames a file or directory. `delete()` deletes a file or directory. Note that there is no method to create a file; that is done with a `FileOutputStream`.

```
public class File extends Object implements Serializable {
    // Public Constructors
            public File(String path);
            public File(String path, String name);
            public File(File dir, String name);
    // Constants
```

```
            public static final String pathSeparator;
            public static final char pathSeparatorChar;
            public static final String separator;
            public static final char separatorChar;
    // Public Instance Methods
            public boolean canRead();
            public boolean canWrite();
            public boolean delete();

java.io.Externalizable (JDK 1.1) | BOOK INDEX | java.io.FileDescriptor (JDK 1.0)

20.18 java.awt.event.KeyEvent (JDK 1.1)

An event of this type indicates that the user has pressed or released a key or typed a character.

Call `getID()` to determine the particular type of key event that has occurred. The constant `KEY_PRESSED` indicates that a key has been pressed, while the constant `KEY_RELEASED` indicates that a key has been released. Not all keystrokes actually correspond to or generate Unicode characters. Modifier keys and function keys, for example, do not correspond to characters. Furthermore, for internationalized input, multiple keystrokes are sometimes required to generate a single character of input. Therefore, `getID()` returns a third constant, `KEY_TYPED`, to indicate a `KeyEvent` that actually contains a character value.

For `KEY_PRESSED` and `KEY_RELEASED` key events, use `getKeyCode()` to obtain the "virtual key code" of the key that was pressed or released. `KeyEvent` defines a number of `VK_` constants that represent these "virtual keys." Note that not all keys on all keyboards have corresponding constants in the `KeyEvent` class, and not all keyboards can generate all of the virtual key codes defined by the class. In JDK 1.1, the `VK_` constants for letter keys, number keys, and some other keys have the same values as the ASCII encodings of the letters and numbers. You should not rely on this to always be the case, however. If the key that was pressed or released corresponds directly to a Unicode character, you can obtain that character by calling `getKeyChar()`. If there is not a corresponding Unicode character, this method returns the constant `CHAR_UNDEFINED`. The `isActionKey()` method returns `true` if the key that was pressed or released does not have a corresponding character.

For `KEY_TYPED` key events, use `getKeyChar()` to return the Unicode character that was typed. If you call `getKeyCode()` for this type of key event, it returns `VK_UNDEFINED`.

See `InputEvent` for information on inherited methods you can use to obtain the keyboard modifiers that were down during the event and other important methods.

Use `getComponent()`, inherited from `ComponentEvent`, to determine what component the event occurred over.

The static method `getKeyText()` returns a (possibly localized) textual name for a given key code. The static method `getKeyModifiersText()` returns a (possibly localized) textual description for a set of modifiers.

The `KeyEvent` has methods that allow you to change the key code, key character, or modifiers of an event. These methods, along with the `consume()` method, allow a `KeyListener` to perform filtering of key events before they are passed to the underlying AWT component.

```
public class KeyEvent extends InputEvent {
    // Public Constructors
            public KeyEvent(Component source, int id, long when, int modifiers, int
keyCode, char keyChar);
            public KeyEvent(Component source, int id, long when, int modifiers, int
keyCode);

25.57 java.lang.String (JDK 1.0)

The String class represents a string of characters. A String object is created by the Java compiler whenever it encounters a string in doublequotes--this method of creation is usually simpler than using a constructor. A number of the methods of this class provide useful string manipulation functions. length() returns the number of characters in a string. charAt() extracts a character from a string. compareTo() compares two strings. equalsIgnoreCase() tests string for equality, ignoring case. startsWith() and endsWith() compare the start and end of a string to a specified value. indexOf() and lastIndexOf() search forward and backwards in a string for a specified character or substring. substring() returns a substring of a string. replace() creates a new copy of the string with one character replaced by another. toUpperCase() and toLowerCase() convert the case of a string. trim() strips whitespace from the start and end of a string. concat() concatenates two strings, which can also be done with the + operator.

Note that String objects are immutable--there is no setCharAt() method to change the contents. The methods above that return a String do not modify the string they are passed, but instead return a modified copy of the string. Use a StringBuffer if you want to manipulate the contents of a string, or use toCharArray() to convert a string to an array of char values.

The static valueOf() methods convert various Java primitive types to strings.

```
public final class String extends Object implements Serializable {
    // Public Constructors
            public String();
            public String(String value);
            public String(char[] value);
            public String(char[] value, int offset, int count);

25.7 java.lang.Character (JDK 1.0)

This class provides an immutable object wrapper around the primitive `char` data type. `charValue()` returns the `char` value of a `Character` object. A number of class methods provide the Java/Unicode equivalent of the C <*ctype.h*> character macros for checking the type of characters and converting to uppercase and lowercase letters. `getType()` returns the character type. The return value is one of the constants defined by the class, which represents a number of broad Unicode character categories.

`digit()` returns the integer equivalent of a given character for a given radix (e.g., radix 16 for hexadecimal). `forDigit()` returns the character that corresponds to the specified value for the specified radix.

```
public final class Character extends Object implements Serializable {
    // Public Constructor
            public Character(char value);
    // Constants
            public static final int MAX_RADIX, MIN_RADIX;

}
```

25.54 java.lang.SecurityManager (JDK 1.0)

This abstract class defines the methods necessary to implement a security policy for the execution of untrusted code. Before performing potentially sensitive operations, Java calls methods of the `SecurityManager` object currently in effect to determine whether the operations are permitted. These methods throw a `SecurityException` if the operation is not permitted.

Normal applications do not need to use or subclass the `SecurityManager` class. It is typically only used by Web browsers, applet viewers, and other programs that need to run untrusted code in a controlled environment.

```
public abstract class SecurityManager extends Object {
    // Protected Constructor
            protected SecurityManager();
    // Protected Instance Variables
            protected boolean inCheck;
    // Public Instance Methods
            public void checkAccept(String host, int port);
            public void checkAccess(Thread g);
            public void checkAccess(ThreadGroup g);
        1.1public void checkAwtEventQueueAccess();
            public void checkConnect(String host, int port);
            public void checkConnect(String host, int port, Object context);
            public void checkCreateClassLoader();
            public void checkDelete(String file);
            public void checkExec(String cmd);
            public void checkExit(int status);
            public void checkLink(String lib);

24.52 java.io.PrintStream (JDK 1.0)

This class is a FilterOutputStream that implements a number of methods for displaying textual representation of Java primitive data types. The print() methods output a standard textual representation of each data type. The println() methods do the same, and follow that representation with a newline. The methods convert various Java primitive types to String representations and then output the resulting string. When an Object is passed to a print() or println(), it is converted to a String by calling its toString() method.

PrintStream is the OutputStream type that makes it easiest to output text. As such, it is the most commonly used of the output streams. The System.out variable is a PrintStream.

Note that in Java 1.0 this class does not handle Unicode characters correctly--it discards the top 8 bits of all 16-bit characters, and thus works only with Latin-1 (ISO8859-1) characters. Although this problem has been fixed in Java 1.1, PrintStream has been superseded in Java 1.1 with PrintWriter. The constructors of this class have been deprecated, but the class itself has not, because it is still used by the System.out and System.err standard output streams.

PrintStream and its PrintWriter replacement output textual representations of Java data types. Use DataOutputStream to output binary representations of data.

```
public class PrintStream extends FilterOutputStream {
    // Public Constructors
        #   public PrintStream(OutputStream out);
        #   public PrintStream(OutputStream out, boolean autoFlush);
    // Public Instance Methods
            public boolean checkError();
            public void close();  // Overrides FilterOutputStream
            public void flush();  // Overrides FilterOutputStream
            public void print(boolean b);

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.53 java.io.PrintWriter (JDK 1.1)

This class is a character output stream that implements a number of `print()` and `println()` methods that output textual representations of primitive values and objects. When you create a `PrintWriter` object, you specify a character or byte output stream that it should write its characters to, and also optionally specify whether the `PrintWriter` stream should be automatically flushed whenever `println()` is called. If you specify a byte output stream as the destination, the `PrintWriter()` constructor automatically creates the necessary `OutputStreamWriter` object to convert characters to bytes using the default encoding.

`PrintWriter` implements the normal `write()`, `flush()`, and `close()` methods that all `Writer` subclasses do. It is more common to use the higher-level `print()` and `println()` methods, each of which converts its argument to a string before outputting it. `println()` has the additional behavior of terminating the line (and optionally flushing the buffer) after printing its argument.

The methods of `PrintWriter` never throw exceptions. Instead, when errors occur, they set an internal flag that you can check by calling `checkError()`. `checkError()` first flushes the internal stream, and then returns `true` if any exception has occurred while writing values to that stream. Once an error has occurred on a `PrintWriter` object, all subsequent calls to `checkError()` return `true`; there is no way to reset the error flag.

`PrintWriter` is the character stream analog to `PrintStream`, which it supersedes. You can usually trivially replace any `PrintStream` objects in a program with `PrintWriter` objects. This is particularly important for internationalized programs. The only valid remaining use for the `PrintStream` class is for the `System.out` and `System.err` standard output streams. See `PrintStream` for details.

```
public class PrintWriter extends Writer {
    // Public Constructors
            public PrintWriter(Writer out);
            public PrintWriter(Writer out, boolean autoFlush);
            public PrintWriter(OutputStream out);
            public PrintWriter(OutputStream out, boolean autoFlush);

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException->InvalidClassException

30.10 java.util.Hashtable (JDK 1.0)

This class implements a hashtable data structure, which allows you to associate values with a key and to efficiently look up the value associated with a given key. A hashtable is essentially an associative array, which stores objects with non-numeric array indices.

`put()` associates a value with a key in a `Hashtable`. `get()` retrieves a value for a specified key. `remove()` deletes a key/value association. `keys()` and `elements()` return `Enumeration` objects that allow you to iterate through the complete set of keys and values stored in the table.

```
public class Hashtable extends Dictionary implements Cloneable, Serializable {
    // Public Constructors
            public Hashtable(int initialCapacity, float loadFactor);
            public Hashtable(int initialCapacity);
            public Hashtable();
    // Public Instance Methods
            public synchronized void clear();
            public synchronized Object clone();  // Overrides Object
            public synchronized boolean contains(Object value);
            public synchronized boolean containsKey(Object key);
            public synchronized Enumeration elements();  // Defines Dictionary
            public synchronized Object get(Object key);  // Defines Dictionary
            public boolean isEmpty();  // Defines Dictionary
            public synchronized Enumeration keys();  // Defines Dictionary
            public synchronized Object put(Object key, Object value);  // Defines 
Dictionary
            public synchronized Object remove(Object key);  // Defines Dictionary
            public int size();  // Defines Dictionary
            public synchronized String toString();  // Overrides Object
    // Protected Instance Methods
            protected void rehash();
}
```

18.27 java.awt.Graphics (JDK 1.0)

This abstract class defines a device-independent interface to graphics. It specifies methods for doing line drawing, area filling, image painting, area copying, and graphics output clipping. Specific subclasses of `Graphics` are implemented for different platforms and different graphics output devices. A `Graphics` object cannot be created directly through a constructor--it must be obtained with the `getGraphics()` method of a `Component` or an `Image`, or copied from an existing `Graphics` object with `create()`. When a `Graphics` object is no longer needed, you should call `dispose()` to free up the window system resources it uses.

```
public abstract class Graphics extends Object {
    // Protected Constructor
            protected Graphics();
    // Public Instance Methods
            public abstract void clearRect(int x, int y, int width, int height);
            public abstract void clipRect(int x, int y, int width, int height);
            public abstract void copyArea(int x, int y, int width, int height, int
dx, int dy);
            public abstract Graphics create();
            public Graphics create(int x, int y, int width, int height);
            public abstract void dispose();
            public void draw3DRect(int x, int y, int width, int height, boolean
raised);
            public abstract void drawArc(int x, int y, int width, int height, int
startAngle, int arcAngle);
            public void drawBytes(byte[] data, int offset, int length, int x, int y);
            public void drawChars(char[] data, int offset, int length, int x, int y);
            public abstract boolean drawImage(Image img, int x, int y, ImageObserver
observer);
            public abstract boolean drawImage(Image img, int x, int y, int width, int
height, ImageObserver observer);
            public abstract boolean drawImage(Image img, int x, int y, Color bgcolor,
ImageObserver observer);
            public abstract boolean drawImage(Image img, int x, int y, int width, int
height, Color bgcolor,
            public abstract boolean drawImage'u'ImageObserver observer);
        1.1  public abstract boolean drawImage(Image img, int dx1, int dy1, int dx2,
int dy2, int sx1, int sy1,

19. The java.awt.datatransfer Package

Contents:

This small package contains classes and interfaces that support a generic inter-application data transfer mechanism. It also provides support for cut-and-paste data transfer on top of that mechanism. This package, and all of its classes and interfaces, are new in Java 1.1. Future releases of Java are likely to extend this package with support for data transfer through drag-and-drop.

Figure 19.1 shows the class hierarchy for `java.datatransfer`. `DataFlavor` and `Transferable` define the basic data transfer mechanism. `Clipboard` and `ClipboardOwner` provide support for cut-and-paste. `StringSelection` is a convenience class that makes it particularly easy to transfer textual data between applications.

Figure 19.1: The java.awt.datatransfer package

[Graphic: Figure 19-1]

19.1 java.awt.datatransfer.Clipboard (JDK 1.1)

This class represents a clipboard on which data may be transferred using the cut-and-paste metaphor. When data is "cut," it should be encapsulated in a `Transferable` object and registered with a `Clipboard` object by calling `setContents()`. A `Clipboard` can only hold a single piece of data at a time, so a `ClipboardOwner` object must be specified when data is placed on the clipboard. This object is notified that it no longer "owns" the clipboard when the data is replaced by other, more recent, data.

When a "paste" is requested by the user, an application requests the data on the `Clipboard` by calling `getContents()`, which returns a `Transferable` object. The methods of this object can be used to negotiate a mutually-compatible data format and to actually transfer the data.

A clipboard name is passed to the `Clipboard()` constructor, and may be retrieved with `getName()`. This name is not actually used in Java 1.1, however.

Note that while applications can create their own private `Clipboard` objects for intra-application cut-and-paste, it is more common for them to use the system clipboard to enable cut-and-paste between applications. You can obtain the system clipboard by calling the `getSystemClipboard()` method of the current `Toolkit` object. Untrusted applet code is not allowed to access the system clipboard, so untrusted applets cannot participate in inter-application cut-and-paste.

```
public class Clipboard extends Object {
    // Public Constructor
            public Clipboard(String name);
    // Protected Instance Variables
            protected Transferable contents;
            protected ClipboardOwner owner;
    // Public Instance Methods
            public synchronized Transferable getContents(Object requestor);
            public String getName();
            public synchronized void setContents(Transferable contents,
ClipboardOwner owner);
}

29.2 java.text.CharacterIterator (JDK 1.1)

This interface defines an API for portably iterating through the characters that comprise a string of text, regardless of the encoding of that text. Such an API is necessary because the number of bytes per character is different for different encodings, and some encodings even use variable-width characters within the same string of text. In addition to allowing iteration, a class that implements the `CharacterIterator` interface for non-Unicode text also performs translation of characters from their native encoding to standard Java Unicode characters.

`CharacterIterator` is similar to `java.util.Enumeration`, but is somewhat more complex than that interface. The `first()` and `last()` methods return the first and last characters in the text, and the `next()` and `prev()` methods allow you to loop forward or backwards through the characters of the text. These methods return the `DONE` constant when they go beyond the first or last character in the text--a test for this constant can be used to terminate a loop.

The `CharacterIterator` interface also allows random access to the characters in a string of text. The `getBeginIndex()` and `getEndIndex()` methods return the character positions for the start and end of the string, and `setIndex()` sets the current position. `getIndex()` returns the index of the current position, and `current()` returns the character at that position.

```
public abstract interface CharacterIterator extends Cloneable {
    // Constants
            public static final char DONE;
    // Public Instance Methods
            public abstract Object clone();  // Overrides Object
            public abstract char current();
            public abstract char first();
            public abstract int getBeginIndex();
            public abstract int getEndIndex();
            public abstract int getIndex();
            public abstract char last();
            public abstract char next();
            public abstract char previous();
            public abstract char setIndex(int position);
}
```

DecimalFormat(), DecimalFormat.setDecimalFormatSymbols()

Returned By:

DecimalFormat.getDecimalFormatSymbols()

29.12 java.text.Format (JDK 1.1)

This abstract class is the base class for all number, date, and string formatting classes in the `java.text` package. It defines two abstract methods that are implemented by subclasses. `format()` converts an object to a string using the formatting rules encapsulated by the `Format` subclass and optionally appends the resulting string to an existing `StringBuffer`. `parseObject()` performs the reverse operation--it parses a formatted string and returns the corresponding object. Status information for these two operations is returned in `FieldPosition` and `ParsePosition` objects. The non-abstract methods of this class are simple shortcuts that rely on implementations of the abstract methods.

See `ChoiceFormat`, `DateFormat`, `MessageFormat`, and `NumberFormat`.

```
public abstract class Format extends Object implements Serializable, Cloneable {
    // Default Constructor: public Format()
    // Public Instance Methods
            public Object clone();  // Overrides Object
            public final String format(Object obj);
            public abstract StringBuffer format(Object obj, StringBuffer toAppendTo,
FieldPosition pos);
            public abstract Object parseObject(String source, ParsePosition status);
            public Object parseObject(String source) throws ParseException;
}
```

Extended By:

DateFormat, MessageFormat, NumberFormat

Passed To:

MessageFormat.setFormat(), MessageFormat.setFormats()

Returned By:

MessageFormat.getFormats()

21.7 java.awt.image.ImageFilter (JDK 1.0)

This class is used in conjunction with a `FilteredImageSource`. It accepts image data through the `ImageConsumer` interface and passes it on to an `ImageConsumer` specified by the controlling `FilteredImageSource`. `ImageFilter` is the superclass of all image filters, and performs no filtering itself. You must subclass it to perform the desired filtering. See `CropImageFilter` and `RGBImageFilter`. The `ImageFilter` methods are the `ImageConsumer` methods invoked by an `ImageProducer`. You should not call them directly.

See `FilteredImageSource` for an example of using an `ImageFilter`.

```
public class ImageFilter extends Object implements ImageConsumer, Cloneable {
    // Default Constructor: public ImageFilter()
    // Protected Instance Variables
            protected ImageConsumer consumer;
    // Public Instance Methods
            public Object clone();  // Overrides Object
            public ImageFilter getFilterInstance(ImageConsumer ic);
            public void imageComplete(int status);  // From ImageConsumer
            public void resendTopDownLeftRight(ImageProducer ip);
            public void setColorModel(ColorModel model);  // From ImageConsumer
            public void setDimensions(int width, int height);  // From ImageConsumer
            public void setHints(int hints);  // From ImageConsumer
            public void setPixels(int x, int y, int w, int h, ColorModel model,
            public void setPixels'u'byte[] pixels, int off, int scansize);  // From
ImageConsumer
            public void setPixels(int x, int y, int w, int h, ColorModel model,
            public void setPixels'u'int[] pixels, int off, int scansize);  // From
ImageConsumer
            public void setProperties(Hashtable props);  // From ImageConsumer
}
```

`CropImageFilter, ReplicateScaleFilter, RGBImageFilter`

Passed To:

`FilteredImageSource()`

Returned By:

`ImageFilter.getFilterInstance()`

29.14 java.text.NumberFormat (JDK 1.1)

This class formats and parses numbers in a locale-specific way. As an abstract class, it cannot be instantiated directly, but it provides a number of static methods that return instances of a concrete subclass which you can use for formatting. The `getInstance()` method returns a `NumberFormat` object suitable for normal formatting of numbers in either the default locale or in a specified locale. `getCurrencyInstance()` and `getPercentInstance()` return `NumberFormat` objects for formatting numbers that represent monetary amounts and percentages in either the default locale or in a specified locale. `getAvailableLocales()` returns an array of locales for which `NumberFormat` objects are available.

Once you have created a suitable `NumberFormat` object, you may customize its locale-independent behavior with `setMaximumFractionDigits()`, `setGroupingUsed()` and similar `set` methods. In order to customize the locale-dependent behavior, you can use `instanceof` to test if the `NumberFormat` object is an instance of `DecimalFormat`, and if so, cast it to that type. The `DecimalFormat` class provides complete control over number formatting. Note, however, that a `NumberFormat` customized in this way may no longer be appropriate for the desired locale.

After creating and customizing a `NumberFormat` object, you can use the various `format()` methods to convert numbers to strings or string buffers, and you can use the `parse()` or `parseObject()` methods to convert strings to numbers.

The constants defined by this class are intended to be used by the `FieldPosition` object.

The `NumberFormat` class in not intended for the display of very large or very small numbers that require exponential notation, and it may not gracefully handle infinite or `NaN` (not-a-number) values.

```
public abstract class NumberFormat extends Format implements Cloneable {
    // Default Constructor: public NumberFormat()
    // Constants
            public static final int FRACTION_FIELD;
            public static final int INTEGER_FIELD;
    // Class Methods
            public static Locale[] getAvailableLocales();
            public static final NumberFormat getCurrencyInstance();
            public static NumberFormat getCurrencyInstance(Locale inLocale);
            public static final NumberFormat getInstance();
            public static NumberFormat getInstance(Locale inLocale);
            public static final NumberFormat getNumberInstance();
            public static NumberFormat getNumberInstance(Locale inLocale);
            public static final NumberFormat getPercentInstance();
            public static NumberFormat getPercentInstance(Locale inLocale);
    // Public Instance Methods
            public Object clone();  // Overrides Format
            public boolean equals(Object obj);  // Overrides Object
            public final StringBuffer format(Object number, StringBuffer toAppendTo,
FieldPosition pos);  // Defines Format
            public final String format(double number);
            public final String format(long number);
            public abstract StringBuffer format(double number, StringBuffer
toAppendTo, FieldPosition pos);
            public abstract StringBuffer format(long number, StringBuffer toAppendTo,
FieldPosition pos);
            public int getMaximumFractionDigits();
            public int getMaximumIntegerDigits();
            public int getMinimumFractionDigits();
            public int getMinimumIntegerDigits();
            public int hashCode();  // Overrides Object
            public boolean isGroupingUsed();
            public boolean isParseIntegerOnly();
            public abstract Number parse(String text, ParsePosition parsePosition);
            public Number parse(String text) throws ParseException;
            public final Object parseObject(String source, ParsePosition
parsePosition);  // Defines Format
            public void setGroupingUsed(boolean newValue);
            public void setMaximumFractionDigits(int newValue);
            public void setMaximumIntegerDigits(int newValue);
            public void setMinimumFractionDigits(int newValue);
            public void setMinimumIntegerDigits(int newValue);
            public void setParseIntegerOnly(boolean value);
}

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

25.47 java.lang.Object (JDK 1.0)

This is the root class in Java. All classes are subclasses of `Object`, and thus all objects can invoke the `public` and `protected` methods of this class. `equals()` tests whether two objects have the same value (i.e., not whether two variables refer to the same object, but whether two distinct objects have byte-for-byte equivalence). For classes that implement the `Cloneable` interface, `clone()` makes a byte-for-byte copy of an `Object`. `getClass()` returns the `Class` object associated with any `Object`, and the `notify()`, `notifyAll()`, and `wait()` methods are used for thread synchronization on a given `Object`.

A number of these `Object` methods should be overridden by subclasses of `Object`. Subclasses should provide their own definition of the `toString()` method so that they can be used with the string concatenation operator and with the `PrintWriter.println()` methods. Defining the `toString()` method for all objects also helps with debugging.

Classes that contain references to other objects may want to override the `equals()` and `clone()` methods (for `Cloneable` objects) so that they recursively call the `equals()` and `clone()` methods of the objects referred to within the original object. Some classes, particularly those that override `equals()`, may also want to override the `hashCode()` method to provide an appropriate hashcode to be used when storing instances in a `Hashtable` data structure.

Classes that allocate system resources other than memory (such as file descriptors or windowing system graphic contexts) should override the `finalize()` method to release these resources when the object is no longer referred to and is about to be garbage collected.

```
public class Object {
    // Default Constructor: public Object()
    // Public Instance Methods
            public boolean equals(Object obj);
            public final native Class getClass();
            public native int hashCode();
            public final native void notify();
            public final native void notifyAll();
            public String toString();
            public final native void wait(long timeout) throws InterruptedException;
            public final void wait(long timeout, int nanos) throws 
InterruptedException;
            public final void wait() throws InterruptedException;
    // Protected Instance Methods
            protected native Object clone() throws CloneNotSupportedException;
            protected void finalize() throws Throwable;
}

29.17 java.text.RuleBasedCollator (JDK 1.1)

This class is a concrete subclass of the abstract `Collator` class. It performs collations using a table of rules that are specified in textual form. Most applications do not use this class directly; instead they call `Collator.getInstance()` to obtain a `Collator` object (typically a `RuleBasedCollator` object) that implements the default collation order for a specified or default locale. You should only need to use this class if you are collating strings for a locale that is not supported by default, or if you need to implement a highly customized collation order.

```
public class RuleBasedCollator extends Collator {
    // Public Constructor
            public RuleBasedCollator(String rules) throws ParseException;
    // Public Instance Methods
            public Object clone();  // Overrides Collator
            public int compare(String source, String target);  // Defines Collator
            public boolean equals(Object obj);  // Overrides Collator
            public CollationElementIterator getCollationElementIterator(String 
source);
            public CollationKey getCollationKey(String source);  // Defines Collator
            public String getRules();
            public int hashCode();  // Defines Collator
}
```

Hierarchy:

Object->Collator(Cloneable, Serializable)->RuleBasedCollator

30.21 java.util.SimpleTimeZone (JDK 1.1)

This concrete subclass of `TimeZone` is a simple implementation of that abstract class, and is suitable for use in locales that use the Gregorian calendar. Programs do not usually need to instantiate this class directly; instead, they use one of the static "factory" methods of `TimeZone` to obtain a suitable `TimeZone` subclass.

You would instantiate this class directly only if you needed to support a time zone with nonstandard daylight savings time rules. In that case, you would use call `setStartRule()` and `setEndRule()` to specify the starting and ending dates of daylight savings time for the time zone.

```
public class SimpleTimeZone extends TimeZone {
    // Public Constructors
            public SimpleTimeZone(int rawOffset, String ID);
            public SimpleTimeZone(int rawOffset, String ID, int startMonth, int 
startDayOfWeekInMonth, int startDayOfWeek, int startTime, int endMonth, int 
endDayOfWeekInMonth, int endDayOfWeek, int endTime);
    // Public Instance Methods
            public Object clone();  // Overrides TimeZone
            public boolean equals(Object obj);  // Overrides Object
            public int getOffset(int era, int year, int month, int day, int 
dayOfWeek, int millis);  // Defines TimeZone
            public int getRawOffset();  // Defines TimeZone
            public synchronized int hashCode();  // Overrides Object
            public boolean inDaylightTime(Date date);  // Defines TimeZone
            public void setEndRule(int month, int dayOfWeekInMonth, int dayOfWeek, 
int time);
            public void setRawOffset(int offsetMillis);  // Defines TimeZone
            public void setStartRule(int month, int dayOfWeekInMonth, int dayOfWeek, 
int time);
            public void setStartYear(int year);
            public boolean useDaylightTime();  // Defines TimeZone
}
```

Hierarchy:

Object->TimeZone(Serializable, Cloneable)->SimpleTimeZone

29.19 java.text.StringCharacterIterator (JDK 1.1)

This class is a trivial implementation of the `CharacterIterator` interface that works for text stored in Java `String` objects. See `CharacterIterator` for details.

```
public final class StringCharacterIterator extends Object implements 
CharacterIterator {
    // Public Constructors
            public StringCharacterIterator(String text);
            public StringCharacterIterator(String text, int pos);
            public StringCharacterIterator(String text, int begin, int end, int pos);
    // Public Instance Methods
            public Object clone();  // Overrides Object
            public char current();  // From CharacterIterator
            public boolean equals(Object obj);  // Overrides Object
            public char first();  // From CharacterIterator
            public int getBeginIndex();  // From CharacterIterator
            public int getEndIndex();  // From CharacterIterator
            public int getIndex();  // From CharacterIterator
            public int hashCode();  // Overrides Object
            public char last();  // From CharacterIterator
            public char next();  // From CharacterIterator
            public char previous();  // From CharacterIterator
            public char setIndex(int p);  // From CharacterIterator
}
```

Hierarchy:

Object->StringCharacterIterator(CharacterIterator(Cloneable))

30.24 java.util.TimeZone (JDK 1.1)

The `TimeZone` class represents a time zone; it is used with the `Calendar` and `DateFormat` classes.

As an abstract class, `TimeZone` cannot be directly instantiated. Instead, you should call the static `getDefault()` method to obtain a `TimeZone` object that represents the time zone inherited from the host operating system. Or, you should call `getTimeZone()` (also static), passing the name of the desired zone. You can obtain a list of the supported time zone names by calling the static `getAvailableIDs()` method.

Once you have a `TimeZone` object, you can call `inDaylightTime()` to determine whether, for a given `Date`, daylight savings time is in effect for that time zone. Call `getID()` to obtain the name of the time zone, and call `getOffset()` for a given date to determine the number of milliseconds to add to GMT to convert to the time zone.

```
public abstract class TimeZone extends Object implements Serializable, Cloneable {
    // Default Constructor: public TimeZone()
    // Class Methods
            public static synchronized String[] getAvailableIDs(int rawOffset);
            public static synchronized String[] getAvailableIDs();
            public static synchronized TimeZone getDefault();
            public static synchronized TimeZone getTimeZone(String ID);
            public static synchronized void setDefault(TimeZone zone);
    // Public Instance Methods
            public Object clone();  // Overrides Object
            public String getID();
            public abstract int getOffset(int era, int year, int month, int day, int 
dayOfWeek, int milliseconds);
            public abstract int getRawOffset();
            public abstract boolean inDaylightTime(Date date);
            public void setID(String ID);
            public abstract void setRawOffset(int offsetMillis);
            public abstract boolean useDaylightTime();
}
```

24.3 java.io.BufferedReader (JDK 1.1)

This class applies buffering to a character input stream, thereby improving the efficiency of character input. You create a `BufferedReader` by specifying some other character input stream that it is to buffer input from. (You can also specify a buffer size at this time, although the default size is usually fine.) Typically you use this sort of buffering when you are using a `FileReader` or `InputStreamReader`.

`BufferedReader` defines the standard set of `Reader` methods, and also provides a `readLine()` method that reads a line of text (not including the line-terminators) and returns it as a `String`.

`BufferedReader` is the character-stream analog of `BufferedInputStream`. It also provides a replacement for the deprecated `readLine()` method of `DataInputStream`, which did not properly convert bytes into characters.

```
public class BufferedReader extends Reader {
    // Public Constructors
            public BufferedReader(Reader in, int sz);
            public BufferedReader(Reader in);
    // Public Instance Methods
            public void close() throws IOException;  // Defines Reader
            public void mark(int readAheadLimit) throws IOException;  // Overrides
Reader
            public boolean markSupported();  // Overrides Reader
            public int read() throws IOException;  // Overrides Reader
            public int read(char[] cbuf, int off, int len) throws IOException;  //
Defines Reader
            public String readLine() throws IOException;
            public boolean ready() throws IOException;  // Overrides Reader
            public void reset() throws IOException;  // Overrides Reader

java.io.BufferedWriter (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.4 java.io.BufferedWriter (JDK 1.1)

This class applies buffering to a character output stream, improving output efficiency by coalescing many small write requests into a single larger request. You create a `BufferedWriter` by specifying some other character output stream to which it sends its buffered and coalesced output. (You can also specify a buffer size at this time, although the default size is usually satisfactory.) Typically you use this sort of buffering when you are using a `FileWriter` or `OutputStreamWriter`.

`BufferedWriter` defines the standard `write()`, `flush()`, and `close()` methods that all output streams define, but it also adds a `newLine()` method, which outputs the platform-dependent line separator (usually a newline character, a carriage return character, or both) to the stream.

`BufferedWriter` is the character-stream analog of `BufferedOutputStream`.

```
public class BufferedWriter extends Writer {
    // Public Constructors
            public BufferedWriter(Writer out);
            public BufferedWriter(Writer out, int sz);
    // Public Instance Methods
            public void close() throws IOException;  // Defines Writer
            public void flush() throws IOException;  // Defines Writer
            public void newLine() throws IOException;
            public void write(int c) throws IOException;  // Overrides Writer
            public void write(char[] cbuf, int off, int len) throws IOException;  //
Defines Writer
            public void write(String s, int off, int len) throws IOException;  //
Overrides Writer
}
```

Hierarchy:

Object->Writer->BufferedWriter

28.6 java.net.DatagramSocket (JDK 1.0)

This class defines a socket that can receive and send unreliable datagram packets over the network using the UDP protocol. A datagram is a very low-level networking interface: it is simply an array of bytes sent over the network. A datagram does not implement any kind of stream-based communication protocol, and there is no connection established between the sender and the receiver. Datagram packets are called "unreliable" because the protocol does not make any attempt to ensure that they arrived or to resend them if they did not. Thus, packets sent through a `DatagramSocket` are not guaranteed to arrive in the order sent, or to arrive at all. On the other hand, this low-overhead protocol makes datagram transmission very fast.

If a port is specified when the `DatagramSocket` is created, that port is used; otherwise, the system assigns a port. `getLocalPort()` returns the port number in use. `send()` sends a `DatagramPacket` through the socket. The packet must contain the destination address to which it should be sent. `receive()` waits for data to arrive at the socket and stores it, along with the address of the sender, into the specified `DatagramPacket`. `close()` closes the socket and frees the port it used for reuse. Once `close()` has been called, the `DatagramSocket` should not be used again.

See `Socket` and `URL` for higher-level interfaces to networking.

```
public class DatagramSocket extends Object {
    // Public Constructors
            public DatagramSocket() throws SocketException;
            public DatagramSocket(int port) throws SocketException;
        1.1public DatagramSocket(int port, InetAddress laddr) throws SocketException;
    // Public Instance Methods
            public void close();
        1.1public InetAddress getLocalAddress();
            public int getLocalPort();
        1.1public synchronized int getSoTimeout() throws SocketException;
            public synchronized void receive(DatagramPacket p) throws IOException;
            public void send(DatagramPacket p) throws IOException;
        1.1public synchronized void setSoTimeout(int timeout) throws SocketException;
}
```

Extended By:

MulticastSocket

24.20 java.io.FileOutputStream (JDK 1.0)

This class is a subclass of `OutputStream` that writes data to a file specified by name, or by a `File` or `FileDescriptor` object. `write()` writes a byte or array of bytes to the file. To write binary data, you typically use this class in conjunction with a `BufferedOutputStream` and a `DataOutputStream`. To write text, you typically use it with a `PrintWriter`, `BufferedWriter`, and an `OutputStreamWriter`. Use `close()` to close a `FileOutputStream` when no further output will be written to it.

```
public class FileOutputStream extends OutputStream {
    // Public Constructors
            public FileOutputStream(String name) throws IOException;
        1.1  public FileOutputStream(String name, boolean append) throws IOException;
            public FileOutputStream(File file) throws IOException;
            public FileOutputStream(FileDescriptor fdObj);
    // Public Instance Methods
            public native void close() throws IOException;  // Overrides OutputStream
            public final FileDescriptor getFD() throws IOException;
            public native void write(int b) throws IOException;  // Defines
OutputStream
            public void write(byte[] b) throws IOException;  // Overrides
OutputStream
            public void write(byte[] b, int off, int len) throws IOException;  //
Overrides OutputStream
    // Protected Instance Methods
            protected void finalize() throws IOException;  // Overrides Object
}
```

Hierarchy:

Object->OutputStream->FileOutputStream

24.25 java.io.FilterOutputStream (JDK 1.0)

This class provides method definitions required to filter the data to be written to the `OutputStream` specified when the `FilterOutputStream` is created. It must be subclassed to perform some sort of filtering operation and may not be instantiated directly. See the subclasses `BufferedOutputStream` and `DataOutputStream`.

```
public class FilterOutputStream extends OutputStream {
    // Public Constructor
            public FilterOutputStream(OutputStream out);
    // Protected Instance Variables
            protected OutputStream out;
    // Public Instance Methods
            public void close() throws IOException;  // Overrides OutputStream
            public void flush() throws IOException;  // Overrides OutputStream
            public void write(int b) throws IOException;  // Defines OutputStream
            public void write(byte[] b) throws IOException;  // Overrides 
OutputStream
            public void write(byte[] b, int off, int len) throws IOException;  // 
Overrides OutputStream
}
```

Hierarchy:

Object->OutputStream->FilterOutputStream

Extended By:

BufferedOutputStream, CheckedOutputStream, DataOutputStream, DeflaterOutputStream, PrintStream

24.26 java.io.FilterReader (JDK 1.1)

This abstract class is intended to act as a superclass for character input streams that read data from some other character input stream, filter it in some way, and then return the filtered data when their own `read()` methods are called.

`FilterReader` is declared `abstract`, so that it cannot be instantiated. But none of its methods are themselves abstract: they all simply call the requested operation on the input stream passed to the `FilterReader()` constructor. If you were allowed to instantiate a `FilterReader`, you'd find that it is a "null filter"--i.e., it simply reads characters from the specified input stream and returns them without filtering of any kind.

Because `FilterReader` implements a "null filter," it is an ideal superclass for classes that want to implement simple filters, but do not want to override all of the methods of `Reader`. In order to create your own filtered character input stream, you should subclass `FilterReader` and override both of its `read()` methods to perform the desired filtering operation. Note that you can implement one of the `read()` methods in terms of the other, and thus only implement the filtration once. Recall that the other `read()` methods defined by `Reader` are implemented in terms of these methods, so you do not need to override those. In some cases, you may also need to override other methods of `FilterReader` as well, and you may want to provide methods or constructors that are specific to your subclass.

`FilterReader` is the character-stream analog to `FilterInputStream`.

```
public abstract class FilterReader extends Reader {
    // Protected Constructor
            protected FilterReader(Reader in);
    // Protected Instance Variables
            protected Reader in;
    // Public Instance Methods
            public void close() throws IOException;  // Defines Reader
            public void mark(int readAheadLimit) throws IOException;  // Overrides
Reader
            public boolean markSupported();  // Overrides Reader
            public int read() throws IOException;  // Overrides Reader
            public int read(char[] cbuf, int off, int len) throws IOException;  //
Defines Reader
            public boolean ready() throws IOException;  // Overrides Reader
            public void reset() throws IOException;  // Overrides Reader
            public long skip(long n) throws IOException;  // Overrides Reader
}
```

java.io.FilterOutputStream (JDK 1.0) BOOK INDEX java.io.FilterWriter (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.27 java.io.FilterWriter (JDK 1.1)

This abstract class is intended to act as a superclass for character output streams that filter the data written to them before writing it to some other character output stream.

`FilterWriter` is declared `abstract`, so that it cannot be instantiated. But none of its methods are themselves abstract: they all simply invoke the corresponding method on the output stream that was passed to the `FilterWriter` constructor. If you were allowed to instantiate a `FilterWriter` object, you'd find that it acts as a "null filter"--that it simply passes the characters written to it along, without any filtration.

Because `FilterWriter` implements a "null filter," it is an ideal superclass for classes that want to implement simple filters without having to override all of the methods of `Writer`. In order to create your own filtered character output stream, you should subclass `FilterWriter` and override all of its `write()` methods to perform the desired filtering operation. Note that you can implement two of the `write()` methods in terms of the third, and thus only implement your filtering algorithm once. In some cases, you may want to override other `Writer` methods as well, and you may often want to add other methods or constructors that are specific to your subclass.

`FilterWriter` is the character-stream analog of `FilterOutputStream`.

```
public abstract class FilterWriter extends Writer {
    // Protected Constructor
            protected FilterWriter(Writer out);
    // Protected Instance Variables
            protected Writer out;
    // Public Instance Methods
            public void close() throws IOException;  // Defines Writer
            public void flush() throws IOException;  // Defines Writer
            public void write(int c) throws IOException;  // Overrides Writer
            public void write(char[] cbuf, int off, int len) throws IOException;  //
Defines Writer
            public void write(String str, int off, int len) throws IOException;  //
Overrides Writer
}

java.io.FilterReader (JDK 1.1) | BOOK INDEX | java.io.InputStream (JDK 1.0)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

31.9 java.util.zip.GZIPInputStream (JDK 1.1)

This class is a subclass of `InflaterInputStream` that reads and uncompresses data compressed in *gzip* format. To create a `GZIPInputStream`, you must simply specify the `InputStream` it is to read compressed data from, and optionally specify a buffer size for the internal decompression buffer. Once a `GZIPInputStream` is created, you can use the `read()` and `close()` methods as you would with any input stream.

```
public class GZIPInputStream extends InflaterInputStream {
    // Public Constructors
            public GZIPInputStream(InputStream in, int size) throws IOException;
            public GZIPInputStream(InputStream in) throws IOException;
    // Constants
            public static final int GZIP_MAGIC;
    // Protected Instance Variables
            protected CRC32 crc;
            protected boolean eos;
    // Public Instance Methods
            public void close() throws IOException;  // Overrides FilterInputStream
            public int read(byte[] buf, int off, int len) throws IOException;  //
Overrides InflaterInputStream
}
```

Hierarchy:

Object->InputStream->FilterInputStream->InflaterInputStream->GZIPInputStream

31.10 java.util.zip.GZIPOutputStream (JDK 1.1)

This class is a subclass of `DeflaterOutputStream` that compresses and writes data using the *gzip* file format. To create a `GZIPOutputStream`, you must specify the `OutputStream` that it is to write to, and may optionally specify a size for the internal compression buffer. Once the `GZIPOutputStream` is created, you can use the `write()` and `close()` methods as you would any other output stream.

```
public class GZIPOutputStream extends DeflaterOutputStream {
    // Public Constructors
            public GZIPOutputStream(OutputStream out, int size) throws IOException;
            public GZIPOutputStream(OutputStream out) throws IOException;
    // Protected Instance Variables
            protected CRC32 crc;
    // Public Instance Methods
            public void close() throws IOException;  // Overrides 
DeflaterOutputStream
            public void finish() throws IOException;  // Overrides 
DeflaterOutputStream
            public synchronized void write(byte[] buf, int off, int len) throws 
IOException;  // Overrides DeflaterOutputStream
}
```

Hierarchy:

Object->OutputStream->FilterOutputStream->DeflaterOutputStream->GZIPOutputStream

24.29 java.io.InputStreamReader (JDK 1.1)

This class is a character input stream that uses a byte input stream as its data source: it reads bytes from a specified `InputStream` and translates them into Unicode characters according to a particular platform- and locale-dependent character encoding. This is a very important internationalization feature in Java 1.1.

When you create an `InputStreamReader`, you specify an `InputStream` from which the `InputStreamReader` is to read bytes, and you also optionally specify the name of the character encoding used by those bytes. If you do not specify an encoding name, the `InputStreamReader` uses the default encoding for the default locale, which is usually the correct thing to do.

The `InputStreamReader` supports the standard `Reader` methods. It also has a `getEncoding()` method that returns the name of the encoding being used to convert bytes to characters.

```
public class InputStreamReader extends Reader {
    // Public Constructors
            public InputStreamReader(InputStream in);
            public InputStreamReader(InputStream in, String enc) throws 
UnsupportedEncodingException;
    // Public Instance Methods
            public void close() throws IOException;  // Defines Reader
            public String getEncoding();
            public int read() throws IOException;  // Overrides Reader
            public int read(char[] cbuf, int off, int len) throws IOException;  // 
Defines Reader
            public boolean ready() throws IOException;  // Overrides Reader
}
```

24.41 java.io.ObjectOutput (JDK 1.1)

This interface extends the `DataOutput` interface and adds methods for serializing objects and writing bytes and arrays of bytes.

```
public abstract interface ObjectOutput extends DataOutput {
    // Public Instance Methods
            public abstract void close() throws IOException;
            public abstract void flush() throws IOException;
            public abstract void write(int b) throws IOException;   // From 
DataOutput
            public abstract void write(byte[] b) throws IOException;  // From 
DataOutput
            public abstract void write(byte[] b, int off, int len) throws 
IOException;  // From DataOutput
            public abstract void writeObject(Object obj) throws IOException;
}
```

Implemented By:

ObjectOutputStream

Passed To:

Externalizable.writeExternal()

24.46 java.io.OutputStream (JDK 1.0)

This abstract class is the superclass of all output streams. It defines the basic output methods that all output stream classes provide.

`write()` writes a single byte or an array or subarray of bytes. `flush()` forces any buffered output to be written. `close()` closes the stream and frees up any system resources associated with it. The stream may not be used once `close()` has been called.

See also `Writer`.

```
public abstract class OutputStream extends Object {
    // Default Constructor: public OutputStream()

24.47 java.io.OutputStreamWriter (JDK 1.1)

This class is a character output stream that uses a byte output stream as the destination for its data: when characters are written to an `OutputStreamWriter`, it translates them into bytes according to a particular locale- and/or platform-specific character encoding, and writes those bytes to the specified `OutputStream`. This is a very important internationalization feature in Java 1.1.

When you create an `OutputStreamWriter`, you specify the `OutputStream` to which it writes bytes, and you optionally specify the name of the character encoding that should be used to convert characters to bytes. If you do not specify an encoding name, the `OutputStreamWriter` uses the default encoding of the default locale, which is usually the correct thing to do.

`OutputStreamWriter` supports the usual `Writer` methods. It also has a `getEncoding()` method which returns the name of the encoding being used to convert characters to bytes.

```
public class OutputStreamWriter extends Writer {
    // Public Constructors
            public OutputStreamWriter(OutputStream out, String enc) throws 
UnsupportedEncodingException;
            public OutputStreamWriter(OutputStream out);
    // Public Instance Methods
            public void close() throws IOException;  // Defines Writer
            public void flush() throws IOException;  // Defines Writer
            public String getEncoding();
            public void write(int c) throws IOException;  // Overrides Writer
            public void write(char[] cbuf, int off, int len) throws IOException;  // 
Defines Writer
            public void write(String str, int off, int len) throws IOException;  // 
Overrides Writer
}
```

java.io.OutputStream (JDK 1.0) BOOK INDEX java.io.PipedInputStream (JDK 1.0)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.49 java.io.PipedOutputStream (JDK 1.0)

This class is an `OutputStream` that implements one half of a pipe, and is useful for communication between threads. A `PipedOutputStream` must be connected to a `PipedInputStream`, which may be specified when the `PipedOutputStream` is created or with the `connect()` method. Data written to the `PipedOutputStream` are available for reading on the `PipedInputStream`.

See `OutputStream` for information on the low-level methods for writing data to a `PipedOutputStream`. A `FilterOutputStream` may be used to provide a higher-level interface for writing data to a `PipedOutputStream`.

```
public class PipedOutputStream extends OutputStream {
    // Public Constructors
            public PipedOutputStream(PipedInputStream snk) throws IOException;
            public PipedOutputStream();
    // Public Instance Methods
            public void close() throws IOException;  // Overrides OutputStream
            public void connect(PipedInputStream snk) throws IOException;
            public synchronized void flush() throws IOException;  // Overrides 
OutputStream
            public void write(int b) throws IOException;  // Defines OutputStream
            public void write(byte[] b, int off, int len) throws IOException;  // 
Overrides OutputStream
}
```

Hierarchy:

Object->OutputStream->PipedOutputStream

Passed To:

PipedInputStream(), PipedInputStream.connect()

24.50 java.io.PipedReader (JDK 1.1)

`PipedReader` is a character input stream that reads characters from a `PipedWriter` character output stream to which it is connected. `PipedReader` implements one-half of a pipe, and is useful for communication between two threads of an application.

A `PipedReader` cannot be used until it is connected to a `PipedWriter` object, which may be passed to the `PipedReader()` constructor or to the `connect()` method.

`PipedReader` inherits most of the methods of its superclass. See `Reader` for more information.

`PipedReader` is the character stream analog of `PipedInputStream`.

```
public class PipedReader extends Reader {
    // Public Constructors
            public PipedReader();
            public PipedReader(PipedWriter src) throws IOException;
    // Public Instance Methods
            public void close() throws IOException;  // Defines Reader
            public void connect(PipedWriter src) throws IOException;
            public int read(char[] cbuf, int off, int len) throws IOException;  //
Defines Reader
}
```

Hierarchy:

Object->Reader->PipedReader

Passed To:

PipedWriter(), PipedWriter.connect()

24.51 java.io.PipedWriter (JDK 1.1)

`PipedWriter` is a character output stream that writes characters to the `PipedReader` character input stream to which it is connected. `PipedWriter` implements one half of a pipe, and is useful for communication between two threads of an application.

A `PipedWriter` cannot be used until it is connected to a `PipedReader` object, which may be passed to the `PipedWriter()` constructor, or to the `connect()` method.

`PipedWriter` inherits most of the methods of its superclass. See `Writer` for more information.

`PipedWriter` is the character stream analog of `PipedOutputStream`.

```
public class PipedWriter extends Writer {
    // Public Constructors
            public PipedWriter();
            public PipedWriter(PipedReader sink) throws IOException;
    // Public Instance Methods
            public void close() throws IOException;  // Defines Writer
            public void connect(PipedReader sink) throws IOException;
            public void flush() throws IOException;  // Defines Writer
            public void write(char[] cbuf, int off, int len) throws IOException;  //
Defines Writer
}
```

Hierarchy:

Object->Writer->PipedWriter

Passed To:

PipedReader(), PipedReader.connect()

24.55 java.io.PushbackReader (JDK 1.1)

This class is a character input stream that uses another input stream as its input source, and adds the ability to push characters back onto the stream. This feature is often useful when writing parsers.

When you create a `PushbackReader` stream, you specify the stream to be read from, and may optionally specify the size of the pushback buffer--i.e., the number of characters that may be pushed back onto the stream or "unread." If you do not specify a size for this buffer, the default size is one character.

`PushbackReader` inherits or overrides all the standard `Reader` methods, and also adds three `unread()` methods that are used to push a single character, an array of characters, or a portion of an array of characters back onto the stream.

This class is the character stream analog of `PushbackInputStream`.

```
public class PushbackReader extends FilterReader {
    // Public Constructors
            public PushbackReader(Reader in, int size);
            public PushbackReader(Reader in);
    // Public Instance Methods
            public void close() throws IOException;  // Overrides FilterReader
            public boolean markSupported();  // Overrides FilterReader
            public int read() throws IOException;  // Overrides FilterReader
            public int read(char[] cbuf, int off, int len) throws IOException;  //
Overrides FilterReader
            public boolean ready() throws IOException;  // Overrides FilterReader
            public void unread(int c) throws IOException;
            public void unread(char[] cbuf, int off, int len) throws IOException;
            public void unread(char[] cbuf) throws IOException;
}
```

Hierarchy:

Object->Reader->FilterReader->PushbackReader

24.56 java.io.RandomAccessFile (JDK 1.0)

This class allows reading and writing of arbitrary bytes, text, and primitive Java data types from or to any specified location in a file. Because this class provides random, rather than sequential, access to files, it is neither a subclass of `InputStream` nor of `OutputStream`, but provides an entirely independent method for reading and writing data from or to files. `RandomAccessFile` implements the same interfaces as `DataInputStream` and `DataOutputStream`, and thus defines the same methods for reading and writing data as those classes do.

The `seek()` method provides random access to the file--it is used to select the position in the file from which, or to which, data should be read or written. The *`mode`* argument to the constructor methods should be "r" for a file that is to be read-only, and "rw" for a file that is to be written (and perhaps read as well).

```
public class RandomAccessFile extends Object implements DataOutput, DataInput {
    // Public Constructors
            public RandomAccessFile(String name, String mode) throws IOException;
            public RandomAccessFile(File file, String mode) throws IOException;
    // Public Instance Methods
            public native void close() throws IOException;
            public final FileDescriptor getFD() throws IOException;
            public native long getFilePointer() throws IOException;
            public native long length() throws IOException;
            public native int read() throws IOException;
            public int read(byte[] b, int off, int len) throws IOException;
            public int read(byte[] b) throws IOException;
            public final boolean readBoolean() throws IOException;  // From DataInput
            public final byte readByte() throws IOException;  // From DataInput
            public final char readChar() throws IOException;  // From DataInput
            public final double readDouble() throws IOException;  // From DataInput

java.io.PushbackReader (JDK 1.1) | BOOK INDEX | java.io.Reader (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.57 java.io.Reader (JDK 1.1)

This abstract class is the superclass of all character input streams. It is an analog to `InputStream`, which is the superclass of all byte input streams. `Reader` defines the basic methods that all character output streams provide.

`read()` returns a single character or an array (or subarray) of characters, blocking if necessary. It returns `-1` if the end of the stream has been reached. `ready()` returns `true` if there are characters available for reading. If `ready()` returns `true`, the next call to `read()` is guaranteed not to block. `close()` closes the character input stream. `skip()` skips a specified number of characters in the input stream. If `markSupported()` returns `true`, then `mark()` "marks" a position in the stream and, if necessary, creates a look-ahead buffer of the specified size. Future calls to `reset()` restore the stream to the marked position, if they occur within the specified look-ahead limit. Note that not all stream types support this mark-and-reset functionality.

To create a subclass of `Reader`, you need only implement the three-argument version of `read()` and `close()`. Most subclasses implement additional methods as well, however.

```
public abstract class Reader extends Object {
    // Protected Constructors
            protected Reader();
            protected Reader(Object lock);
    // Protected Instance Variables
            protected Object lock;
    // Public Instance Methods
            public abstract void close() throws IOException;
            public void mark(int readAheadLimit) throws IOException;
            public boolean markSupported();
            public int read() throws IOException;
            public int read(char[] cbuf) throws IOException;
            public abstract int read(char[] cbuf, int off, int len) throws 
IOException;
            public boolean ready() throws IOException;
            public void reset() throws IOException;
            public long skip(long n) throws IOException;
}
```

28.16 java.net.Socket (JDK 1.0)

This class implements a socket for interprocess communication over the network. The constructor methods create the socket and connect it to the specified host and port. You may also optionally specify whether communication through the socket should be based on an underlying reliable connection-based stream protocol, or on an underlying unreliable (but faster) datagram protocol. A stream protocol is the default.

Once the socket is created, `getInputStream()` and `getOutputStream()` return `InputStream` and `OutputStream` objects that you can use just as you would for file input and output. `getInetAddress()` and `getPort()` return the address and port that the socket is connected to. `getLocalPort()` returns the local port that the socket is using.

```
public class Socket extends Object {
    // Public Constructors
            public Socket(String host, int port) throws UnknownHostException, 
IOException;
            public Socket(InetAddress address, int port) throws IOException;
        1.1public Socket(String host, int port, InetAddress localAddr, int localPort) 
throws IOException;
        1.1public Socket(InetAddress address, int port, InetAddress localAddr, int 
localPort) throws IOException;

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.63 java.io.StringReader (JDK 1.1)

This class is a character input stream that uses a `String` object as the source of the characters it returns. When you create a `StringReader`, you must specify the `String` that it is to read from.

`StringReader` defines the normal `Reader` methods, and supports `mark()` and `reset()`. If `reset()` is called before `mark()` has been called, the stream is reset to the beginning of the specified string.

`StringReader` is a character stream analog to `StringBufferInputStream`, which is deprecated in Java 1.1. `StringReader` is also similar to `CharArrayReader`.

```
public class StringReader extends Reader {
    // Public Constructor
            public StringReader(String s);
    // Public Instance Methods
            public void close();  // Defines Reader
            public void mark(int readAheadLimit) throws IOException;  // Overrides 
Reader
            public boolean markSupported();  // Overrides Reader
            public int read() throws IOException;  // Overrides Reader
            public int read(char[] cbuf, int off, int len) throws IOException;  // 
Defines Reader
            public boolean ready();  // Overrides Reader
            public void reset() throws IOException;  // Overrides Reader
            public long skip(long ns) throws IOException;  // Overrides Reader
}
```

Hierarchy:

Object->Reader->StringReader

24.64 java.io.StringWriter (JDK 1.1)

This class is a character output stream that uses an internal `StringBuffer` object as the destination of the characters written to the stream. When you create a `StringWriter`, you may optionally specify an initial size for the `StringBuffer`, but you do not specify the `StringBuffer` itself--it is managed internally by the `StringWriter`, and grows as necessary to accommodate the characters written to it.

`StringWriter` defines the standard `write()`, `flush()`, and `close()` methods that all `Writer` subclasses do, and also defines two methods to obtain the characters that have been written into the stream's internal buffer. `toString()` returns the contents of the internal buffer as a `String`, and `getBuffer()` returns the buffer itself. Note that `getBuffer()` returns a reference to the actual internal buffer, not a copy of it, so any changes you make to the buffer are reflected in subsequent calls to `toString()`.

`StringWriter` is quite similar to `CharArrayWriter`, but does not have a byte stream analog.

```
public class StringWriter extends Writer {
    // Public Constructor
            public StringWriter();
    // Protected Constructor
            protected StringWriter(int initialSize);
    // Public Instance Methods
            public void close();  // Defines Writer
            public void flush();  // Defines Writer
            public StringBuffer getBuffer();
            public String toString();  // Overrides Object
            public void write(int c);  // Overrides Writer
            public void write(char[] cbuf, int off, int len);  // Defines Writer
            public void write(String str);  // Overrides Writer
            public void write(String str, int off, int len);  // Overrides Writer
}
```

Object->Writer->StringWriter

java.io.StringReader (JDK 1.1) BOOK INDEX java.io.SyncFailedException (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.69 java.io.Writer (JDK 1.1)

This abstract class is the superclass of all character output streams. It is an analog to `OutputStream`, which is the superclass of all byte output streams. `Writer` defines the basic `write()`, `flush()`, and `close()` methods that all character output streams provide.

The five versions of the `write()` method write a single character, a character array or subarray, or a string or substring to the destination of the stream. The most general version of this method--the one that writes a specified portion of a character array--is abstract and must be implemented by all subclasses. By default, the other `write()` methods are implemented in terms of this abstract one.

The `flush()` method is another abstract method that all subclasses must implement. It should force any output buffered by the stream to be written to its destination. If that destination is itself a character or byte output stream, it should invoke the `flush()` method of the destination stream as well.

The `close()` method is also abstract. Subclasses must implement this method so that it flushes and then closes the current stream, and also closes whatever destination stream it is connected to. Once the stream has been closed, any future calls to `write()` or `flush()` should throw an `IOException`.

```
public abstract class Writer extends Object {
    // Protected Constructors
            protected Writer();
            protected Writer(Object lock);
    // Protected Instance Variables
            protected Object lock;
    // Public Instance Methods
            public abstract void close() throws IOException;
            public abstract void flush() throws IOException;
            public void write(int c) throws IOException;
            public void write(char[] cbuf) throws IOException;
            public abstract void write(char[] cbuf, int off, int len) throws
IOException;
            public void write(String str) throws IOException;
            public void write(String str, int off, int len) throws IOException;
}

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

31.15 java.util.zip.ZipFile (JDK 1.1)

This class reads the contents of ZIP files. It uses a random access file internally so that the entries of the ZIP file do not have to be read sequentially as they do with the `ZipInputStream` class.

A `ZipFile` object can be created by specifying the ZIP file to be read either as a `String` filename or as a `File` object. Once created, the `getEntry()` method returns a `ZipEntry` object for a named entry, and the `entries()` method returns an `Enumeration` object that allows you to loop through all the `ZipEntry` objects for the file. To read the contents of a specific `ZipEntry` within the ZIP file, pass the `ZipEntry` to `getInputStream()`--this returns an `InputStream` object from which you can read the entry's contents.

```
public class ZipFile extends Object {
    // Public Constructors
            public ZipFile(String name) throws IOException;
            public ZipFile(File file) throws ZipException, IOException;
    // Public Instance Methods
            public void close() throws IOException;
            public Enumeration entries();
            public ZipEntry getEntry(String name);
            public InputStream getInputStream(ZipEntry ze) throws IOException;
            public String getName();
}
```

31.16 java.util.zip.ZipInputStream (JDK 1.1)

This class is a subclass of `InflaterInputStream` that reads the entries of a ZIP file in sequential order. A `ZipInputStream` is created by specifying the `InputStream` from which it is to read the contents of the ZIP file. Once the `ZipInputStream` is created, the `getNextEntry()` method is used to begin reading of data from the next entry in the ZIP file. This method must be called before `read()` is called to begin reading of the first entry. Note that `getNextEntry()` returns a `ZipEntry` object that describes the entry being read. Also note that `getNextEntry()` returns `null` when there are no more entries to be read from the ZIP file.

The `read()` methods of `ZipInputStream` read until the end of the current entry and then return `-1` indicating that there are no more data to read. To continue with the next entry in the ZIP file, you must call `getNextEntry()` again. Similarly, the `skip()` method only skips bytes within the current entry. `closeEntry()` can be called to skip the remaining data in the current entry, but it is usually easier simply to call `getNextEntry()` to begin the next entry.

```
public class ZipInputStream extends InflaterInputStream {
    // Public Constructor
            public ZipInputStream(InputStream in);
    // Public Instance Methods
            public void close() throws IOException;  // Overrides FilterInputStream
            public void closeEntry() throws IOException;
            public ZipEntry getNextEntry() throws IOException;
            public int read(byte[] b, int off, int len) throws IOException;  //
Overrides InflaterInputStream
            public long skip(long n) throws IOException;  // Overrides
InflaterInputStream
}
```

Hierarchy:

Object->InputStream->FilterInputStream->InflaterInputStream->ZipInputStream

25.16 java.lang.Compiler (JDK 1.0)

The static methods of this class provide an interface to the just-in-time (JIT) byte-code to native code compiler in use by the Java interpreter. If no JIT compiler is in use by the VM, these methods do nothing.

`compileClass()` asks the JIT compiler to compile the specified class. `compileClasses()` asks the JIT compiler to compile all classes that match the specified name. These methods return `true` if the compilation was successful, or `false` if it failed or if there is no JIT compiler on the system. `enable()` and `disable()` turn just-in-time compilation on and off. `command()` asks the JIT compiler to perform some compiler-specific operation. This is a hook for vendor extensions. No standard operations have been defined.

```
public final class Compiler extends Object {
    // No Constructor
    // Class Methods
            public static native Object command(Object any);
            public static native boolean compileClass(Class clazz);
            public static native boolean compileClasses(String string);
            public static native void disable();
            public static native void enable();
}
```

24.61 java.io.StreamTokenizer (JDK 1.0)

This class performs lexical analysis of a specified input stream and breaks the input up into tokens. It can be extremely useful when writing simple parsers.

`nextToken()` returns the next token in the stream--this is either one of the constants defined by the class (which represent end-of-file, end-of-line, a parsed floating-point number, and a parsed word) or a character value. `pushBack()` "pushes" the token back onto the stream, so that it is returned by the next call to `nextToken()`. The public variables `sval` and `nval` contain the string and numeric values (if applicable) of the most recently read token. They are applicable when the returned token is `TT_WORD` and `TT_NUMBER`. `lineno()` returns the current line number.

The remaining methods allow you to specify how tokens are recognized. `wordChars()` specifies a range of characters that should be treated as parts of words. `whitespaceChars()` specifies a range of characters that serve to delimit tokens. `ordinaryChars()` and `ordinaryChar()` specify characters that are never part of tokens and should be returned as-is. `resetSyntax()` makes all characters "ordinary." `eolIsSignificant()` specifies whether end-of-line is significant. If so, the `TT_EOL` constant is returned for end-of-lines. Otherwise they are treated as whitespace.

`commentChar()` specifies a character that begins a comment that lasts until the end of the line. No characters in the comment are returned. `slashStarComments()` and `slashSlashComments()` specify whether the `StreamTokenizer` should recognize C and C++-style comments. If so, no parts of the comments are returned as tokens. `quoteChar()` specifies a character used to delimit strings. When a string token is parsed, the quote character is returned as the token value, and the body of the string is stored in the `sval` variable. `lowerCaseMode()` specifies whether `TT_WORD` tokens should be converted to all lowercase characters before being stored in `sval`. `parseNumbers()` specifies that the `StreamTokenizer` should recognize and return double-precision floating-point number tokens.

```
public class StreamTokenizer extends Object {
    // Public Constructors
        #   public StreamTokenizer(InputStream is);
        1.1  public StreamTokenizer(Reader r);
    // Constants
            public static final int TT_EOF;
            public static final int TT_EOL;
            public static final int TT_NUMBER;
            public static final int TT_WORD;
    // Public Instance Variables
            public double nval;
            public String sval;
            public int ttype;
    // Public Instance Methods
            public void commentChar(int ch);
            public void eolIsSignificant(boolean flag);
            public int lineno();
            public void lowerCaseMode(boolean fl);
            public int nextToken() throws IOException;
            public void ordinaryChar(int ch);
            public void ordinaryChars(int low, int hi);
            public void parseNumbers();
            public void pushBack();
            public void quoteChar(int ch);
            public void resetSyntax();
            public void slashSlashComments(boolean flag);
            public void slashStarComments(boolean flag);
            public String toString();  // Overrides Object
            public void whitespaceChars(int low, int hi);
            public void wordChars(int low, int hi);
}
```

java.io.StreamCorruptedException (JDK 1.1) | BOOK INDEX | java.io.StringBufferInputStream (JDK 1.0; Deprecated.)

29.5 java.text.CollationKey (JDK 1.1)

`CollationKey` objects are used to compare strings more quickly than is possible with `Collation.compare()`. Objects of this class are returned by `Collation.getCollationKey()`. To compare two `CollationKey` objects, invoke the `compareTo()` method of key `A`, passing the key `B` as an argument (both `CollationKey` objects must be created through the same `Collation` object). The return value of this method is less than zero if the key `A` is collated before the key `B`. It is equal to zero if they are equivalent for the purposes of collation, and it is greater than zero if the key `A` is collated after the key `B`.

Use `getSourceString()` to obtain the string represented by a `CollationKey`.

```
public final class CollationKey extends Object {
    // No Constructor
    // Public Instance Methods
            public int compareTo(CollationKey target);
            public boolean equals(Object target);  // Overrides Object
            public String getSourceString();
            public int hashCode();  // Overrides Object
            public byte[] toByteArray();
}
```

Passed To:

CollationKey.compareTo()

Returned By:

21.6 java.awt.image.ImageConsumer (JDK 1.0)

This interface defines the methods necessary for a class that consumes image data to communicate with a class that produces image data. The methods defined by this interface should never be called by a program directly; instead, they are invoked by an `ImageProducer` to pass the image data and other information about the image to the `ImageConsumer`. The constants defined by this interface are values passed to the `setHints()` and `imageComplete()` methods.

Unless you want to do low-level manipulation of image data, you never need to use or implement an `ImageConsumer`.

```
public abstract interface ImageConsumer {
    // Constants
            public static final int COMPLETESCANLINES;
            public static final int IMAGEABORTED;
            public static final int IMAGEERROR;
            public static final int RANDOMPIXELORDER;
            public static final int SINGLEFRAME;
            public static final int SINGLEFRAMEDONE;
            public static final int SINGLEPASS;
            public static final int STATICIMAGEDONE;
            public static final int TOPDOWNLEFTRIGHT;
    // Public Instance Methods
            public abstract void imageComplete(int status);
            public abstract void setColorModel(ColorModel model);
            public abstract void setDimensions(int width, int height);
            public abstract void setHints(int hintflags);
            public abstract void setPixels(int x, int y, int w, int h, ColorModel
model, byte[] pixels, int off, int scansize);
            public abstract void setPixels(int x, int y, int w, int h, ColorModel
model, int[] pixels, int off, int scansize);
            public abstract void setProperties(Hashtable props);
}
```

Implemented By:

`ImageFilter, PixelGrabber`

Passed To:

`FilteredImageSource.addConsumer(), FilteredImageSource.isConsumer(), FilteredImageSource.removeConsumer(), FilteredImageSource.requestTopDownLeftRightResend(), FilteredImageSource.startProduction(), ImageFilter.getFilterInstance(), ImageProducer.addConsumer(), ImageProducer.isConsumer(), ImageProducer.removeConsumer(), ImageProducer.requestTopDownLeftRightResend(), ImageProducer.startProduction(), MemoryImageSource.addConsumer(), MemoryImageSource.isConsumer(), MemoryImageSource.removeConsumer(), MemoryImageSource.requestTopDownLeftRightResend(), MemoryImageSource.startProduction()`

Type Of:

`ImageFilter.consumer`

20.9 java.awt.event.ContainerEvent (JDK 1.1)

An event of this type serves as notification that the source `Container` has had a child added to it or removed from it. Note that this event is a notification only; the AWT adds or removes the child internally, and the recipient of this event need take no action itself.

`getChild()` returns the child `Component` that was added or removed, and `getContainer()` returns the `Container` that it was added to or removed from. `getContainer()` is simply a convenient alternative to `getSource()`.

`getID()` returns the constant `COMPONENT_ADDED` or `COMPONENT_REMOVED` to indicate whether the specified child was added or removed.

```
public class ContainerEvent extends ComponentEvent {
    // Public Constructor
            public ContainerEvent(Component source, int id, Component child);
    // Constants
            public static final int COMPONENT_ADDED;
            public static final int COMPONENT_REMOVED;
            public static final int CONTAINER_FIRST;
            public static final int CONTAINER_LAST;
    // Public Instance Methods
            public Component getChild();
            public Container getContainer();
            public String paramString();  // Overrides ComponentEvent
}
```

Hierarchy:

`Object->EventObject(Serializable)->AWTEvent->ComponentEvent->ContainerEvent`

Passed To:

`AWTEventMulticaster.componentAdded(), AWTEventMulticaster.componentRemoved(), Container.processContainerEvent(), ContainerAdapter.componentAdded(),` `ContainerAdapter.componentRemoved(), ContainerListener.componentAdded(), ContainerListener.componentRemoved()`

20.6 java.awt.event.ComponentEvent (JDK 1.1)

An event of this type serves as notification that the source `Component` has been moved, resized, shown, or hidden. Note that this event is a notification only: the AWT handles these `Component` operations internally, and the recipient of the event need take no action itself.

`getComponent()` returns the component that was moved, resized, shown or hidden. It is simply a convenient alternative to `getSource()`.

`getID()` returns one of four `COMPONENT_` constants to indicate what operation was performed on the `Component`.

```
public class ComponentEvent extends AWTEvent {
    // Public Constructor
            public ComponentEvent(Component source, int id);
    // Constants
            public static final int COMPONENT_FIRST;
            public static final int COMPONENT_HIDDEN;
            public static final int COMPONENT_LAST;
            public static final int COMPONENT_MOVED;
            public static final int COMPONENT_RESIZED;
            public static final int COMPONENT_SHOWN;
    // Public Instance Methods
            public Component getComponent();
            public String paramString();  // Overrides AWTEvent
}
```

Hierarchy:

```
Object->EventObject(Serializable)->AWTEvent->ComponentEvent
```

Extended By:

ContainerEvent, FocusEvent, InputEvent, PaintEvent, WindowEvent

Passed To:

AWTEventMulticaster.componentHidden(), AWTEventMulticaster.componentMoved(), AWTEventMulticaster.componentResized(), AWTEventMulticaster.componentShown(), Component.processComponentEvent(), ComponentAdapter.componentHidden(), ComponentAdapter.componentMoved(), ComponentAdapter.componentResized(), ComponentAdapter.componentShown(), ComponentListener.componentHidden(), ComponentListener.componentMoved(), ComponentListener.componentResized(), ComponentListener.componentShown()

20.8 java.awt.event.ContainerAdapter (JDK 1.1)

This class is a trivial implementation of `ContainerListener`; it provides empty bodies for each of the methods of that interface. When you are not interested in all of these methods, it is often easier to subclass `ContainerAdapter` than it is to implement `ContainerListener` from scratch.

```
public abstract class ContainerAdapter extends Object implements ContainerListener {
    // Default Constructor: public ContainerAdapter()
    // Public Instance Methods
            public void componentAdded(ContainerEvent e);  // From ContainerListener
            public void componentRemoved(ContainerEvent e);  // From 
ContainerListener
}
```

Hierarchy:

```
Object->ContainerAdapter(ContainerListener(EventListener))
```

20.10 java.awt.event.ContainerListener (JDK 1.1)

This interface defines the methods that an object must implement to "listen" for container events on AWT components. When a `ContainerEvent` occurs, an AWT component notifies its registered `ContainerListener` objects by invoking one of their methods.

An easy way to implement this interface is by subclassing the `ContainerAdapter` class.

```
public abstract interface ContainerListener extends EventListener {
    // Public Instance Methods
            public abstract void componentAdded(ContainerEvent e);
            public abstract void componentRemoved(ContainerEvent e);
}
```

Implemented By:

AWTEventMulticaster, ContainerAdapter

Passed To:

AWTEventMulticaster.add(), AWTEventMulticaster.remove(), Container.addContainerListener(), Container.removeContainerListener()

Returned By:

AWTEventMulticaster.add(), AWTEventMulticaster.remove()

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

30.23 java.util.StringTokenizer (JDK 1.0)

This class, when instantiated with a String, breaks the string up into tokens separated by any of the characters in the specified string of delimiters. (For example, words separated by space and tab characters are tokens.) The hasMoreTokens() and nextToken() methods can be used to obtain the tokens in order. countTokens() returns the number of tokens in the string. Note that StringTokenizer implements the Enumeration interface, so you may also access the tokens with the familiar hasMoreElements() and nextElement() methods.

When you create a StringTokenizer you may specify a string of delimiter characters to use for the entire string, or you may rely on the default whitespace delimiters. You may also specify whether the delimiters themselves should be returned as tokens. You may optionally specify a new string of delimiter characters when you call nextToken().

```
public class StringTokenizer extends Object implements Enumeration {
    // Public Constructors
            public StringTokenizer(String str, String delim, boolean returnTokens);
            public StringTokenizer(String str, String delim);
            public StringTokenizer(String str);
    // Public Instance Methods
            public int countTokens();
            public boolean hasMoreElements();  // From Enumeration
            public boolean hasMoreTokens();
            public Object nextElement();  // From Enumeration
            public String nextToken();
            public String nextToken(String delim);
}
```

28.4 java.net.ContentHandlerFactory (JDK 1.0)

This interface defines a method that creates and returns an appropriate `ContentHandler` object for a specified MIME type. A system-wide `ContentHandlerFactory` interface may be specified by using the `URLConnection.setContentHandlerFactory()` method.

Normal applications never need to use or implement this interface.

```
public abstract interface ContentHandlerFactory {
    // Public Instance Methods
            public abstract ContentHandler createContentHandler(String mimetype);
}
```

Passed To:

URLConnection.setContentHandlerFactory()

28.19 java.net.SocketImplFactory (JDK 1.0)

This interface defines a method that creates `SocketImpl` objects. `SocketImplFactory` objects may be registered to create `SocketImpl` objects for the `Socket` and `ServerSocket` classes.

Normal applications never need to use or implement this interface.

```
public abstract interface SocketImplFactory {
    // Public Instance Methods
            public abstract SocketImpl createSocketImpl();
}
```

Passed To:

ServerSocket.setSocketFactory(), Socket.setSocketImplFactory()

18.17 java.awt.Cursor (JDK 1.1)

This class represents a mouse cursor. It defines a number of constants, each of which specify one of the supported cursor images. Pass one of these constants to the constructor to create a cursor of the specified type, and call `getType()` to determine the type of an existing `Cursor` object.

Since there are only a fixed number of available cursors, the static method `getPredefinedCursor()` is more efficient than the `Cursor()` constructor--it maintains a cache of `Cursor` objects that can be reused. The static `getDefaultCursor()` method returns the system default cursor.

```
public class Cursor extends Object implements Serializable {
    // Public Constructor
            public Cursor(int type);
    // Cursor Constants
            public static final int DEFAULT_CURSOR;
            public static final int CROSSHAIR_CURSOR, HAND_CURSOR, MOVE_CURSOR;
            public static final int TEXT_CURSOR, WAIT_CURSOR;
            public static final int N_RESIZE_CURSOR, S_RESIZE_CURSOR;
            public static final int E_RESIZE_CURSOR, W_RESIZE_CURSOR;
            public static final int NE_RESIZE_CURSOR, NW_RESIZE_CURSOR;
            public static final int SE_RESIZE_CURSOR, SW_RESIZE_CURSOR;
    // Class Variables
            protected static Cursor[] predefined;
    // Class Methods
            public static Cursor getDefaultCursor();
            public static Cursor getPredefinedCursor(int type);
    // Public Instance Methods
            public int getType();
}
```

Passed To:

`Component.setCursor(), ComponentPeer.setCursor()`

Returned By:

`Component.getCursor(), Cursor.getDefaultCursor(), Cursor.getPredefinedCursor()`

Type Of:

`Cursor.predefined`

23.9 java.beans.Introspector (JDK 1.1)

The `Introspector` is a class that is never instantiated. Its static `getBeanInfo()` methods provide a way to obtain information about a Java bean, and are typically only invoked by application builders or similar tools. `getBeanInfo()` first looks for a `BeanInfo` class for the specified Java bean class. For a class named `x`, it looks for a `BeanInfo` class named `xBeanInfo`, first in the current package, and then in each of the packages in the `BeanInfo` search path.

If no `BeanInfo` class is found, or if the `BeanInfo` class found does not provide complete information about the bean properties, events, and methods, `getBeanInfo()` "introspects" on the bean class by using the `java.lang.reflect` package to fill in the missing information. When explicit information is provided by a `BeanInfo` class, `getBeanInfo()` treats it as definitive. When determining information through introspection, however, it examines each of the bean's superclasses in turn, looking for a `BeanInfo` class at that level or using introspection. When calling `getBeanInfo()`, you may optionally specify a second class argument that specifies a superclass for which, and above which, `getBeanInfo()` does not introspect.

```
public class Introspector extends Object {
    // No Constructor
    // Class Methods
            public static String decapitalize(String name);
            public static BeanInfo getBeanInfo(Class beanClass) throws 
IntrospectionException;
            public static BeanInfo getBeanInfo(Class beanClass, Class stopClass) 
throws IntrospectionException;
            public static String[] getBeanInfoSearchPath();
            public static void setBeanInfoSearchPath(String[] path);
}
```

26.5 java.lang.reflect.Member (JDK 1.1)

This interface defines the methods shared by all members (fields, methods, and constructors) of a class. `getName()` returns the name of the member, `getModifiers()` returns its modifiers, and `getDeclaringClass()` returns the `Class` object that represents the class of which the member is a part.

```
public abstract interface Member {
    // Constants
            public static final int DECLARED;
            public static final int PUBLIC;
    // Public Instance Methods
            public abstract Class getDeclaringClass();
            public abstract int getModifiers();
            public abstract String getName();
}
```

Implemented By:

Constructor, Field, Method

30.17 java.util.Properties (JDK 1.0)

This class is an extension of `Hashtable` that allows key/value pairs to be read from and written to a stream. The `Properties` class is used to implement the system properties list, which supports user customization by allowing programs to look up the value of named resources.

When you create a `Properties` object, you may specify another `Properties` object that contains default values. Keys (property names) and values are associated in a `Properties` object with the `Hashtable` method `put()`. Values are looked up with `getProperty()`--if this method does not find the key in the current `Properties` object, it looks in the default `Properties` object that was passed to the constructor method. A default value may also be specified in case the key is not found at all.

`propertyNames()` returns an enumeration of all property names (keys) stored in the `Properties` object and (recursively) also all property names stored in the default `Properties` object associated with it. `list()` prints the properties stored in a `Properties` object. It is useful for debugging. `save()` writes a `Properties` object to a stream. `load()` reads key/value pairs from a stream and stores them in a `Properties` object.

```
public class Properties extends Hashtable {
    // Public Constructors
            public Properties();
            public Properties(Properties defaults);
    // Protected Instance Variables
            protected Properties defaults;
    // Public Instance Methods
            public String getProperty(String key);
            public String getProperty(String key, String defaultValue);
            public void list(PrintStream out);
        1.1public void list(PrintWriter out);
            public synchronized void load(InputStream in) throws IOException;
            public Enumeration propertyNames();
            public synchronized void save(OutputStream out, String header);
}
```

31.13 java.util.zip.ZipEntry (JDK 1.1)

This class describes a single entry (typically a compressed file) stored within a ZIP file. The various methods get and set various pieces of information about the entry. The `ZipEntry` class is used by the `ZipFile` and `ZipInputStream`, which read ZIP files, and by the `ZipOutputStream`, which writes ZIP files.

When reading a ZIP file, the `ZipEntry` objects returned by the `ZipFile` or `ZipInputStream` contain the name, size, modification time, and other information about each entry in the file. When writing a ZIP file, on the other hand, you must create your own `ZipEntry` objects, and initialize them to contain the entry name and other appropriate information before writing the contents of the entry.

```
public class ZipEntry extends Object {
    // Public Constructor
            public ZipEntry(String name);
    // Constants
            public static final int DEFLATED;
            public static final int STORED;
    // Public Instance Methods
            public String getComment();
            public long getCompressedSize();
            public long getCrc();
            public byte[] getExtra();
            public int getMethod();
            public String getName();
            public long getSize();

20.15 java.awt.event.ItemEvent (JDK 1.1)

An event of this type indicates that an item within an `ItemSelectable` component has had its selection state changed.

`getItemSelectable()` is a convenient alternative to `getSource()` that returns the `ItemSelectable` object that originated the event. `getItem()` returns an object that represents the item that was selected or deselected.

`getID()` returns the type of the `ItemEvent`. The standard AWT components always generate item events of type `ITEM_STATE_CHANGED`. The `getStateChange()` method returns the new selection state of the item: it returns one of the constants `SELECTED` or `DESELECTED`. (This value can be misleading for `Checkbox` components that are part of a `CheckboxGroup`. If the user attempts to deselect a selected component, a `DESELECTED` event is delivered, but the `CheckboxGroup` immediately re-selects the component to enforce its requirement that at least one `Checkbox` be selected at all times.)

```
public class ItemEvent extends AWTEvent {
    // Public Constructor
            public ItemEvent(ItemSelectable source, int id, Object item, int stateChange);
    // Constants
            public static final int DESELECTED;
            public static final int ITEM_FIRST;
            public static final int ITEM_LAST;
            public static final int ITEM_STATE_CHANGED;
            public static final int SELECTED;
    // Public Instance Methods
            public Object getItem();
            public ItemSelectable getItemSelectable();

21.14 java.awt.image.ReplicateScaleFilter (JDK 1.1)

This class implements an `ImageFilter` that scales an image to a specified pixel size. It uses a very simple scaling algorithm in which rows and columns of image pixels are duplicated or omitted as necessary to achieve the desired size. See `AreaAveragingScaleFilter` for a scaling filter that results in smoother images.

The methods of this class are `ImageConsumer` methods used for communication between the image filter and the `FilteredImageSource` that uses it. Applications do not usually call these methods directly.

The easiest way to use this filter is to call `Image.getScaledInstance()`, specifying an appropriate hint constant.

```
public class ReplicateScaleFilter extends ImageFilter {
    // Public Constructor
            public ReplicateScaleFilter(int width, int height);
    // Protected Instance Variables
            protected int destHeight;
            protected int destWidth;
            protected Object outpixbuf;
            protected int srcHeight;
            protected int srcWidth;
            protected int[] srccols;
            protected int[] srcrows;
    // Public Instance Methods
            public void setDimensions(int w, int h);  // Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model,
            public void setPixels'u'byte[] pixels, int off, int scansize);  //
Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model,
            public void setPixels'u'int[] pixels, int off, int scansize);  //

25.49 java.lang.Process (JDK 1.0)

This class describes a process that is running externally to the Java interpreter. Note that a `Process` is a very different thing than a `Thread`. The `Process` class is abstract and may not be instantiated. Call one of the `Runtime.exec()` methods to start a process and return a corresponding `Process` object.

`waitFor()` blocks until the `Process` exits. `exitValue()` returns the exit code of the process. `destroy()` kills the process. `getInputStream()` returns an `InputStream` from which you can read any bytes the process sends to its standard error stream. `getErrorStream()` returns an `InputStream` from which you can read any bytes the process sends to its standard output stream. `getOutputStream()` returns an `OutputStream` that you can use to send bytes to the standard input stream of the process.

```
public abstract class Process extends Object {
    // Default Constructor: public Process()
    // Public Instance Methods
            public abstract void destroy();
            public abstract int exitValue();
            public abstract InputStream getErrorStream();
            public abstract InputStream getInputStream();
            public abstract OutputStream getOutputStream();
            public abstract int waitFor() throws InterruptedException;
}
```

24.68 java.io.WriteAbortedException (JDK 1.1)

This exception is thrown when reading a stream of data that is incomplete because an exception was thrown while it was being written. The `detail` field may contain the exception that terminated the output stream. The `getMessage()` method has been overridden to include the message of this `detail` exception, if any.

```
public class WriteAbortedException extends ObjectStreamException {
    // Public Constructor
            public WriteAbortedException(String s, Exception ex);
    // Public Instance Variables
            public Exception detail;
    // Public Instance Methods
            public String getMessage();  // Overrides Throwable
}
```

Returned By:

Toolkit.createMenuItem()

28.9 java.net.HttpURLConnection (JDK 1.1)

This class is a specialization of `URLConnection`. An instance of this class is returned when the `openConnection()` method is called for a `URL` object that uses the HTTP protocol.

The many constants defined by this class are the status codes returned by HTTP servers. `setRequestMethod()` specifies what kind of HTTP request is made. The contents of this request must be sent through the `OutputStream` returned by the `getOutputStream()` method of the superclass. Once an HTTP request has been sent, `getResponseCode()` returns the HTTP server's response code as an integer, and `getResponseMessage()` returns the server's response message. The `disconnect()` method closes the connection, and the static `setFollowRedirects()` specifies whether URL connections that use the HTTP protocol should automatically follow redirect responses sent by HTTP servers.

In order to successfully use this class, you need to understand the details of the HTTP protocol.

```
public abstract class HttpURLConnection extends URLConnection {
    // Protected Constructor
            protected HttpURLConnection(URL u);
    // Response Code Constants
            public static final int HTTP_ACCEPTED, HTTP_BAD_GATEWAY, HTTP_BAD_METHOD;

30.4 java.util.Dictionary (JDK 1.0)

This abstract class is the superclass of `Hashtable`. Other hashtable-like data structures might also extend this class. See `Hashtable` for more information.

```
public abstract class Dictionary extends Object {
    // Default Constructor: public Dictionary()
    // Public Instance Methods
            public abstract Enumeration elements();
            public abstract Object get(Object key);
            public abstract boolean isEmpty();
            public abstract Enumeration keys();
            public abstract Object put(Object key, Object value);
            public abstract Object remove(Object key);
            public abstract int size();
}
```

Extended By:

Hashtable

30.22 java.util.Stack (JDK 1.0)

This class implements a last-in-first-out stack of objects. `push()` puts an object on the top of the stack. `pop()` removes and returns the top object from the stack. `peek()` returns the top object without removing it.

```
public class Stack extends Vector {
    // Default Constructor: public Stack()
    // Public Instance Methods
            public boolean empty();
            public synchronized Object peek();
            public synchronized Object pop();
            public Object push(Object item);
            public synchronized int search(Object o);
}
```

Hierarchy:

Object->Vector(Cloneable, Serializable)->Stack

31.11 java.util.zip.Inflater (JDK 1.1)

This class implements the general ZLIB data decompression algorithm used by *gzip*, *PKZip*, and other data compression applications. It decompresses or "inflates" data compressed through the `Deflater` class.

The important methods of this class are `setInput()`, which specifies input data to be decompressed, and `inflate()`, which decompresses the input data into an output buffer. A number of other methods exist so that this class can be used for stream-based decompression, as it is in the higher-level classes such as `GZIPInputStream` and `ZipInputStream`. These stream-based classes are sufficient in most cases. Most applications do not need to use `Inflater` directly.

```
public class Inflater extends Object {
    // Public Constructors
            public Inflater(boolean nowrap);
            public Inflater();
    // Public Instance Methods
            public synchronized native void end();
            public synchronized boolean finished();
            public synchronized native int getAdler();
            public synchronized int getRemaining();
            public synchronized native int getTotalIn();
            public synchronized native int getTotalOut();
            public synchronized native int inflate(byte[] b, int off, int len) throws
DataFormatException;
            public int inflate(byte[] b) throws DataFormatException;
            public synchronized boolean needsDictionary();
            public synchronized boolean needsInput();
            public synchronized native void reset();
            public synchronized native void setDictionary(byte[] b, int off, int
len);
            public void setDictionary(byte[] b);
            public synchronized void setInput(byte[] b, int off, int len);
            public void setInput(byte[] b);
    // Protected Instance Methods
            protected void finalize();  // Overrides Object
}
```

Passed To:

InflaterInputStream()

Type Of:

InflaterInputStream.inf

18.51 java.awt.PrintJob (JDK 1.1)

A PrintJob object represents a single printing session or "job." The job may consist of one or more individual pages.

PrintJob is abstract so it cannot be instantiated directly. Instead, you must call the getPrintJob() method of the Toolkit object. Calling this method posts an appropriate print dialog box to request information from the user, such as which printer should be used. An application has no control over this process, but may pass a Properties object in which the dialog stores the user's printing preferences. This Properties object can then be reused when initiating subsequent print jobs.

Once a PrintJob object has been obtained from the Toolkit object, you call the getGraphics() method of PrintJob to obtain a Graphics object. Any drawing done with this Graphics object is printed rather than being displayed on-screen. The object returned by getGraphics() implements the PrintGraphics interface. Do not make any assumptions about the initial state of the Graphics object; in particular note that you must specify a font before you can draw any text.

When you are done drawing all the desired output on a page, call the dispose() method of the Graphics object to force the current page to be printed. You can call PrintJob.getGraphics() and Graphics.dispose() repeatedly to print any number of pages required by your application. Note, however, that if the lastPageFirst() method returns true, the user has requested that pages be printed in reverse order. It is up to your application to implement this feature.

The getPageDimension() method returns the size of the page in pixels. getPageResolution() returns the resolution of the page in pixels per inch. This resolution is closer to a screen resolution (70 to 100 pixels per inch) rather than a typical printer resolution (300 to 600 pixels per inch). This means that on-screen drawings can be drawn directly to the printer without scaling. It also means, however, that you cannot take full advantage of the extra resolution provided by printers.

When you are done with a PrintJob, and you have called dispose() on the Graphics object returned by getGraphics(), you should call end() to terminate the job.

```
public abstract class PrintJob extends Object {
    // Default Constructor: public PrintJob()
    // Public Instance Methods
            public abstract void end();
            public void finalize();  // Overrides Object
            public abstract Graphics getGraphics();
            public abstract Dimension getPageDimension();
            public abstract int getPageResolution();
            public abstract boolean lastPageFirst();
}
```

24.45 java.io.OptionalDataException (JDK 1.1)

This exception is thrown by the `readObject()` method of an `ObjectInputStream` when it encounters primitive type data where it expects object data. Despite the exception name, this data is not "optional," and object deserialization is aborted.

```
public class OptionalDataException extends ObjectStreamException {
    // No Constructor
    // Public Instance Variables
            public boolean eof;
            public int length;
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException->OptionalDataException

Thrown By:

ObjectInputStream.readObject()

26.2 java.lang.reflect.Constructor (JDK 1.1)

This class represents a constructor method of a class. Instances of `Constructor` are obtained by calling `getConstructor()` and related methods of `java.lang.Class`. `Constructor` implements the `Member` interface, so you can use the methods of that interface to obtain the constructor name, modifiers, and declaring class. In addition, `getParameterTypes()` and `getExceptionTypes()` also return important information about the represented constructor.

In addition to these methods that return information about the constructor, the `newInstance()` method allows the constructor to be invoked with an array of arguments in order to create a new instance of the class that declares the constructor. If any of the arguments to the constructor are of primitive types, they must be converted to their corresponding wrapper object types in order to be passed to `newInstance()`. If the constructor causes an exception, the `Throwable` object it throws is wrapped within the `InvocationTargetException` that is thrown by `newInstance()`. Note that `newInstance()` is much more useful than the `newInstance()` method of `java.lang.Class` because it can pass arguments to the constructor.

```
public final class Constructor extends Object implements Member {
    // No Constructor
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
            public Class getDeclaringClass();  // From Member

19.3 java.awt.datatransfer.DataFlavor (JDK 1.1)

Objects of this type define a data type or format for the purposes of data transfer. A `DataFlavor` is characterized by two values. The first is a descriptive human-readable name, passed to a `DataFlavor()` constructor or set with `setHumanPresentableName()`.

The second component of a `DataFlavor` specifies the type of data to be transferred in a more machine-readable way. The two `DataFlavor()` constructors allow two distinct ways to specify this data type. One way is by directly specifying the representation class of the data. This is a `Class` object that defines the Java type that the recipient of a data transfer is passed. The other way to specify the data type represented by a `DataFlavor` is to pass a string that specifies the MIME type of the data to be transferred.

When you construct a `DataFlavor` object by specifying the representation type of the data, the MIME type of the `DataFlavor` is automatically set to:

```
application/x-java-serialized-object class=classname
```

This indicates that the object is to be transferred using the data format of the Java object serialization protocol. When you pass a MIME type string to the `DataFlavor()` constructor, on the other hand, the representation class of the `DataFlavor` is automatically set to the `Class` object for `java.io.InputStream`. This means that the recipient of the data transfer is given an `InputStream` object from which it can read and parse data in the specified MIME format.

Because the same MIME type can be specified with a number of slightly different strings, the `DataFlavor` class converts the MIME type to a canonical form so that it can be uniquely identified and compared. Use `isMimeTypeEqual()` to compare the MIME type of a `DataFlavor` object with another MIME type, or with the MIME type of another `DataFlavor`.

Because textual data is so often transferred, the `DataFlavor` class defines constants for two commonly-used data flavors. `stringFlavor` represents text transferred as a `String` object, while `plainTextFlavor` represents text transferred through an `InputStream`, using the `text/plain` MIME type.

```
public class DataFlavor extends Object {
    // Public Constructors
            public DataFlavor(Class representationClass, String 
humanPresentableName);
            public DataFlavor(String mimeType, String humanPresentableName);
    // Class Variables
            public static DataFlavor plainTextFlavor;
            public static DataFlavor stringFlavor;
    // Public Instance Methods
            public boolean equals(DataFlavor dataFlavor);
            public String getHumanPresentableName();
            public String getMimeType();
            public Class getRepresentationClass();
            public boolean isMimeTypeEqual(String mimeType);
            public final boolean isMimeTypeEqual(DataFlavor dataFlavor);
            public void setHumanPresentableName(String humanPresentableName);
    // Protected Instance Methods

`Many methods`

26.3 java.lang.reflect.Field (JDK 1.1)

This class represents a field of a class. Instances of `Field` are obtained by calling the `getField()` and related methods of `java.lang.Class`. `Field` implements the `Member` interface, so once you have obtained a `Field` object, you can use `getName()`, `getModifiers()`, and `getDeclaringClass()` to determine the name, modifiers, and class of the field. Additionally, `getType()` returns the type of the field.

The `set()` method sets the value of the represented field for a specified object to a given value. (If the represented field is `static`, then no object need be specified for it to be set upon, of course.) If the field is of a primitive type, its value can be specified using a wrapper object of type `Boolean`, `Integer`, and so on, or it can be set using the `setBoolean()`, `setInt()`, and related methods.

Similarly, the `get()` method queries the value of the represented field for a specified object and returns the field value as an `Object`. Various other methods query the field value and return it as various primitive types.

```
public final class Field extends Object implements Member {
    // No Constructor
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
            public native Object get(Object obj) throws IllegalArgumentException, 
IllegalAccessException;
            public native boolean getBoolean(Object obj) throws 
IllegalArgumentException, IllegalAccessException;
            public native byte getByte(Object obj) throws IllegalArgumentException,

28.10 java.net.InetAddress (JDK 1.0)

This class represents an Internet address, and is used when creating `DatagramPacket` or `Socket` objects. The class does not have a public constructor function, but instead supports three static methods which return one or more instances of `InetAddress`. `getLocalHost()` returns an `InetAddress` for the local host. `getByName()` returns the `InetAddress` of a host specified by name. `getAllByName()` returns an array of `InetAddress` that represents all of the available addresses for a host specified by name. Instance methods are `getHostName()`, which returns the hostname of an `InetAddress`, and `getAddress()`, which returns the Internet IP address as an array of bytes, with the highest-order byte as the first element of the array.

```
public final class InetAddress extends Object implements Serializable {
    // No Constructor
    // Class Methods
            public static InetAddress[] getAllByName(String host) throws
UnknownHostException;
            public static InetAddress getByName(String host) throws
UnknownHostException;
            public static InetAddress getLocalHost() throws UnknownHostException;
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
            public byte[] getAddress();
            public String getHostAddress();
            public String getHostName();
            public int hashCode();  // Overrides Object
        1.1public boolean isMulticastAddress();
            public String toString();  // Overrides Object
}
```

Passed To:

DatagramPacket(), DatagramPacket.setAddress(), DatagramSocket(), DatagramSocketImpl.bind(), DatagramSocketImpl.join(), DatagramSocketImpl.leave(), DatagramSocketImpl.peek(), MulticastSocket.joinGroup(), MulticastSocket.leaveGroup(), MulticastSocket.setInterface(), SecurityManager.checkMulticast(), ServerSocket(), Socket(), SocketImpl.bind(), SocketImpl.connect()

Returned By:

DatagramPacket.getAddress(), DatagramSocket.getLocalAddress(), InetAddress.getAllByName(), InetAddress.getByName(), InetAddress.getLocalHost(), MulticastSocket.getInterface(), ServerSocket.getInetAddress(), Socket.getInetAddress(), Socket.getLocalAddress(), SocketImpl.getInetAddress()

Type Of:

SocketImpl.address

18.45 java.awt.MenuShortcut (JDK 1.1)

This class represents a keystroke used to select a `MenuItem` without actually pulling down the menu. A `MenuShortcut` object can be specified for a `MenuItem` when the `MenuItem` is created or by calling the item's `setShortcut()` method. The keystroke sequence for the menu shortcut automatically appears in the label for the menu item, so you need not add this information yourself.

When you create a `MenuShortcut`, you specify the key code of the shortcut--this is one of the `VK_` constants defined by `java.awt.event.KeyEvent`, and is not always the same as a corresponding character code. You may also optionally specify a `boolean` value that, if `true`, indicates that the `MenuShortcut` requires the **Shift** key to be held down.

Note that menu shortcuts are triggered in a platform-dependent way. When you create a shortcut, you specify only the keycode and an optional **Shift** modifier. The shortcut is not triggered, however, unless an additional modifier key is held down. On Windows platforms, for example, the **Ctrl** key is used for menu shortcuts. You can query the platform-specific menu shortcut key with `Toolkit.getMenuShortcutKeyMask()`.

```
public class MenuShortcut extends Object implements Serializable {
    // Public Constructors
            public MenuShortcut(int key);
            public MenuShortcut(int key, boolean useShiftModifier);
    // Public Instance Methods
            public boolean equals(MenuShortcut s);
            public int getKey();
            public String toString();  // Overrides Object
            public boolean usesShiftModifier();
    // Protected Instance Methods
            protected String paramString();
}
```

Passed To:

`MenuBar.deleteShortcut(), MenuBar.getShortcutMenuItem(), MenuItem(), MenuItem.setShortcut(), MenuShortcut.equals()`

Returned By:

`MenuItem.getShortcut()`

26.6 java.lang.reflect.Method (JDK 1.1)

This class represents a method. Instances of `Method` are obtained by calling the `getMethod()` and related methods of `java.lang.Class`. `Method` implements the `Member` interface, so you can use the methods of that interface to obtain the method name, modifiers, and declaring class. In addition, `getReturnType()`, `getParameterTypes()`, and `getExceptionTypes()` also return important information about the represented method.

Perhaps most important, the `invoke()` method allows the method represented by the `Method` object to be invoked with a specified array of argument values. If any of the arguments are of primitive types, they must be converted to their corresponding wrapper object types in order to be passed to `invoke()`. If the represented method is an instance method (i.e., if it is not `static`), the instance on which it should be invoked must also be passed to `invoke()`. The return value of the represented method is returned by `invoke()`. If the return value is a primitive value, it is first converted to the corresponding wrapper type. If the invoked method causes an exception, the `Throwable` object it throws is wrapped within the `InvocationTargetException` that is thrown by `invoke()`.

```
public final class Method extends Object implements Member {
    // No Constructor
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
            public Class getDeclaringClass();  // From Member
            public Class[] getExceptionTypes();
            public native int getModifiers();  // From Member
            public String getName();  // From Member
            public Class[] getParameterTypes();
            public Class getReturnType();
            public int hashCode();  // Overrides Object
            public native Object invoke(Object obj, Object[] args) throws 
IllegalAccessException, IllegalArgumentException, InvocationTargetException;
            public String toString();  // Overrides Object
}
```

18.47 java.awt.Point (JDK 1.0)

This class holds the X and Y coordinates of a two-dimensional point. The `move()` method sets the coordinates, and the `translate()` method adds the specified values to the coordinates. The `x` and `y` fields are public and may be manipulated directly.

```
public class Point extends Object implements Serializable {
    // Public Constructors
        1.1  public Point();
        1.1  public Point(Point p);
            public Point(int x, int y);
    // Public Instance Variables
            public int x;
            public int y;
    // Public Instance Methods
            public boolean equals(Object obj);  // Overrides Object
        1.1  public Point getLocation();
            public int hashCode();  // Overrides Object
            public void move(int x, int y);
        1.1  public void setLocation(Point p);
        1.1  public void setLocation(int x, int y);
            public String toString();  // Overrides Object

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.17 java.io.FileDescriptor (JDK 1.0)

This class is a platform-independent representation of a low-level handle to an open file or an open socket. The static `in`, `out`, and `err` variables are `FileDescriptor` objects that represent the system standard input, output, and error streams, respectively. There is no public constructor method to create a `FileDescriptor` object. You can obtain one with the `getFD()` method of `FileInputStream`, `FileOutputStream`, and `RandomAccessFile`.

```
public final class FileDescriptor extends Object {
    // Default Constructor: public FileDescriptor()
    // Constants
            public static final FileDescriptor err;
            public static final FileDescriptor in;
            public static final FileDescriptor out;
    // Public Instance Methods
        1.1  public native void sync() throws SyncFailedException;
            public native boolean valid();
}
```

Passed To:

FileInputStream(), FileOutputStream(), FileReader(), FileWriter(), SecurityManager.checkRead(), SecurityManager.checkWrite()

Returned By:

DatagramSocketImpl.getFileDescriptor(), FileInputStream.getFD(), FileOutputStream.getFD(), RandomAccessFile.getFD(), SocketImpl.getFileDescriptor()

Type Of:

DatagramSocketImpl.fd, FileDescriptor.err, FileDescriptor.in, FileDescriptor.out, SocketImpl.fd

25.51 java.lang.Runtime (JDK 1.0)

This class encapsulates a number of platform-dependent system functions. The static method `getRuntime()` returns the `Runtime` object for the current platform, and this object can be used to perform system functions in a platform-independent way.

`exec()` starts a new process running externally to the interpreter. Note that any processes run outside of Java may be system-dependent.

`exit()` causes the Java interpreter to exit and return a specified return code.

`freeMemory()` returns the approximate amount of free memory. `totalMemory()` returns the total amount of memory available to the Java interpreter. `gc()` forces the garbage collector to run synchronously, which may free up more memory. Similarly, `runFinalization()` forces the `finalize()` methods of unreferenced objects to be run immediately. This may free up system resources that those objects were holding.

`load()` loads a dynamic library with a fully specified path name. `loadLibrary()` loads a dynamic library with only the library name specified; it looks in platform-dependent locations for the specified library. These libraries generally contain native code definitions for native methods.

`traceInstructions()` and `traceMethodCalls()` enable and disable tracing by the interpreter.

Note that some of the `Runtime` methods are more commonly called via the static methods of the `System` class.

```
public class Runtime extends Object {
    // No Constructor
    // Class Methods
            public static Runtime getRuntime();
        1.1public static void runFinalizersOnExit(boolean value);
    // Public Instance Methods
            public Process exec(String command) throws IOException;
            public Process exec(String command, String[] envp) throws IOException;
            public Process exec(String[] cmdarray) throws IOException;
            public Process exec(String[] cmdarray, String[] envp) throws IOException;
            public void exit(int status);
            public native long freeMemory();
            public native void gc();
        #   public InputStream getLocalizedInputStream(InputStream in);
        #   public OutputStream getLocalizedOutputStream(OutputStream out);
            public synchronized void load(String filename);
            public synchronized void loadLibrary(String libname);
            public native void runFinalization();
            public native long totalMemory();
            public native void traceInstructions(boolean on);
            public native void traceMethodCalls(boolean on);
}
```

25.64 java.lang.Throwable (JDK 1.0)

This is the root class of the Java exception and error hierarchy. All exceptions and errors are subclasses of `Throwable`. The `getMessage()` method retrieves any error message associated with the exception or error. `printStackTrace()` prints a stack trace that shows where the exception occurred. `fillInStackTrace()` extends the stack trace when the exception is partially handled, and then re-thrown.

```
public class Throwable extends Object implements Serializable {
    // Public Constructors
            public Throwable();
            public Throwable(String message);
    // Public Instance Methods
            public native Throwable fillInStackTrace();
        1.1public String getLocalizedMessage();
            public String getMessage();
            public void printStackTrace();
            public void printStackTrace(PrintStream s);
        1.1public void printStackTrace(PrintWriter s);
            public String toString();  // Overrides Object
}
```

21.2 java.awt.image.ColorModel (JDK 1.0)

This abstract class defines a color model--i.e., a scheme for representing a color. Subclasses implement the methods of this interface to convert their particular representation of a pixel value into the default RGB color model. The static method `getRGBDefault()` returns a `ColorModel` object that implements the default color model--RGB plus alpha transparency. You generally never need to call the instance methods of a `ColorModel`--they are called internally by other image manipulation classes.

See also `DirectColorModel` and `IndexColorModel`.

```
public abstract class ColorModel extends Object {
    // Public Constructor
            public ColorModel(int bits);
    // Protected Instance Variables
            protected int pixel_bits;
    // Class Methods
            public static ColorModel getRGBdefault();
    // Public Instance Methods
            public void finalize();  // Overrides Object
            public abstract int getAlpha(int pixel);
            public abstract int getBlue(int pixel);
            public abstract int getGreen(int pixel);
            public int getPixelSize();
            public int getRGB(int pixel);
            public abstract int getRed(int pixel);
}
```

Extended By:

`DirectColorModel, IndexColorModel`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

23.17 java.beans.PropertyEditorManager (JDK 1.1)

The PropertyEditorManager class is never meant to be instantiated; it defines static methods for registering and looking up PropertyEditor classes for a specified property type.

A Java bean may specify a particular PropertyEditor class for a given property by specifying it in a PropertyDescriptor object for the property. If it does not do this, the PropertyEditorManager is used to register and look up editors. A bean or an application builder tool may call the registerEditor() method to register a PropertyEditor for properties of a specified type. Application builders and bean Customizer classes may call the findEditor() method to obtain a PropertyEditor for a given property type.

If no editor has been registered for a given type, the PropertyEditorManager attempts to locate one. For a type *x*, it looks for a class *x*Editor first in the same package as *x*, and then in each package listed in the property editor search path.

```
public class PropertyEditorManager extends Object {
    // Default Constructor: public PropertyEditorManager()
    // Class Methods
            public static PropertyEditor findEditor(Class targetType);
            public static String[] getEditorSearchPath();
            public static void registerEditor(Class targetType, Class editorClass);
            public static void setEditorSearchPath(String[] path);
}
```

24.13 java.io.DataOutputStream (JDK 1.0)

This class is a subclass of `FilterOutputStream` that allows you to write Java primitive data types in a portable binary format. Create a `DataOutputStream` by specifying the `OutputStream` that is to be filtered in the call to the constructor.

Many of this class's methods write a single Java primitive type, in binary format to the output stream. `write()` writes a single byte, an array, or a subarray of bytes. `flush()` forces any buffered data to be output. `size()` returns the number of bytes written so far.

`writeUTF()` outputs a Java string of Unicode characters using a slightly modified version of the UTF-8 "transformation format." UTF-8 is an ASCII-compatible encoding of Unicode characters that is often used for the transmission and storage of Unicode text. Except for the `writeUTF()` method, this class is used for binary output of data. Textual output should be done with `PrintWriter`, or `PrintStream` in Java 1.0.

`DataOutputStream` only has methods to output primitive types. Use `ObjectOutputStream` to output object values.

```
public class DataOutputStream extends FilterOutputStream implements DataOutput {
    // Public Constructor
            public DataOutputStream(OutputStream out);
    // Protected Instance Variables
            protected int written;
    // Public Instance Methods
            public void flush() throws IOException;  // Overrides FilterOutputStream
            public final int size();
            public synchronized void write(int b) throws IOException;  // Overrides
FilterOutputStream
            public synchronized void write(byte[] b, int off, int len) throws
IOException;  // Overrides FilterOutputStream
            public final void writeBoolean(boolean v) throws IOException;  // From
DataOutput
            public final void writeByte(int v) throws IOException;  // From
DataOutput
            public final void writeBytes(String s) throws IOException;  // From
DataOutput
            public final void writeChar(int v) throws IOException;  // From
DataOutput
            public final void writeChars(String s) throws IOException;  // From
DataOutput
            public final void writeDouble(double v) throws IOException;  // From
DataOutput
            public final void writeFloat(float v) throws IOException;  // From
DataOutput
            public final void writeInt(int v) throws IOException;  // From DataOutput
            public final void writeLong(long v) throws IOException;  // From
DataOutput

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18.32 java.awt.Image (JDK 1.0)

This abstract class represents a displayable image in a platform-independent way. An `Image` object may not be instantiated directly through a constructor; it must be obtained through a call like `Applet.getImage()` or `Component.createImage()`. `getSource()` method returns the `ImageProducer` object that produces the image data. `getGraphics()` returns a `Graphics` object that can be used for drawing into offscreen images (but not images that are downloaded or generated by an `ImageProducer`).

```
public abstract class Image extends Object {
    // Default Constructor: public Image()
    // Constants
        1.1  public static final int SCALE_AREA_AVERAGING;
        1.1  public static final int SCALE_DEFAULT;
        1.1  public static final int SCALE_FAST;
        1.1  public static final int SCALE_REPLICATE;
        1.1  public static final int SCALE_SMOOTH;
            public static final Object UndefinedProperty;
    // Public Instance Methods
            public abstract void flush();
            public abstract Graphics getGraphics();
            public abstract int getHeight(ImageObserver observer);
            public abstract Object getProperty(String name, ImageObserver observer);
        1.1  public Image getScaledInstance(int width, int height, int hints);
            public abstract ImageProducer getSource();
            public abstract int getWidth(ImageObserver observer);
}
```

Passed To:

`Component.checkImage(), Component.imageUpdate(), Component.prepareImage(), ComponentPeer.checkImage(), ComponentPeer.prepareImage(), Frame.setIconImage(), FramePeer.setIconImage(), Graphics.drawImage(), ImageObserver.imageUpdate(), MediaTracker.addImage(), MediaTracker.removeImage(), PixelGrabber(), Toolkit.checkImage(), Toolkit.prepareImage()`

Returned By:

`Applet.getImage(), AppletContext.getImage(), BeanInfo.getIcon(), Component.createImage(), ComponentPeer.createImage(), Frame.getIconImage(), Image.getScaledInstance(), SimpleBeanInfo.getIcon(), SimpleBeanInfo.loadImage(),` `Toolkit.createImage(), Toolkit.getImage()`

20.12 java.awt.event.FocusEvent (JDK 1.1)

An event of this type indicates that a `Component` has gained or lost focus on a temporary or permanent basis.

Use the inherited `getComponent()` method to determine which component has gained or lost focus. Use `getID()` to determine the type of focus event; it returns `FOCUS_GAINED` or `FOCUS_LOST`.

When focus is lost, you can call `isTemporary()` to determine whether it is a temporary loss of focus. Temporary focus loss occurs when the window that contains the component loses focus, for example, or when focus is temporarily diverted to a popup menu or a scrollbar. Similarly, you can also use `isTemporary()` to determine whether focus is being granted to a component on a temporary basis.

```
public class FocusEvent extends ComponentEvent {
    // Public Constructors
            public FocusEvent(Component source, int id, boolean temporary);
            public FocusEvent(Component source, int id);
    // Constants
            public static final int FOCUS_FIRST;
            public static final int FOCUS_GAINED;
            public static final int FOCUS_LAST;
            public static final int FOCUS_LOST;
    // Public Instance Methods
            public boolean isTemporary();
            public String paramString();  // Overrides ComponentEvent
}
```

Hierarchy:

`Object->EventObject(Serializable)->AWTEvent->ComponentEvent->FocusEvent`

Passed To:

`AWTEventMulticaster.focusGained(), AWTEventMulticaster.focusLost(),` `Component.processFocusEvent()`, `FocusAdapter.focusGained()`, `FocusAdapter.focusLost()`, `FocusListener.focusGained()`, `FocusListener.focusLost()`

20.11 java.awt.event.FocusAdapter (JDK 1.1)

This class is a trivial implementation of `FocusListener`; it provides empty bodies for each of the methods of that interface. When you are not interested in all of these methods, it is often easier to subclass `FocusAdapter` than it is to implement `FocusListener` from scratch.

```
public abstract class FocusAdapter extends Object implements FocusListener {
    // Default Constructor: public FocusAdapter()
    // Public Instance Methods
            public void focusGained(FocusEvent e);  // From FocusListener
            public void focusLost(FocusEvent e);  // From FocusListener
}
```

Hierarchy:

```
Object->FocusAdapter(FocusListener(EventListener))
```

20.13 java.awt.event.FocusListener (JDK 1.1)

This interface defines the methods that an object must implement to "listen" for focus events on AWT components. When a `FocusEvent` occurs, an AWT component notifies its registered `FocusListener` objects by invoking one of their methods.

An easy way to implement this interface is by subclassing the `FocusAdapter` class.

```
public abstract interface FocusListener extends EventListener {
    // Public Instance Methods
            public abstract void focusGained(FocusEvent e);
            public abstract void focusLost(FocusEvent e);
}
```

Implemented By:

`AWTEventMulticaster, FocusAdapter`

Passed To:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove(), Component.addFocusListener(), Component.removeFocusListener()`

Returned By:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove()`

24.43 java.io.ObjectStreamClass (JDK 1.1)

This class is used to represent a class that is being serialized. An `ObjectStreamClass` object contains the name of a class and its unique version identifier. This class does not have a constructor; you should use the static `lookup()` method to obtain an `ObjectStreamClass` object for a given `Class` object. The `forClass()` instance method performs the opposite operation--it returns the `Class` object that corresponds to a given `ObjectStreamClass`.

Most applications never need to use this class.

```
public class ObjectStreamClass extends Object implements Serializable {
    // No Constructor
    // Class Methods
            public static ObjectStreamClass lookup(Class cl);
    // Public Instance Methods
            public Class forClass();
            public String getName();
            public long getSerialVersionUID();
            public String toString();  // Overrides Object
}
```

Passed To:

ObjectInputStream.resolveClass()

Returned By:

ObjectStreamClass.lookup()

java.io.ObjectOutputStream (JDK 1.1) BOOK INDEX java.io.ObjectStreamException (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

25.8 java.lang.Class (JDK 1.0)

This class represents a Java class or interface, or, in Java 1.1, any Java type. There is one `Class` object for each class that is loaded into the Java Virtual Machine, and in Java 1.1 there are special `Class` objects that represent the Java primitive types. The `TYPE` constants defined by `Boolean`, `Integer`, and the other primitive "wrapper classes" hold these special `Class` objects. Array types are also represented by `Class` objects in Java 1.1.

There is no constructor for this class. You can obtain a `Class` object by calling the `getClass()` method of any instance of the desired class. In Java 1.1, a `Class` object may also be referred to by appending `.class` to the name of a class. Finally, and most interestingly, a class can be dynamically loaded by passing its fully-qualified name (i.e., package name plus class name) to the static `Class.forName()` method. This method loads the named class, if it is not already loaded, into the Java interpreter, and returns a `Class` object for it.

The `newInstance()` method creates an instance of a given class--this allows you to create instances of dynamically loaded classes for which you cannot use the `new` keyword. Note that this method only works when the target class has a no-argument constructor. See `newInstance()` in `java.lang.reflect.Constructor` for a more powerful way to instantiate dynamically loaded classes.

`getName()` returns the name of the class. `getSuperclass()` returns its superclass. `isInterface()` tests whether the `Class` object represents an interface, and `getInterfaces()` returns an array of the interfaces that this class implements. The various other `get` and `is` methods return other information about the represented class, and form part of the Java Reflection API, along with the classes in `java.lang.reflect`.

```
public final class Class extends Object implements Serializable {
    // No Constructor

23.2 java.beans.BeanInfo (JDK 1.1)

The `BeanInfo` interface defines the methods that a class must implement in order to export information about a Java bean. The `Introspector` class knows how to obtain all the basic information required about a bean. A bean that wants to be more "programmer-friendly" may provide a class that implements this interface, however, in order to provide additional information about itself (such as an icon and description strings for each of its properties, events, and methods). Note that a bean developer defines a class that implements the methods of this interface. Typically only builder applications and similar tools actually invoke the methods defined here.

The methods `getBeanDescriptor()`, `getEventSetDescriptors()`, `getPropertyDescriptors()`, and `getMethodDescriptors()` should return appropriate descriptor objects for the bean, or `null`, if the bean does not provide explicit bean, event set, property, or method descriptor objects. The `getDefaultEventIndex()` and `getDefaultPropertyIndex()` methods return values that specify the "default" event and property--i.e., that are most likely to be of interest to a programmer using the bean. These methods should return -1 if there are no defaults.

The `getIcon()` method should return an image object suitable for representing the bean in a palette or menu of available beans. The argument passed to this method is one of the four constants defined by the class; it specifies the type and size of icon requested. If the requested icon cannot be provided, `getIcon()` should return `null`.

A `BeanInfo` class is allowed to return `null` or -1 if it cannot provide the requested information. In this case, the `Introspector` class provides basic values for the omitted information from its own introspection of the bean. See `SimpleBeanInfo` for a trivial implementation of this interface, suitable for convenient subclassing.

```
public abstract interface BeanInfo {
    // Constants
            public static final int ICON_COLOR_16x16;
            public static final int ICON_COLOR_32x32;
            public static final int ICON_MONO_16x16;
            public static final int ICON_MONO_32x32;
    // Public Instance Methods
```

```
            public abstract BeanInfo[] getAdditionalBeanInfo();
            public abstract BeanDescriptor getBeanDescriptor();
            public abstract int getDefaultEventIndex();
            public abstract int getDefaultPropertyIndex();
            public abstract EventSetDescriptor[] getEventSetDescriptors();
            public abstract Image getIcon(int iconKind);
            public abstract MethodDescriptor[] getMethodDescriptors();
            public abstract PropertyDescriptor[] getPropertyDescriptors();
}
```

23.20 java.beans.SimpleBeanInfo (JDK 1.1)

The `SimpleBeanInfo` class is a trivial implementation of the `BeanInfo` interface. The methods of this class all return `null` or `-1`, indicating that no bean information is available. To use this class, you need only to override the method or methods that return the particular type of bean information you want to provide.

In addition, `SimpleBeanInfo` provides a convenience method, `loadImage()`, that takes a resource name as an argument and returns an `Image object`. This method is useful when defining the `getIcon()` method.

```
public class SimpleBeanInfo extends Object implements BeanInfo {
    // Default Constructor: public SimpleBeanInfo()
    // Public Instance Methods
            public BeanInfo[] getAdditionalBeanInfo();  // From BeanInfo
            public BeanDescriptor getBeanDescriptor();  // From BeanInfo
            public int getDefaultEventIndex();  // From BeanInfo
            public int getDefaultPropertyIndex();  // From BeanInfo
            public EventSetDescriptor[] getEventSetDescriptors();  // From BeanInfo
            public Image getIcon(int iconKind);  // From BeanInfo
            public MethodDescriptor[] getMethodDescriptors();  // From BeanInfo
            public PropertyDescriptor[] getPropertyDescriptors();  // From BeanInfo
            public Image loadImage(String resourceName);
}
```

23.5 java.beans.EventSetDescriptor (JDK 1.1)

An EventSetDescriptor object is a type of FeatureDescriptor that describes a single set of events supported by a Java bean. A "set" of events corresponds to the one or more methods supported by a single EventListener interface. The BeanInfo class for a Java bean optionally creates EventSetDescriptor objects to describe the event sets the bean supports. Typically, only application builders and similar tools use the get and is methods of EventSetDescriptor objects to obtain the event-set description information.

To create an EventSetDescriptor object, you must specify the class of the bean that supports the event set, the base name of the event set, the class of the EventListener interface that corresponds to the event set, and the methods within this interface that are invoked when particular events within the set occur. Optionally, you may also specify the methods of the bean class that are used to add and remove EventListener objects. The various constructors allow you to specify methods by name, as java.lang.reflect.Method objects, or as MethodDescriptor objects.

Once you have created an EventSetDescriptor, you can use setUnicast() to specify whether it represents a unicast event and setInDefaultEventSet() to specify whether the event set should be treated as the default event set by builder applications. The methods of the FeatureDescriptor superclass allow additional information about the property to be specified.

```
public class EventSetDescriptor extends FeatureDescriptor {
    // Public Constructors
            public EventSetDescriptor(Class sourceClass, String eventSetName, Class 
listenerType, 
            public EventSetDescriptor'u'String listenerMethodName) throws 
IntrospectionException;
            public EventSetDescriptor(Class sourceClass, String eventSetName, Class 
listenerType, 
            public EventSetDescriptor'u'String[] listenerMethodNames, String 
addListenerMethodName 
            public EventSetDescriptor'u'String removeListenerMethodName) throws 
IntrospectionException;
            public EventSetDescriptor(String eventSetName, Class listenerType, 
Method[] listenerMethods, 
            public EventSetDescriptor'u'Method addListenerMethod, Method 
removeListenerMethod) 
            public EventSetDescriptor'u'throws IntrospectionException;
            public EventSetDescriptor(String eventSetName, Class listenerType, 
            public EventSetDescriptor'u'MethodDescriptor[] listenerMethodDescriptors, 
Method addListenerMethod, 
            public EventSetDescriptor'u'Method removeListenerMethod) throws 
IntrospectionException;
```

```
    // Public Instance Methods
            public Method getAddListenerMethod();
            public MethodDescriptor[] getListenerMethodDescriptors();
            public Method[] getListenerMethods();
            public Class getListenerType();
            public Method getRemoveListenerMethod();
            public boolean isInDefaultEventSet();
            public boolean isUnicast();
            public void setInDefaultEventSet(boolean inDefaultEventSet);
            public void setUnicast(boolean unicast);
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

28.5 java.net.DatagramPacket (JDK 1.0)

This class implements a "packet" of data that may be sent or received over the network through a `DatagramSocket`. One of the `DatagramPacket` constructors specifies an array of binary data to be sent with its destination address and port. A packet created with this constructor may then be sent with the `send()` method of a `DatagramSocket`. The other `DatagramPacket` constructor specifies an array of bytes into which data should be received. The `receive()` method of `DatagramSocket` waits for data and stores it in a `DatagramPacket` created in this way. The contents and sender of a received packet may be queried with the `DatagramPacket` instance methods.

```
public final class DatagramPacket extends Object {
    // Public Constructors
            public DatagramPacket(byte[] ibuf, int ilength);
            public DatagramPacket(byte[] ibuf, int ilength, InetAddress iaddr, int 
iport);
    // Public Instance Methods
            public synchronized InetAddress getAddress();
            public synchronized byte[] getData();
            public synchronized int getLength();
            public synchronized int getPort();
        1.1public synchronized void setAddress(InetAddress iaddr);
        1.1public synchronized void setData(byte[] ibuf);
        1.1public synchronized void setLength(int ilength);
        1.1public synchronized void setPort(int iport);
}
```

Passed To:

DatagramSocket.receive(), DatagramSocket.send(), DatagramSocketImpl.receive(), DatagramSocketImpl.send(), MulticastSocket.send()

21.4 java.awt.image.DirectColorModel (JDK 1.0)

This class is a `ColorModel` that extracts the red, green, blue, and alpha values directly from the bits of the pixel. The arguments to the constructor methods specify the number of significant bits in the pixel and the mask used to extract each of the color components from the pixel. The default RGB color model is a `DirectColorModel`.

You should not need to instantiate any kind of `ColorModel` object unless you are processing image data that does not use the standard RGB color format.

```
public class DirectColorModel extends ColorModel {
    // Public Constructors
            public DirectColorModel(int bits, int rmask, int gmask, int bmask);
            public DirectColorModel(int bits, int rmask, int gmask, int bmask, int 
amask);
    // Public Instance Methods
            public final int getAlpha(int pixel);  // Defines ColorModel
            public final int getAlphaMask();
            public final int getBlue(int pixel);  // Defines ColorModel
            public final int getBlueMask();
            public final int getGreen(int pixel);  // Defines ColorModel
            public final int getGreenMask();
            public final int getRGB(int pixel);  // Overrides ColorModel
            public final int getRed(int pixel);  // Defines ColorModel
            public final int getRedMask();
}
```

Hierarchy:

```
Object->ColorModel->DirectColorModel
```

21.10 java.awt.image.IndexColorModel (JDK 1.0)

This class is a `ColorModel` that determines the red, green, blue, and alpha values for a pixel by using the pixel value as an index into colormap arrays. If no array of alpha values is specified, all pixels are considered fully opaque, except for one optionally specified reserved value that is fully transparent. This color model is useful when working with image data that is defined in terms of a color map.

You should not need to instantiate any kind of `ColorModel` object unless you are processing image data that does not use the standard RGB color format.

```
public class IndexColorModel extends ColorModel {
    // Public Constructors
            public IndexColorModel(int bits, int size, byte[] r, byte[] g, byte[] b);
            public IndexColorModel(int bits, int size, byte[] r, byte[] g, byte[] b, 
int trans);
            public IndexColorModel(int bits, int size, byte[] r, byte[] g, byte[] b, 
byte[] a);
            public IndexColorModel(int bits, int size, byte[] cmap, int start, 
boolean hasalpha);
            public IndexColorModel(int bits, int size, byte[] cmap, int start, 
boolean hasalpha, int trans);
    // Public Instance Methods
            public final int getAlpha(int pixel);  // Defines ColorModel
            public final void getAlphas(byte[] a);
            public final int getBlue(int pixel);  // Defines ColorModel
            public final void getBlues(byte[] b);
            public final int getGreen(int pixel);  // Defines ColorModel
            public final void getGreens(byte[] g);
            public final int getMapSize();
            public final int getRGB(int pixel);  // Overrides ColorModel
            public final int getRed(int pixel);  // Defines ColorModel
            public final void getReds(byte[] r);
            public final int getTransparentPixel();
}
```

Hierarchy:

`Object->ColorModel->IndexColorModel`

Passed To:

```
RGBImageFilter.filterIndexColorModel()
```

Returned By:

```
RGBImageFilter.filterIndexColorModel()
```

29.11 java.text.FieldPosition (JDK 1.1)

FieldPosition objects are optionally passed to the format() methods of the Format class and its subclasses to return additional information about the formatting that has been performed. The getBeginIndex() and getEndIndex() methods of this class are used to return the starting and ending character positions of some field of the formatted string. The integer value passed to the FieldPosition() constructor specifies what field of the returned string should have its bounds returned. The NumberFormat and DateFormat classes define various constants (which end with the string _FIELD) that can be used here. Typically, this bounds information is useful for aligning formatted strings in columns--for example, aligning the decimal points in a column of numbers.

```
public class FieldPosition extends Object {
    // Public Constructor
            public FieldPosition(int field);
    // Public Instance Methods
            public int getBeginIndex();
            public int getEndIndex();
            public int getField();
}
```

Passed To:

ChoiceFormat.format(), DateFormat.format(), DecimalFormat.format(), Format.format(), MessageFormat.format(), NumberFormat.format(), SimpleDateFormat.format()

18.55 java.awt.Shape (JDK 1.1)

This interface encapsulates some very generic information about geometric shapes. All `Shape` objects must have a bounding box--i.e., a rectangle that completely encloses the represented shape.

When the forthcoming Java2D API is integrated with the AWT, this interface may be changed. For this reason, Java 1.1 applications can use this interface, but should not implement it in their own classes.

```
public abstract interface Shape {
    // Public Instance Methods
            public abstract Rectangle getBounds();
}
```

Implemented By:

`Polygon, Rectangle`

Passed To:

`Graphics.setClip()`

Returned By:

`Graphics.getClip()`

30.20 java.util.ResourceBundle (JDK 1.1)

This abstract class allows subclasses to define sets of localized resources which can then be dynamically loaded as needed by internationalized programs. Such resources may include user-visible text and images that appear in an application, and even more complex things such as `Menu` objects.

Use `getBundle()` to load a `ResourceBundle` subclass that is appropriate for the default or the specified locale. Use `getObject()`, `getString()`, and `getStringArray()` to look up a named resource in a bundle. To define a bundle, provide implementations of `handleGetObject()` and `getKeys()`. It is often easier, however, to subclass `ListResourceBundle`, or to provide a property file that is used by `PropertyResourceBundle`. The name of any localized `ResourceBundle` class you define should include the locale language code, and, optionally, the locale country code.

```
public abstract class ResourceBundle extends Object {
    // Default Constructor: public ResourceBundle()
    // Protected Instance Variables
            protected ResourceBundle parent;
    // Class Methods
            public static final ResourceBundle getBundle(String baseName) throws 
MissingResourceException;
            public static final ResourceBundle getBundle(String baseName, Locale 
locale);
    // Public Instance Methods
            public abstract Enumeration getKeys();
            public final Object getObject(String key) throws 
MissingResourceException;
            public final String getString(String key) throws 
MissingResourceException;
            public final String[] getStringArray(String key) throws 
MissingResourceException;
    // Protected Instance Methods
            protected abstract Object handleGetObject(String key) throws 
MissingResourceException;
            protected void setParent(ResourceBundle parent);
}
```

Extended By:

TextAreaPeer, TextFieldPeer

31.2 java.util.zip.CheckedInputStream (JDK 1.1)

This class is a subclass of `java.io.FilterInputStream`; it allows a stream to be read and a checksum computed on its contents at the same time. This is useful when you want to check the integrity of a stream of data against a published checksum value.

To create a `CheckedInputStream`, you must specify both the stream that it should read and also a `Checksum` object, such as `CRC32`, that implements the particular checksum algorithm you desire. The `read()` and `skip()` methods are the same as those of other input streams. As bytes are read, they are incorporated into the checksum that is being computed. Note that the `getChecksum()` method does not return the checksum value itself, but rather the `Checksum` object. You must call the `getValue()` method of this object to obtain the checksum value.

```
public class CheckedInputStream extends FilterInputStream {
    // Public Constructor
            public CheckedInputStream(InputStream in, Checksum cksum);
    // Public Instance Methods
            public Checksum getChecksum();
            public int read() throws IOException;  // Overrides FilterInputStream
            public int read(byte[] buf, int off, int len) throws IOException;  //
Overrides FilterInputStream
            public long skip(long n) throws IOException;  // Overrides
FilterInputStream
}
```

Hierarchy:

Object->InputStream->FilterInputStream->CheckedInputStream

31.3 java.util.zip.CheckedOutputStream (JDK 1.1)

This class is a subclass of `java.io.FilterOutputStream` that allows data to be written to a stream and a checksum computed on that data at the same time.

To create a `CheckedOutputStream` you must specify the output stream that it is to write its data to, and you must also specify a `Checksum` object, such as an instance of `Adler32`, that implements the particular checksum algorithm you desire. The `write()` methods are similar to those of other `OutputStream` classes. The `getChecksum()` method returns the `Checksum` object. Note that you must call `getValue()` on this object in order to obtain the actual checksum value.

```
public class CheckedOutputStream extends FilterOutputStream {
    // Public Constructor
            public CheckedOutputStream(OutputStream out, Checksum cksum);
    // Public Instance Methods
            public Checksum getChecksum();
            public void write(int b) throws IOException;  // Overrides
FilterOutputStream
            public void write(byte[] b, int off, int len) throws IOException;  //
Overrides FilterOutputStream
}
```

Hierarchy:

Object->OutputStream->FilterOutputStream->CheckedOutputStream

30.13 java.util.MissingResourceException (JDK 1.1)

This exception signals that no `ResourceBundle` could be located for the desired locale, or that a named resource could not be found within a given `ResourceBundle`.

`getClassName()` returns the name of the `ResourceBundle` class in question, and `getKey()` returns the name of the resource that could not be located.

```
public class MissingResourceException extends RuntimeException {
    // Public Constructor
            public MissingResourceException(String s, String className, String key);
    // Public Instance Methods
            public String getClassName();
            public String getKey();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->MissingResourceException

Thrown By:

Locale.getISO3Country(), Locale.getISO3Language(), ResourceBundle.getBundle(), ResourceBundle.getObject(), ResourceBundle.getString(), ResourceBundle.getStringArray(), ResourceBundle.handleGetObject()

20.21 java.awt.event.MouseEvent (JDK 1.1)

An event of this type indicates that the user has moved the mouse or pressed one of the mouse buttons.

Call `getID()` to determine the specific type of mouse event that has occurred. This method returns one of the following seven constants, which corresponds to a method in either the `MouseListener` or `MouseMotionListener` interface.

`MOUSE_PRESSED`

The user has pressed a mouse button.

`MOUSE_RELEASED`

The user has released a mouse button.

`MOUSE_CLICKED`

The user has pressed and released a mouse button without any intervening mouse drag.

`MOUSE_DRAGGED`

The user has moved the mouse while holding a button down

`MOUSE_MOVED`

The user has moved the mouse without holding any buttons down.

`MOUSE_ENTERED`

The mouse pointer has entered the component. `MOUSE_EXITED`

The mouse pointer has left the component

Use `getX()` and `getY()` or `getPoint()` to obtain the coordinates of the mouse event. Use `translatePoint()` to modify these coordinates by a specified amount.

Use `getModifiers()` and other methods and constants inherited from `InputEvent` to determine the mouse button or keyboard modifiers that were down when the event occurred. See `InputEvent` for details. Note that mouse button modifiers are not reported for `MOUSE_RELEASED` events, since, technically, the mouse button in question is no longer pressed. This can be surprising.

Use `getComponent()`, inherited from `ComponentEvent`, to determine over which component the event occurred.

For mouse events of type `MOUSE_CLICKED`, `MOUSE_PRESSED`, or `MOUSE_RELEASED`, call `getClickCount()` to determine how many consecutive clicks have occurred.

If you are using popup menus, use `isPopupTrigger()` to test whether the current event represents the standard platform-dependent popup menu trigger event.

```
public class MouseEvent extends InputEvent {
    // Public Constructor
            public MouseEvent(Component source, int id, long when, int modifiers, int
x, int y,
            public MouseEvent'u'int clickCount, boolean popupTrigger);
    // Constants
            public static final int MOUSE_CLICKED;
            public static final int MOUSE_DRAGGED;
            public static final int MOUSE_ENTERED;
            public static final int MOUSE_EXITED;
            public static final int MOUSE_FIRST;
            public static final int MOUSE_LAST;
            public static final int MOUSE_MOVED;
            public static final int MOUSE_PRESSED;
            public static final int MOUSE_RELEASED;
    // Public Instance Methods
            public int getClickCount();
            public Point getPoint();
            public int getX();
            public int getY();
            public boolean isPopupTrigger();
            public String paramString();  // Overrides ComponentEvent
            public synchronized void translatePoint(int x, int y);
}
```

Hierarchy:

Object->EventObject(Serializable)->AWTEvent->ComponentEvent->InputEvent->MouseEvent
```

Passed To:

```
AWTEventMulticaster.mouseClicked(), AWTEventMulticaster.mouseDragged(),
AWTEventMulticaster.mouseEntered(), AWTEventMulticaster.mouseExited(),
AWTEventMulticaster.mouseMoved(), AWTEventMulticaster.mousePressed(),
AWTEventMulticaster.mouseReleased(), Component.processMouseEvent(),
Component.processMouseMotionEvent(), MouseAdapter.mouseClicked(),
MouseAdapter.mouseEntered(), MouseAdapter.mouseExited(), MouseAdapter.mousePressed(),
MouseAdapter.mouseReleased(), MouseListener.mouseClicked(),
MouseListener.mouseEntered(), MouseListener.mouseExited(),
MouseListener.mousePressed(), MouseListener.mouseReleased(),
MouseMotionAdapter.mouseDragged(), MouseMotionAdapter.mouseMoved(),
```

`MouseMotionListener.mouseDragged(), MouseMotionListener.mouseMoved()`

28.3 java.net.ContentHandler (JDK 1.0)

This abstract class defines a method that reads data from a `URLConnection` and returns an object representing that data. Each subclass that implements this method is responsible for handling a different type of content (i.e., a different MIME type). Applications never create `ContentHandler` objects directly--they are created, when necessary, by the registered `ContentHandlerFactory` object. Applications should also never call `ContentHandler` methods directly--they should call `URL.getContent()` or `URLConnection.getContent()` instead. You only need to subclass `ContentHandler` if you are writing a Web browser or similar application that needs to parse and understand some new content type.

```
public abstract class ContentHandler extends Object {
    // Default Constructor: public ContentHandler()
    // Public Instance Methods
            public abstract Object getContent(URLConnection urlc) throws IOException;
}
```

Returned By:

ContentHandlerFactory.createContentHandler()

30.11 java.util.ListResourceBundle (JDK 1.1)

This abstract class provides a simple way to define a `ResourceBundle`. You may find it easier to subclass `ListResourceBundle` than to subclass `ResourceBundle` directly.

`ListResourceBundle` provides implementations for the abstract `handleGetObject()` and `getKeys()` methods defined by `ResourceBundle`, and it adds its own abstract `getContents()` method that your subclasses must override. `getContents()` returns an `Object[][]`--an array of arrays of objects. This array can have any number of elements. Each element of this array must itself be an array with two elements: the first element of each subarray should be a `String` that specifies the name of a resource, and the corresponding second element should be the value of that resource--this value can be an `Object` of any desired type.

See also `ResourceBundle` and `PropertyResourceBundle`.

```
public abstract class ListResourceBundle extends ResourceBundle {
    // Default Constructor: public ListResourceBundle()
    // Public Instance Methods
            public Enumeration getKeys();  // Defines ResourceBundle
            public final Object handleGetObject(String key);  // Defines 
ResourceBundle
    // Protected Instance Methods
            protected abstract Object[][] getContents();
}
```

Hierarchy:

Object->ResourceBundle->ListResourceBundle

28.8 java.net.FileNameMap (JDK 1.1)

This interface defines a single method that is called to obtain the MIME type of a file based on the name of a file. The `fileNameMap` field of the `URLConnection` class refers to an object that implements this interface. The filename-to-file-type map it implements is used by the static `URLConnection.guessContentTypeFromName()` method.

```
public abstract interface FileNameMap {
    // Public Instance Methods
            public abstract String getContentTypeFor(String fileName);
}
```

Type Of:

URLConnection.fileNameMap

18.11 java.awt.CheckboxGroup (JDK 1.0)

A `CheckboxGroup` object enforces mutual exclusion (also known as "radio button" behavior) among any number of `Checkbox` buttons. A `Checkbox` component can specify a `CheckboxGroup` object when created or with `Checkbox.setCheckboxGroup()`. If a `Checkbox` with a given `CheckboxGroup` object is selected, then the `CheckboxGroup` ensures that the previously selected `Checkbox` becomes unselected.

```
public class CheckboxGroup extends Object implements Serializable {
    // Public Constructor
            public CheckboxGroup();
    // Public Instance Methods
        #   public Checkbox getCurrent();
        1.1 public Checkbox getSelectedCheckbox();
        #   public synchronized void setCurrent(Checkbox box);
        1.1 public synchronized void setSelectedCheckbox(Checkbox box);
            public String toString();  // Overrides Object
}
```

Passed To:

`Checkbox(), Checkbox.setCheckboxGroup(), CheckboxPeer.setCheckboxGroup()`

Returned By:

`Checkbox.getCheckboxGroup()`

java.awt.Checkbox (JDK 1.0) BOOK INDEX java.awt.CheckboxMenuItem (JDK 1.0)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

29.15 java.text.ParseException (JDK 1.1)

This exception signals that a string had an incorrect format and could not be parsed. It is typically thrown by the `parse()` or `parseObject()` methods of `Format` and its subclasses, but is also thrown by certain methods in the `java.text` package that are passed patterns or other rules in string form. The `getErrorOffset()` method of this class returns the character position at which the parsing error occurred in the offending string.

```
public class ParseException extends Exception {
    // Public Constructor
            public ParseException(String s, int errorOffset);
    // Public Instance Methods
            public int getErrorOffset();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->ParseException

Thrown By:

DateFormat.parse(), Format.parseObject(), MessageFormat.parse(), NumberFormat.parse(), RuleBasedCollator()

25.20 java.lang.ExceptionInInitializerError (JDK 1.1)

This error is thrown by the Java Virtual Machine when an exception occurs in the static initializer of a class. You can use the `getException()` method to obtain the `Throwable` object that was thrown from the initializer.

```
public class ExceptionInInitializerError extends LinkageError {
    // Public Constructors
            public ExceptionInInitializerError();
            public ExceptionInInitializerError(Throwable thrown);
            public ExceptionInInitializerError(String s);
    // Public Instance Methods
            public Throwable getException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->ExceptionInInitializerError

18.43 java.awt.MenuContainer (JDK 1.0)

This interface defines the methods necessary for `MenuContainer` types such as the `Menu`, `Frame`, and `MenuBar` objects. Unless you implement new menu-like components, you never need to use it.

```
public abstract interface MenuContainer {
    // Public Instance Methods
            public abstract Font getFont();
            public abstract boolean postEvent(Event evt);
            public abstract void remove(MenuComponent comp);
}
```

Implemented By:

`Component, Frame, Menu, MenuBar`

Returned By:

`MenuComponent.getParent()`

29.16 java.text.ParsePosition (JDK 1.1)

`ParsePosition` objects are passed to the `parse()` and `parseObject()` methods of `Format` and its subclasses. The `ParsePosition` class represents the position in a string at which parsing should begin or at which parsing stopped. Before calling a `parse()` method, you can specify the starting position of parsing by passing the desired index to the `ParsePosition()` constructor, or by calling the `setIndex()` of an existing `ParsePosition` object. When `parse()` returns, you can determine where parsing ended by calling `getIndex()`. When parsing multiple objects or values from a string, a single `ParsePosition` object can be used sequentially.

```
public class ParsePosition extends Object {
    // Public Constructor
            public ParsePosition(int index);
    // Public Instance Methods
            public int getIndex();
            public void setIndex(int index);
}
```

Passed To:

ChoiceFormat.parse(), DateFormat.parse(), DateFormat.parseObject(), DecimalFormat.parse(), Format.parseObject(), MessageFormat.parse(), MessageFormat.parseObject(), NumberFormat.parse(), NumberFormat.parseObject(), SimpleDateFormat.parse()

23.7 java.beans.IndexedPropertyDescriptor (JDK 1.1)

An `IndexedPropertyDescriptor` object is a type of `PropertyDescriptor` that describes a Java bean property that is (or behaves like) an array. The `BeanInfo` class for a Java bean optionally creates and initializes `IndexedPropertyDescriptor` objects to describe the indexed properties that the bean supports. Typically, only application builders and similar tools use the descriptor objects to obtain indexed property description information.

You create an `IndexedPropertyDescriptor` by specifying the name of the indexed property and the `Class` object for the bean. If you have not followed the standard "design patterns" for accessor method naming, you may also specify the accessor methods for the property, either as method names or as `java.lang.reflect.Method` objects. Once you have created an `IndexedPropertyDescriptor` object, you can use the methods of `PropertyDescriptor` and `FeatureDescriptor` to provide additional information about the indexed property.

```
public class IndexedPropertyDescriptor extends PropertyDescriptor {
    // Public Constructors
            public IndexedPropertyDescriptor(String propertyName, Class beanClass)
throws IntrospectionException;
            public IndexedPropertyDescriptor(String propertyName, Class beanClass,
String getterName,
            public IndexedPropertyDescriptor'u'String setterName, String
indexedGetterName,
            public IndexedPropertyDescriptor'u'String indexedSetterName) throws
IntrospectionException;
            public IndexedPropertyDescriptor(String propertyName, Method getter,
Method setter, Method indexedGetter,
            public IndexedPropertyDescriptor'u'Method indexedSetter) throws
IntrospectionException;
    // Public Instance Methods
            public Class getIndexedPropertyType();
            public Method getIndexedReadMethod();
            public Method getIndexedWriteMethod();
}
```

Hierarchy:

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

23.3 java.beans.Beans (JDK 1.1)

The `Beans` class is never meant to be instantiated; its static methods provide miscellaneous JavaBeans features.

The `instantiate()` method creates an instance of a bean. The specified bean name represents either a serialized bean file or a bean class file; it is interpreted relative to the specified `ClassLoader` object.

The `setDesignTime()` and `isDesignTime()` methods are used to set and query a flag that indicates whether beans are being used in an application builder environment. Similarly, `setGuiAvailable()` and `isGuiAvailable()` set and query a flag that indicates whether the Java Virtual Machine is running in an environment in which a GUI is available. (Note that untrusted applet code cannot call `setDesignTime()` or `setGuiAvailable()`.)

The `isInstanceOf()` method is a replacement for the Java `instanceof` operator for use with beans. Currently, it behaves just like `instanceof`, but in the future it may work with beans that consist of a set of Java objects, each of which provides a different "view" of a bean. Similarly, the `getInstanceOf()` method is a replacement for the Java cast operator. It converts a bean to a superclass or interface type. Currently, it behaves just like a cast, but you should use it for future compatibility with multiclass beans.

```
public class Beans extends Object {
    // Default Constructor: public Beans()
    // Class Methods
            public static Object getInstanceOf(Object bean, Class targetType);
            public static Object instantiate(ClassLoader cls, String beanName)
            public static Object instantiate'u'throws IOException,
ClassNotFoundException;
            public static boolean isDesignTime();
            public static boolean isGuiAvailable();
            public static boolean isInstanceOf(Object bean, Class targetType);
            public static void setDesignTime(boolean isDesignTime) throws
SecurityException;
            public static void setGuiAvailable(boolean isGuiAvailable) throws
SecurityException;
}
```

28.12 java.net.MulticastSocket (JDK 1.1)

This subclass of `DatagramSocket` is used to send and receive multicast UDP packets. It extends `DatagramSocket` by adding `joinGroup()` and `leaveGroup()` methods to join and leave multicast groups. The IP address specified to these methods should be a valid multicast address in the range of 224.0.0.1 to 239.255.255.255. Note that you do not have to join a group to send a packet to a multicast address, but you must join the group to receive packets sent to that address.

`MulticastSocket` defines a variant `send()` method that allows you to specify a time-to-live (TTL) value for the packet you send. This value specifies the number of network "hops" the packet may travel before it expires. You can also set a default TTL for all packets sent though a `MulticastSocket` with `setTTL()`.

Note that untrusted applets are not allowed to use multicast sockets.

```
public class MulticastSocket extends DatagramSocket {
    // Public Constructors
            public MulticastSocket() throws IOException;
            public MulticastSocket(int port) throws IOException;
    // Public Instance Methods
            public InetAddress getInterface() throws SocketException;
            public byte getTTL() throws IOException;
            public void joinGroup(InetAddress mcastaddr) throws IOException;
            public void leaveGroup(InetAddress mcastaddr) throws IOException;
            public synchronized void send(DatagramPacket p, byte ttl) throws
IOException;
            public void setInterface(InetAddress inf) throws SocketException;
            public void setTTL(byte ttl) throws IOException;
}
```

Hierarchy:

Object->DatagramSocket->MulticastSocket

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

30.18 java.util.PropertyResourceBundle (JDK 1.1)

This class is a concrete subclass of `ResourceBundle`. It reads a `Properties` file from a specified `InputStream` and implements the `ResourceBundle` API for looking up named resources from the resulting `Properties` object.

A `Properties` file contains lines of the form:

`name=value`

Each such line defines a named property with the specified `String` value.

Although you can instantiate a `PropertyResourceBundle` yourself, it is more common to simply define a `Properties` file, and then allow `ResourceBundle.getBundle()` to look up that file and return the necessary `PropertyResourceBundle` object.

See also `Properties` and `ResourceBundle`.

```
public class PropertyResourceBundle extends ResourceBundle {
    // Public Constructor
            public PropertyResourceBundle(InputStream stream) throws IOException;
    // Public Instance Methods
            public Enumeration getKeys();  // Defines ResourceBundle
            public Object handleGetObject(String key);  // Defines ResourceBundle
}
```

Hierarchy:

Object->ResourceBundle->PropertyResourceBundle

24.35 java.io.LineNumberReader (JDK 1.1)

This class is a character input stream that keeps track of the number of lines of text that have been read from it. It supports the usual `Reader` methods, and also the `readLine()` method introduced by its superclass. In addition to these methods, you can call `getLineNumber()` to query the number of lines set so far. You can also call `setLineNumber()` to set the line number for the current line. Subsequent lines are numbered sequentially from this specified starting point.

This class is a character-stream analog to `LineNumberInputStream`, which has been deprecated in Java 1.1.

```
public class LineNumberReader extends BufferedReader {
    // Public Constructors
            public LineNumberReader(Reader in);
            public LineNumberReader(Reader in, int sz);
    // Public Instance Methods
            public int getLineNumber();
            public void mark(int readAheadLimit) throws IOException;  // Overrides 
BufferedReader
            public int read() throws IOException;  // Overrides BufferedReader
            public int read(char[] cbuf, int off, int len) throws IOException;  // 
Overrides BufferedReader
            public String readLine() throws IOException;  // Overrides BufferedReader
            public void reset() throws IOException;  // Overrides BufferedReader
            public void setLineNumber(int lineNumber);
            public long skip(long n) throws IOException;  // Overrides BufferedReader
}
```

Hierarchy:

Object->Reader->BufferedReader->LineNumberReader

23.10 java.beans.MethodDescriptor (JDK 1.1)

A `MethodDescriptor` object is a type of `FeatureDescriptor` that describes a method supported by a Java bean. The `BeanInfo` class for a Java bean optionally creates `MethodDescriptor` objects that describe the methods the bean exports. While a `BeanInfo` class creates and initializes `MethodDescriptor` objects, it is typically only application builders and similar tools that use these objects to obtain information about the methods supported by a bean.

To create a `MethodDescriptor`, you must specify the `java.lang.reflect.Method` object for the method, and optionally specify an array of `ParameterDescriptor` objects that describe the parameters of the method. Once you have created a `MethodDescriptor` object, you can use `FeatureDescriptor` methods to provide additional information about each method.

```
public class MethodDescriptor extends FeatureDescriptor {
    // Public Constructors
            public MethodDescriptor(Method method);
            public MethodDescriptor(Method method, ParameterDescriptor[] 
parameterDescriptors);
    // Public Instance Methods
            public Method getMethod();
            public ParameterDescriptor[] getParameterDescriptors();
}
```

Hierarchy:

Object->FeatureDescriptor->MethodDescriptor

        1.1  public abstract Dimension getPreferredSize(int columns);
            public abstract Dimension minimumSize(int cols);
            public abstract Dimension preferredSize(int cols);
        1.1  public abstract void setEchoChar(char echoChar);
            public abstract void setEchoCharacter(char c);
}
```

Hierarchy:

(TextFieldPeer(TextComponentPeer(ComponentPeer)))

Returned By:

Toolkit.createTextField()

23.12 java.beans.PropertyChangeEvent (JDK 1.1)

The `PropertyChangeEvent` class is a subclass of `java.util.EventObject`. An event of this type is sent to interested `PropertyChangeListener` objects whenever a Java bean changes a "bound" property, or whenever a `PropertyEditor` or `Customizer` changes a property value. A `PropertyChangeEvent` is also sent to registered `VetoableChangeListener` objects when a bean attempts to change the value of a "constrained" property.

When creating a `PropertyChangeEvent`, you normally specify the bean that generated the event, the programmatic (locale-independent) name of the property that changed, and the old and new values of the property. If the values cannot be determined, `null` should be passed instead. If the event is a notification that more than one property value changed, the name should also be `null`.

While Java beans must generate and send `PropertyChangeEvent` objects, it is typically only application builders and similar tools that are interested in receiving them.

```
public class PropertyChangeEvent extends EventObject {
    // Public Constructor
            public PropertyChangeEvent(Object source, String propertyName, Object 
oldValue, Object newValue);
    // Public Instance Methods
            public Object getNewValue();
            public Object getOldValue();
            public Object getPropagationId();
            public String getPropertyName();
            public void setPropagationId(Object propagationId);
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18.21 java.awt.EventQueue (JDK 1.1)

This class implements an event queue for AWT events in Java 1.1. When an `EventQueue` is created, a new thread is automatically created and started to remove events from the front of the queue and dispatch them to the appropriate component. It is this thread, created by the `EventQueue`, that notifies event listeners and executes most of the code in a typical GUI-driven application.

An application can create and use its own private `EventQueue`, but all AWT events are placed on and dispatched from a single system `EventQueue`. Use the `getSystemEventQueue()` method of the `Toolkit` class to get the system `EventQueue` object.

`getNextEvent()` removes and returns the event at the front of the queue. It blocks if there are no events in the queue. `peekEvent()` returns the event at the front of the queue without removing it from the queue. Passed an optional `AWTEvent id` field, it returns the first event of the specified type. Finally, `postEvent()` places a new event on the end of the event queue.

Most applications do not need to use the `EventQueue` class at all; they can simply rely on the system to dispatch events automatically.

```
public class EventQueue extends Object {
    // Public Constructor
            public EventQueue();
    // Public Instance Methods
            public synchronized AWTEvent getNextEvent() throws InterruptedException;
            public synchronized AWTEvent peekEvent();
            public synchronized AWTEvent peekEvent(int id);
            public synchronized void postEvent(AWTEvent theEvent);
}
```

Returned By:

`Toolkit.getSystemEventQueue(), Toolkit.getSystemEventQueueImpl()`

18.50 java.awt.PrintGraphics (JDK 1.1)

The `Graphics` object returned by the `getGraphics()` method of `PrintJob` always implements this `PrintGraphics` interface. You can use this fact to distinguish a `Graphics` object that draws to the screen from one that generates hardcopy. This is a useful thing to do in a `paint()` method when you want to generate hardcopy that differs somewhat from what is displayed on-screen.

The `getPrintJob()` method defined by this interface can also be used, of course, to return the `PrintJob` with which the `PrintGraphics` object is associated.

```
public abstract interface PrintGraphics {
    // Public Instance Methods
            public abstract PrintJob getPrintJob();
}
```

23.19 java.beans.PropertyVetoException (JDK 1.1)

The `PropertyVetoException` signals that a `VetoableChangeListener` that received a `PropertyChangeEvent` for a "constrained" property of a bean has vetoed that proposed change.

When this exception is received, the property in question should revert back to its original value, and any `VetoableChangeListener` objects that have already been notified of the property change must be re-notified to indicate that the property has reverted to its old value. The `VetoableChangeSupport` class handles this re-notification automatically and re-throws the `PropertyVetoException` to notify its caller that the change was rejected.

```
public class PropertyVetoException extends Exception {
    // Public Constructor
            public PropertyVetoException(String mess, PropertyChangeEvent evt);
    // Public Instance Methods
            public PropertyChangeEvent getPropertyChangeEvent();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->PropertyVetoException

Thrown By:

VetoableChangeListener.vetoableChange(), VetoableChangeSupport.fireVetoableChange()

23.15 java.beans.PropertyDescriptor (JDK 1.1)

A `PropertyDescriptor` object is a type of `FeatureDescriptor` that describes a single property of a Java bean. The `BeanInfo` class for a Java bean optionally creates and initializes `PropertyDescriptor` objects to describe the properties that the bean supports. Typically, only application builders and similar tools use the `get` and `is` methods to obtain this property description information.

You create a `PropertyDescriptor` by specifying the name of the property and the `Class` object for the bean. If you have not followed the standard "design patterns" for accessor method naming, you may also specify the accessor methods for the property. Once a `PropertyDescriptor` is created, the `setBound()` and `setConstrained()` methods allow you to specify whether the property is bound and/or constrained. `setPropertyEditorClass()` allows you to specify a specific property editor that should be used to edit the value of this property (this is useful, for example, when the property is an enumerated type with a specific list of supported values). The methods of the `FeatureDescriptor` superclass allow additional information about the property to be specified.

```
public class PropertyDescriptor extends FeatureDescriptor {
    // Public Constructors
            public PropertyDescriptor(String propertyName, Class beanClass) throws
IntrospectionException;
            public PropertyDescriptor(String propertyName, Class beanClass, String
getterName,
            public PropertyDescriptor'u'String setterName) throws
IntrospectionException;
            public PropertyDescriptor(String propertyName, Method getter, Method
setter) throws IntrospectionException;
    // Public Instance Methods
            public Class getPropertyEditorClass();
            public Class getPropertyType();
            public Method getReadMethod();
            public Method getWriteMethod();
            public boolean isBound();
            public boolean isConstrained();
            public void setBound(boolean bound);
            public void setConstrained(boolean constrained);
            public void setPropertyEditorClass(Class propertyEditorClass);
}
```

Hierarchy:

Object->FeatureDescriptor->PropertyDescriptor

Extended By:

IndexedPropertyDescriptor

Returned By:

BeanInfo.getPropertyDescriptors(), SimpleBeanInfo.getPropertyDescriptors()

30.8 java.util.EventObject (JDK 1.1)

`EventObject` serves as a superclass for all events objects used by the Java 1.1 AWT event model and the JavaBeans event model. This class defines a very generic type of event; it is extended by the more specific event classes in the `java.awt`, `java.awt.event`, and `java.beans` packages.

The only common feature shared by all events is a source object, which is the object that in some way "generated" the event. The source object is passed to the `EventObject()` constructor, and is returned by the `getSource()` method.

```
public class EventObject extends Object implements Serializable {
    // Public Constructor
            public EventObject(Object source);
    // Protected Instance Variables
            protected transient Object source;
    // Public Instance Methods
            public Object getSource();
            public String toString();  // Overrides Object
}
```

Extended By:

AWTEvent, PropertyChangeEvent

26.4 java.lang.reflect.InvocationTargetException (JDK 1.1)

An object of this class is thrown by `Method.invoke()` and `Constructor.newInstance()` when an exception is thrown by the method or constructor invoked through those methods. The `InvocationTargetException` class serves as a wrapper around the object that was thrown; that object can be retrieved with the `getTargetException()` method.

```
public class InvocationTargetException extends Exception {
    // Public Constructors
            public InvocationTargetException(Throwable target);
            public InvocationTargetException(Throwable target, String s);
    // Protected Constructor
            protected InvocationTargetException();
    // Public Instance Methods
            public Throwable getTargetException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->InvocationTargetException

Thrown By:

Constructor.newInstance(), Method.invoke()

19.4 java.awt.datatransfer.StringSelection (JDK 1.1)

This convenience class implements the `Transferable` and `ClipboardOwner` interfaces in order to make it very easy to transfer `String` values through the AWT data transfer mechanism. It is able to transfer `String` values using either the `DataFlavor.stringFlavor` or `DataFlavor.plainTextFlavor` data flavors.

To create a `StringSelection` object, simply pass the `String` you want to transfer to the `StringSelection()` constructor. You can then make the `StringSelection` available for transfer by passing it to the `setContents()` method of the `Clipboard`. You need never call the methods of `StringSelection` yourself.

```
public class StringSelection extends Object implements Transferable, ClipboardOwner {
    // Public Constructor
            public StringSelection(String data);
    // Public Instance Methods
            public synchronized Object getTransferData(DataFlavor flavor)
            public synchronized Object getTransferData'u'throws
UnsupportedFlavorException, IOException;
            public synchronized Object getTransferData'u'// From Transferable
            public synchronized DataFlavor[] getTransferDataFlavors();  // From
Transferable
            public boolean isDataFlavorSupported(DataFlavor flavor);  // From
Transferable
            public void lostOwnership(Clipboard clipboard, Transferable contents);
// From ClipboardOwner
}
```

19.5 java.awt.datatransfer.Transferable (JDK 1.1)

This interface defines the methods that a class must define if it is to act as the source object in a data transfer operation.

`getTransferDataFlavors()` should return an array of `DataFlavor` objects that specify the data types or formats in which the object can provide its data. The `DataFlavor` objects should be ordered from best format (most richly descriptive) to worst format.

`isDataFlavorSupported()` must return a boolean value indicating whether it can transfer data using a specified `DataFlavor`. Finally, `getTransferData()` must return an object that represents the data formatted as required by the specified `DataFlavor`.

`StringSelection` is a pre-defined class that implements the `Transferable` interface for the transfer of string data.

```
public abstract interface Transferable {
    // Public Instance Methods
            public abstract Object getTransferData(DataFlavor flavor) throws 
UnsupportedFlavorException, IOException;
            public abstract DataFlavor[] getTransferDataFlavors();
            public abstract boolean isDataFlavorSupported(DataFlavor flavor);
}
```

`Clipboard.setContents(), ClipboardOwner.lostOwnership(), StringSelection.lostOwnership()`

Returned By:

`Clipboard.getContents()`

Type Of:

`Clipboard.contents`

20.25 java.awt.event.PaintEvent (JDK 1.1)

An event of this type indicates that a component should have its `update()` method invoked. (The `update()` method typically, by default, invokes the `paint()` method.)

`PaintEvent` differs from the other event types in `java.awt.event` in that it does not have a corresponding `EventListener` interface. `PaintEvent` is essentially for internal use by the AWT redisplay framework, so your programs should not try to handle it the way they handle other events. Instead, applets and custom components should simply override their `paint()` and/or `update()` methods to redraw themselves appropriately. AWT automatically invokes `update()` (which typically invokes `paint()`) when a `PaintEvent` arrives.

Although you do not typically use the `PaintEvent`, redraw events are implemented through this class for simplicity, so that they are on equal footing with other event types, and so that advanced programs can manipulate them through the `EventQueue`.

```
public class PaintEvent extends ComponentEvent {
    // Public Constructor
            public PaintEvent(Component source, int id, Rectangle updateRect);
    // Constants
            public static final int PAINT;
            public static final int PAINT_FIRST;
            public static final int PAINT_LAST;
            public static final int UPDATE;
    // Public Instance Methods
            public Rectangle getUpdateRect();
            public String paramString();  // Overrides ComponentEvent
            public void setUpdateRect(Rectangle updateRect);
}
```

Hierarchy:

```
Object->EventObject(Serializable)->AWTEvent->ComponentEvent->PaintEvent
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

31.4 java.util.zip.Checksum (JDK 1.1)

This interface defines the methods required to compute a checksum on a stream of data. The checksum is computed based on the bytes of data supplied by the `update()` methods, and the current value of the checksum can be obtained at any time with the `getValue()` method. `reset()` resets the checksum to its default value--use this method before beginning a new stream of data.

Note that the checksum value computed by a `Checksum` object and returned through the `getValue()` method must fit into a `long` value. Therefore, this interface is not suitable for the cryptographic checksum algorithms used in cryptography and security.

The classes `CheckedInputStream` and `CheckedOutputStream` provide a higher-level API for computing a checksum on a stream of data.

```
public abstract interface Checksum {
    // Public Instance Methods
            public abstract long getValue();
            public abstract void reset();
            public abstract void update(int b);
            public abstract void update(byte[] b, int off, int len);
}
```

20.29 java.awt.event.WindowEvent (JDK 1.1)

An event of this type indicates that an important action has occurred for a `Window` object.

Call `getWindow()` to determine the `Window` object that is the source of this event. Call `getID()` to determine the specific type of event that has occurred. Each of the following seven constants corresponds to one of the methods of the `WindowListener` interface:

`WINDOW_OPENED`

This type indicates that the window has been created and opened; it is only delivered the first time that a window is opened.

`WINDOW_CLOSING`

This type indicates that the user has requested that the window be closed through the system menu, or through a close button on the window's border, or by invoking a platform-defined keystroke, such as **Alt-F4** in Windows. The application should respond to this event by calling `hide()` or `destroy()` on the `Window` object.

`WINDOW_CLOSED`

This event type is delivered after a window is closed by a call to `hide()` or `destroy()`.

`WINDOW_ICONIFIED`

This event type is delivered when the user iconifies the window.

`WINDOW_DEICONIFIED`

This event type is delivered when the user de-iconifies the window.

WINDOW_ACTIVATED

This event type is delivered when the window is activated--that is, when it is given the keyboard focus and becomes the "active" window.

WINDOW_DEACTIVATED

This event type is delivered when the window ceases to be the active window, typically when the user activates some other window.

```
public class WindowEvent extends ComponentEvent {
    // Public Constructor
            public WindowEvent(Window source, int id);
    // Constants
            public static final int WINDOW_ACTIVATED;
            public static final int WINDOW_CLOSED;
            public static final int WINDOW_CLOSING;
            public static final int WINDOW_DEACTIVATED;
            public static final int WINDOW_DEICONIFIED;
            public static final int WINDOW_FIRST;
            public static final int WINDOW_ICONIFIED;
            public static final int WINDOW_LAST;
            public static final int WINDOW_OPENED;
    // Public Instance Methods
            public Window getWindow();
            public String paramString();  // Overrides ComponentEvent
}
```

```

30.6 java.util.Enumeration (JDK 1.0)

This interface defines the methods necessary to enumerate, or iterate through, a set of values, such as the set of values contained in a hashtable or binary tree. It is particularly useful for data structures, like hashtables, for which elements cannot simply be looked up by index, as they can in arrays. An `Enumeration` is usually not instantiated directly, but instead is created by the object that is to have its values enumerated. A number of classes, such as `Vector` and `Hashtable`, have methods that return `Enumeration` objects.

To use an `Enumeration` object, you use its two methods in a loop: `hasMoreElements()` returns `true` if there are more values to be enumerated, and can be used to determine whether a loop should continue. Within a loop, a call to `nextElement()` returns a value from the enumeration. An `Enumeration` makes no guarantees about the order in which the values are returned. The values in an `Enumeration` may be iterated through only once--there is no way to reset it to the beginning.

```
public abstract interface Enumeration {
    // Public Instance Methods
            public abstract boolean hasMoreElements();
            public abstract Object nextElement();
}
```

19.2 java.awt.datatransfer.ClipboardOwner (JDK 1.1)

This interface defines the single method that an object that places data on a `Clipboard` must implement. This method is used to notify the object when its data on the clipboard is replaced by other, more recent, data. An object that places data on a clipboard must remain ready to satisfy requests for that data until `lostOwnership()` is called.

```
public abstract interface ClipboardOwner {
    // Public Instance Methods
            public abstract void lostOwnership(Clipboard clipboard, Transferable
contents);
}
```

Implemented By:

`StringSelection`

Passed To:

`Clipboard.setContents()`

Type Of:

`Clipboard.owner`

20.20 java.awt.event.MouseAdapter (JDK 1.1)

This class is a trivial implementation of `MouseListener`; it provides empty bodies for each of the methods of that interface. When you are not interested in all of these methods, it is often easier to subclass `MouseAdapter` than it is to implement `MouseListener` from scratch.

```
public abstract class MouseAdapter extends Object implements MouseListener {
    // Default Constructor: public MouseAdapter()
    // Public Instance Methods
            public void mouseClicked(MouseEvent e);  // From MouseListener
            public void mouseEntered(MouseEvent e);  // From MouseListener
            public void mouseExited(MouseEvent e);  // From MouseListener
            public void mousePressed(MouseEvent e);  // From MouseListener
            public void mouseReleased(MouseEvent e);  // From MouseListener
}
```

Hierarchy:

```
Object->MouseAdapter(MouseListener(EventListener))
```

20.22 java.awt.event.MouseListener (JDK 1.1)

This interface defines the methods that an object must implement to "listen" for mouse events on AWT components. When a `MouseEvent` occurs, an AWT component notifies its registered `MouseListener` objects (or `MouseMotionListener` objects if the event involves mouse motion) by invoking one of their methods.

An easy way to implement this interface is by subclassing the `MouseAdapter` class.

```
public abstract interface MouseListener extends EventListener {
    // Public Instance Methods
            public abstract void mouseClicked(MouseEvent e);
            public abstract void mouseEntered(MouseEvent e);
            public abstract void mouseExited(MouseEvent e);
            public abstract void mousePressed(MouseEvent e);
            public abstract void mouseReleased(MouseEvent e);
}
```

Implemented By:

`AWTEventMulticaster, MouseAdapter`

Passed To:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove(), Component.addMouseListener(), Component.removeMouseListener()`

Returned By:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove()`

20.23 java.awt.event.MouseMotionAdapter (JDK 1.1)

This class is a trivial implementation of `MouseMotionListener`; it provides empty bodies for each of the methods of that interface. When you are not interested in all of these methods, it is often easier to subclass `MouseMotionAdapter` than it is to implement `MouseMotionListener` from scratch.

```
public abstract class MouseMotionAdapter extends Object implements
MouseMotionListener {
    // Default Constructor: public MouseMotionAdapter()
    // Public Instance Methods
            public void mouseDragged(MouseEvent e);  // From MouseMotionListener
            public void mouseMoved(MouseEvent e);  // From MouseMotionListener
}
```

Hierarchy:

```
Object->MouseMotionAdapter(MouseMotionListener(EventListener))
```

20.24 java.awt.event.MouseMotionListener (JDK 1.1)

This interface defines the methods that an object must implement to "listen" for mouse motion events on AWT components. When a `MouseEvent` occurs involving a mouse drag or mouse motion with no buttons down, an AWT component notifies its registered `MouseMotionListener` objects by invoking one of their methods.

An easy way to implement this is by subclassing the `MouseMotionAdapter` class.

```
public abstract interface MouseMotionListener extends EventListener {
    // Public Instance Methods
            public abstract void mouseDragged(MouseEvent e);
            public abstract void mouseMoved(MouseEvent e);
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

30.19 java.util.Random (JDK 1.0)

This class implements a pseudo-random number generator. `nextDouble()` and `nextFloat()` return a value between 0.0 and 1.0. `nextLong()` and `nextInt()` return `long` and `int` values distributed across the range of those data types. `nextGaussian()` returns pseudo-random values with a Gaussian distribution--the mean of the values is 0.0, and the standard deviation is 1.0. You can use the `setSeed()` method or the optional constructor argument to initialize the pseudo-random number generator with some variable seed value other than the current time (the default), or with a constant to ensure a repeatable sequence of pseudo-randomness.

```
public class Random extends Object implements Serializable {
    // Public Constructors
            public Random();
            public Random(long seed);
    // Public Instance Methods
        1.1public void nextBytes(byte[] bytes);
            public double nextDouble();
            public float nextFloat();
            public synchronized double nextGaussian();
            public int nextInt();
            public long nextLong();
            public synchronized void setSeed(long seed);
    // Protected Instance Methods
        1.1protected synchronized int next(int bits);
}
```

Passed To:

BigInteger()

29.4 java.text.CollationElementIterator (JDK 1.1)

A `CollationElementIterator` object is returned by the `getCollationElementIterator()` method of the `RuleBasedCollator` object. The purpose of this class is to allow a program to iterate (with the `next()` method) through the characters of a string, returning ordering values for each of the "collation keys" in the string. Note that collation keys are not exactly the same thing as characters. In the traditional Spanish collation order, for example, the two-character sequence "ch" is treated as a single collation key that comes alphabetically between the letters "c" and "d."

The value returned by the `next()` method is the collation order of the next collation key in the string. This numeric value can be directly compared to the value returned by `next()` for other `CollationElementIterator` objects. The value returned by `next()` can also be decomposed into primary, secondary, and tertiary ordering values with the static methods of this class.

This class is used by `RuleBasedCollator` to implement its `compare()` method, and to create `CollationKey` objects. Few applications ever need to use it directly.

```
public final class CollationElementIterator extends Object {
    // No Constructor
    // Constants
            public static final int NULLORDER;
    // Class Methods
            public static final int primaryOrder(int order);
            public static final short secondaryOrder(int order);
            public static final short tertiaryOrder(int order);
    // Public Instance Methods
            public int next();
            public void reset();
}
```

Returned By:

RuleBasedCollator.getCollationElementIterator()

20.26 java.awt.event.TextEvent (JDK 1.1)

An event of this type indicates that the user has edited the text value that appears in a `TextField`, `TextArea`, or other `TextComponent`. This event is triggered by any change to the displayed text. Note that this is not the same as the `ActionEvent` sent by the `TextField` object when the user edits the text and strikes the **Return** key.

Use the inherited `getSource()` to determine the object that was the source of this event. You have to cast that object to its `TextComponent` type. Call `getID()` to determine the type of a `TextEvent`. The standard AWT components always generate text events of type `TEXT_VALUE_CHANGED`.

```
public class TextEvent extends AWTEvent {
    // Public Constructor
            public TextEvent(Object source, int id);
    // Constants
            public static final int TEXT_FIRST;
            public static final int TEXT_LAST;
            public static final int TEXT_VALUE_CHANGED;
    // Public Instance Methods
            public String paramString();  // Overrides AWTEvent
}
```

Hierarchy:

`Object->EventObject(Serializable)->AWTEvent->TextEvent`

Passed To:

`AWTEventMulticaster.textValueChanged()`, `TextComponent.processTextEvent()`, `TextListener.textValueChanged()`

23.13 java.beans.PropertyChangeListener (JDK 1.1)

This interface is an extension of java.util.EventListener and defines the method that a class must implement in order to be notified when property changes occur. A PropertyChangeEvent is sent out to all registered PropertyChangeListener objects whenever a bean changes one of its "bound" properties, or whenever a PropertyEditor or Customizer changes the value of a property.

```
public abstract interface PropertyChangeListener extends EventListener {
    // Public Instance Methods
            public abstract void propertyChange(PropertyChangeEvent evt);
}
```

Passed To:

Customizer.addPropertyChangeListener(), Customizer.removePropertyChangeListener(), PropertyChangeSupport.addPropertyChangeListener(), PropertyChangeSupport.removePropertyChangeListener(), PropertyEditor.addPropertyChangeListener(), PropertyEditor.removePropertyChangeListener(), PropertyEditorSupport.addPropertyChangeListener(), PropertyEditorSupport.removePropertyChangeListener()

24.11 java.io.DataInputStream (JDK 1.0)

This class is a type of `FilterInputStream` that allows you to read binary representations of Java primitive data types in a portable way. Create a `DataInputStream` by specifying the `InputStream` that is to be filtered in the call to the constructor.

Many of this class's methods read and return a single Java primitive type, in binary format, from the stream. `readUnsignedByte()` and `readUnsignedShort()` read unsigned values and return them as `int` values, since unsigned `byte` and `short` types are not supported in Java. `read()` reads data into an array of bytes, blocking until at least some data are available. By contrast, `readFully()` reads data into an array of bytes, but blocks until all of the requested data become available. `skipBytes()` blocks until the specified number of bytes have been read and discarded.

`readLine()` reads characters from the stream until it encounters a newline, a carriage return, or a newline carriage return pair. The returned string is not terminated with a newline or carriage return. This method is deprecated in Java 1.1; see `BufferedReader` for an alternative. `readUTF()` reads a string of Unicode text encoded in a slightly modified version of the UTF-8 "transformation format." UTF-8 is an ASCII-compatible encoding of Unicode characters that is often used for the transmission and storage of Unicode text. This class uses a modified UTF-8 encoding that never contains embedded null characters.

`DataInputStream` only reads primitive Java types. Use `ObjectInputStream` to read object values.

```
public class DataInputStream extends FilterInputStream implements DataInput {
    // Public Constructor
            public DataInputStream(InputStream in);
    // Class Methods
            public static final String readUTF(DataInput in) throws IOException;
    // Public Instance Methods
            public final int read(byte[] b) throws IOException;  // Overrides
FilterInputStream
            public final int read(byte[] b, int off, int len) throws IOException;  //
Overrides FilterInputStream
            public final boolean readBoolean() throws IOException;  // From DataInput
            public final byte readByte() throws IOException;  // From DataInput
            public final char readChar() throws IOException;  // From DataInput
            public final double readDouble() throws IOException;  // From DataInput
            public final float readFloat() throws IOException;  // From DataInput
            public final void readFully(byte[] b) throws IOException;  // From
DataInput
            public final void readFully(byte[] b, int off, int len) throws
IOException;  // From DataInput
            public final int readInt() throws IOException;  // From DataInput
```

```
        #   public final String readLine() throws IOException;  // From DataInput
            public final long readLong() throws IOException;  // From DataInput
            public final short readShort() throws IOException;  // From DataInput
            public final String readUTF() throws IOException;  // From DataInput
            public final int readUnsignedByte() throws IOException;  // From 
DataInput
            public final int readUnsignedShort() throws IOException;  // From 
DataInput
            public final int skipBytes(int n) throws IOException;  // From DataInput
}
```

Hierarchy:

Object->InputStream->FilterInputStream->DataInputStream(DataInput)

24.10 java.io.DataInput (JDK 1.0)

This interface defines the methods required for streams that can read Java primitive data types in a machine-independent binary format. It is implemented by `DataInputStream` and `RandomAccessFile`. See `DataInputStream` for more information on the methods.

```
public abstract interface DataInput {
    // Public Instance Methods
            public abstract boolean readBoolean() throws IOException;
            public abstract byte readByte() throws IOException;
            public abstract char readChar() throws IOException;
            public abstract double readDouble() throws IOException;
            public abstract float readFloat() throws IOException;
            public abstract void readFully(byte[] b) throws IOException;
            public abstract void readFully(byte[] b, int off, int len) throws
IOException;
            public abstract int readInt() throws IOException;
            public abstract String readLine() throws IOException;
            public abstract long readLong() throws IOException;
            public abstract short readShort() throws IOException;
            public abstract String readUTF() throws IOException;
            public abstract int readUnsignedByte() throws IOException;
            public abstract int readUnsignedShort() throws IOException;
            public abstract int skipBytes(int n) throws IOException;
}
```

Extended By:

ObjectInput

Implemented By:

DataInputStream, RandomAccessFile

Passed To:

DataInputStream.readUTF()

24.15 java.io.Externalizable (JDK 1.1)

This interface defines the methods that must be implemented by an object that wants complete control over the way it is serialized. The `writeExternal()` and `readExternal()` methods should be implemented to write and read object data in some arbitrary format, using the methods of the `DataOutput` and `DataInput` objects. `Externalizable` objects must serialize their own fields, and are also responsible for serializing the fields of their superclasses.

Most objects do not need to define a custom output format and can use the `Serializable` interface instead of `Externalizable` for serialization.

```
public abstract interface Externalizable extends Serializable {
    // Public Instance Methods
            public abstract void readExternal(ObjectInput in) throws IOException, 
ClassNotFoundException;
            public abstract void writeExternal(ObjectOutput out) throws IOException;
}
```

25.50 java.lang.Runnable (JDK 1.0)

This interface specifies the `run()` method that is required for use with the `Thread` class. Any class that implements this interface can provide the "body" of a thread. See `Thread` for more information.

```
public abstract interface Runnable {
    // Public Instance Methods
            public abstract void run();
}
```

Implemented By:

Thread

Passed To:

Thread()

22.12 java.awt.peer.LabelPeer (JDK 1.0)

```
public abstract interface LabelPeer extends ComponentPeer {
    // Public Instance Methods
            public abstract void setAlignment(int alignment);
            public abstract void setText(String label);
}
```

Returned By:

Toolkit.createLabel()

22.4 java.awt.peer.CheckboxPeer (JDK 1.0)

```
public abstract interface CheckboxPeer extends ComponentPeer {
    // Public Instance Methods
            public abstract void setCheckboxGroup(CheckboxGroup g);
            public abstract void setLabel(String label);
            public abstract void setState(boolean state);
}
```

Returned By:

Toolkit.createCheckbox()

21.3 java.awt.image.CropImageFilter (JDK 1.0)

This class implements an `ImageFilter` that crops an image to a specified rectangle. The methods defined by this class are used for communication between the filter and its `FilteredImageSource` and should never be called directly.

```
public class CropImageFilter extends ImageFilter {
    // Public Constructor
            public CropImageFilter(int x, int y, int w, int h);
    // Public Instance Methods
            public void setDimensions(int w, int h);  // Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model,
            public void setPixels'u'byte[] pixels, int off, int scansize);  //
Overrides ImageFilter
            public void setPixels(int x, int y, int w, int h, ColorModel model,
            public void setPixels'u'int[] pixels, int off, int scansize);  //
Overrides ImageFilter
            public void setProperties(Hashtable props);  // Overrides ImageFilter
}
```

Hierarchy:

```
Object->ImageFilter(ImageConsumer, Cloneable)->CropImageFilter
```

22.9 java.awt.peer.FileDialogPeer (JDK 1.0)

```
public abstract interface FileDialogPeer extends DialogPeer {
    // Public Instance Methods
            public abstract void setDirectory(String dir);
            public abstract void setFile(String file);
            public abstract void setFilenameFilter(FilenameFilter filter);
}
```

Hierarchy:

(FileDialogPeer(DialogPeer(WindowPeer(ContainerPeer(ComponentPeer)))))

Returned By:

Toolkit.createFileDialog()

22.11 java.awt.peer.FramePeer (JDK 1.0)

```
public abstract interface FramePeer extends WindowPeer {
    // Public Instance Methods
            public abstract void setIconImage(Image im);
            public abstract void setMenuBar(MenuBar mb);
            public abstract void setResizable(boolean resizeable);
            public abstract void setTitle(String title);
}
```

Hierarchy:

(FramePeer(WindowPeer(ContainerPeer(ComponentPeer))))

Returned By:

Toolkit.createFrame()

22.22 java.awt.peer.ScrollbarPeer (JDK 1.0)

```
public abstract interface ScrollbarPeer extends ComponentPeer {
    // Public Instance Methods
            public abstract void setLineIncrement(int l);
            public abstract void setPageIncrement(int l);
            public abstract void setValues(int value, int visible, int minimum, int 
maximum);
}
```

Returned By:

Toolkit.createScrollbar()

22.8 java.awt.peer.DialogPeer (JDK 1.0)

```
public abstract interface DialogPeer extends WindowPeer {
    // Public Instance Methods
            public abstract void setResizable(boolean resizeable);
            public abstract void setTitle(String title);
}
```

Hierarchy:

(DialogPeer(WindowPeer(ContainerPeer(ComponentPeer))))

Extended By:

FileDialogPeer

Returned By:

Toolkit.createDialog()

22.3 java.awt.peer.CheckboxMenuItemPeer (JDK 1.0)

```
public abstract interface CheckboxMenuItemPeer extends MenuItemPeer {
    // Public Instance Methods
            public abstract void setState(boolean t);
}
```

Hierarchy:

(CheckboxMenuItemPeer(MenuItemPeer(MenuComponentPeer)))

Returned By:

Toolkit.createCheckboxMenuItem()

22.20 java.awt.peer.PopupMenuPeer (JDK 1.1)

```
public abstract interface PopupMenuPeer extends MenuPeer {
    // Public Instance Methods
            public abstract void show(Event e);
}
```

Hierarchy:

(PopupMenuPeer(MenuPeer(MenuItemPeer(MenuComponentPeer))))

Returned By:

Toolkit.createPopupMenu()

20.27 java.awt.event.TextListener (JDK 1.1)

This interface defines the method that an object must implement to "listen" for text events on AWT components. When a `TextEvent` occurs, an AWT component notifies its registered `TextListener` objects by invoking their `textValueChanged()` methods.

```
public abstract interface TextListener extends EventListener {
    // Public Instance Methods
            public abstract void textValueChanged(TextEvent e);
}
```

Implemented By:

`AWTEventMulticaster`

Passed To:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove(), TextComponent.addTextListener(), TextComponent.removeTextListener()`

Returned By:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove()`

Type Of:

`TextComponent.textListener`

22.26 java.awt.peer.WindowPeer (JDK 1.0)

```
public abstract interface WindowPeer extends ContainerPeer {
    // Public Instance Methods
            public abstract void toBack();
            public abstract void toFront();
}
```

Hierarchy:

(WindowPeer(ContainerPeer(ComponentPeer)))

Extended By:

DialogPeer, FramePeer

Returned By:

Toolkit.createWindow()

25.69 java.lang.Void (JDK 1.1)

The Void class may not be instantiated, and serves merely as a placeholder for its static TYPE field, which is a Class object constant that represents the void type.

```
public final class Void extends Object {
    // No Constructor
    // Constants
            public static final Class TYPE;
}
```

30.16 java.util.Observer (JDK 1.0)

This interface defines the `update()` method required for an object to "observe" subclasses of `Observable`. An `Observer` registers interest in an `Observable()` by calling the `Observable.addObserver()` method. `Observer` objects that have been registered in this way will have their `update()` method invoked by the `Observable` when that object has changed.

```
public abstract interface Observer {
    // Public Instance Methods
            public abstract void update(Observable o, Object arg);
}
```

Passed To:

Observable.addObserver(), Observable.deleteObserver()

24.40 java.io.ObjectInputValidation (JDK 1.1)

A class implements this interface and defines the `validateObject()` method in order to be able to validate itself when it, and all the objects it depends on, have been completely deserialized from an `ObjectInputStream`. The `validateObject()` method is only invoked, however, if the object is passed to `ObjectInputStream.registerValidation()`; this must be done from the `readObject()` method of the object. Note that if an object is deserialized as part of a larger object graph, its `validateObject()` method is not invoked until the entire graph is read, and the original call to `ObjectInputStream.readObject()` is about to return.

`validateObject()` should throw an `InvalidObjectException` if the object fails validation. This stops object serialization, and causes the original call to `ObjectInputStream.readObject()` to terminate with the `InvalidObjectException` exception.

```
public abstract interface ObjectInputValidation {
    // Public Instance Methods
            public abstract void validateObject() throws InvalidObjectException;
}
```

Passed To:

ObjectInputStream.registerValidation()

23.21 java.beans.VetoableChangeListener (JDK 1.1)

This interface is an extension of `java.util.EventListener` and defines the method that a class must implement in order to be notified when a Java bean makes a change to a "constrained" property. A `PropertyChangeEvent` is passed to the `vetoableChange()` method when such a change occurs, and if the `VetoableChangeListener` wants to prevent the change from occurring, this method should throw a `PropertyVetoException`.

```
public abstract interface VetoableChangeListener extends EventListener {
    // Public Instance Methods
            public abstract void vetoableChange(PropertyChangeEvent evt) throws
PropertyVetoException;
}
```

Passed To:

VetoableChangeSupport.addVetoableChangeListener(), VetoableChangeSupport.removeVetoableChangeListener()

20.28 java.awt.event.WindowAdapter (JDK 1.1)

This class is a trivial implementation of `WindowListener`; it provides empty bodies for each of the methods of that interface. When you are not interested in all of these methods, it is often easier to subclass `WindowAdapter` than it is to implement `WindowListener` from scratch.

```
public abstract class WindowAdapter extends Object implements WindowListener {
    // Default Constructor: public WindowAdapter()
    // Public Instance Methods
            public void windowActivated(WindowEvent e);  // From WindowListener
            public void windowClosed(WindowEvent e);  // From WindowListener
            public void windowClosing(WindowEvent e);  // From WindowListener
            public void windowDeactivated(WindowEvent e);  // From WindowListener
            public void windowDeiconified(WindowEvent e);  // From WindowListener
            public void windowIconified(WindowEvent e);  // From WindowListener
            public void windowOpened(WindowEvent e);  // From WindowListener
}
```

Hierarchy:

```
Object->WindowAdapter(WindowListener(EventListener))
```

20.30 java.awt.event.WindowListener (JDK 1.1)

This interface defines the methods that an object must implement to "listen" for window events on AWT components. When a `WindowEvent` occurs, an AWT component notifies its registered `WindowListener` objects by invoking one of their methods.

An easy way to implement this interface is by subclassing the `WindowAdapter` class.

```
public abstract interface WindowListener extends EventListener {
    // Public Instance Methods
            public abstract void windowActivated(WindowEvent e);
            public abstract void windowClosed(WindowEvent e);
            public abstract void windowClosing(WindowEvent e);
            public abstract void windowDeactivated(WindowEvent e);
            public abstract void windowDeiconified(WindowEvent e);
            public abstract void windowIconified(WindowEvent e);
            public abstract void windowOpened(WindowEvent e);
}
```

Implemented By:

`AWTEventMulticaster, WindowAdapter`

Passed To:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove(),`
`Window.addWindowListener(), Window.removeWindowListener()`

Returned By:

`AWTEventMulticaster.add(), AWTEventMulticaster.remove()`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.12 java.io.DataOutput (JDK 1.0)

This interface defines the methods required for streams that can write character data or Java primitive data types in a machine-independent binary format. It is implemented by `DataOutputStream` and `RandomAccessFile`. See `DataOutputStream` for more information on the methods.

```
public abstract interface DataOutput {
    // Public Instance Methods
            public abstract void write(int b) throws IOException;
            public abstract void write(byte[] b) throws IOException;
            public abstract void write(byte[] b, int off, int len) throws 
IOException;
            public abstract void writeBoolean(boolean v) throws IOException;
            public abstract void writeByte(int v) throws IOException;
            public abstract void writeBytes(String s) throws IOException;
            public abstract void writeChar(int v) throws IOException;
            public abstract void writeChars(String s) throws IOException;
            public abstract void writeDouble(double v) throws IOException;
            public abstract void writeFloat(float v) throws IOException;
            public abstract void writeInt(int v) throws IOException;
            public abstract void writeLong(long v) throws IOException;
            public abstract void writeShort(int v) throws IOException;
            public abstract void writeUTF(String str) throws IOException;
}

18.4 java.awt.AWTException (JDK 1.0)

Signals that an exception has occurred in the `java.awt` package.

```
public class AWTException extends Exception {
    // Public Constructor
            public AWTException(String msg);
}
```

Hierarchy:

```
Object->Throwable(Serializable)->Exception->AWTException
```

18.31 java.awt.IllegalComponentStateException (JDK 1.1)

This exception signals that an AWT component is not in the appropriate state (for example, it hasn't been added to a container yet or is currently hidden) for some requested operation.

```
public class IllegalComponentStateException extends IllegalStateException {
    // Public Constructors
            public IllegalComponentStateException();
            public IllegalComponentStateException(String s);
}
```

Hierarchy:

```
Object->Throwable(Serializable)->Exception->RuntimeException->
IllegalStateException->IllegalComponentStateException
```

9.3 Serialization and Class Versioning

When an object is serialized, some information about its class must obviously be serialized with it, so that the correct class file can be loaded when the object is deserialized. This information about the class is represented by the `java.io.ObjectStreamClass` class. It contains the fully-qualified name of the class and a version number. The version number is very important because an early version of a class may not be able to deserialize a serialized instance created by a later version of the same class.

The version number of a class is stored in a constant `long` field named `serialVersionUID`. For example, a class might declare its version number with a field like this:

```
static final long serialVersionUID = 280432937854755317L;
```

If a class does not define a `serialVersionUID` constant, the `ObjectOutputStream` automatically computes a unique version number for it by applying the Secure Hash Algorithm (SHA) to the name of the class, its interfaces, fields, and methods. In this case, any change to a field in a class or to a non-private class method signature results in a change to the automatically-computed unique version number.

If you need to make minor changes to a class without breaking serialization compatibility, you should explicitly declare a `serialVersionUID` constant so that an updated and incompatible version number is not automatically generated. You can use the *serialver* program that is provided with the JDK to compute an initial value for this constant for the first version of your class. When you make minor, compatible changes to the class, leave the constant unchanged. Then, if you make larger changes that break serialization compatibility, run *serialver* again to generate an updated version number.

9.4 Serialized Applets

One of the uses of object serialization in Java 1.1 is for serialized applets. As discussed in Chapter 15, *Java-Related HTML Tags*, the `<APPLET>` tag has a new attribute, `OBJECT`, that can be used in place of the `CODE` attribute to specify a serialized object file instead of a class file. When such an `<APPLET>` tag is encountered, the applet viewer or Web browser creates the applet by deserializing it.

The reason that this is an interesting thing to do is that it allows an applet to be shipped in a pre-initialized state. The code for the applet need not even include the code that performed the initialization. For example, imagine a GUI builder tool that allows a programmer to build a GUI using a point-and-click interface. Such a tool could create a tree of AWT components within an `Applet` panel, and then serialize the applet, including all of the GUI components it contains. When deserialized, the applet would have a complete GUI, despite the fact that the applet's class file does not contain any code to create the GUI.

You can experiment with applet serialization with the JDK 1.1 *appletviewer* program. Start an applet running in *appletviewer* in the usual way. This loads the applet and runs its `init()` and `start()` methods. Next, select the **Stop** item from the menu to stop the applet. Now use the **Save** menu item to serialize the applet to a file. By convention, your serialized applet file should be given a *.ser* extension. If the applet refers to any non-serializable objects, you may not be able to serialize it. For example, you may encounter problems serializing applets that use threads or images.

Once you have serialized an applet, create an HTML file with an `<APPLET>` tag something like this:

```
<APPLET OBJECT="MyApplet.ser" WIDTH=400 HEIGHT=200></APPLET >
```

Finally, you can use *appletviewer* with this new HTML file. It should deserialize and display the applet. When created in this way, the applet's `init()` method is not called (since it was called before serialization), but its `start()` method is called (because the applet should have been stopped before serialization).

Serialization and Class Versioning | BOOK INDEX | Advanced Serialization

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9.5 Advanced Serialization

The Object Serialization API also has some advanced features beyond those demonstrated above. One such feature is the `Externalizable` interface. If a class implements this interface, the `ObjectInputStream` and `ObjectOutputStream` classes use an object's `readExternal()` and `writeExternal()` methods to read and write its state from a stream. Most classes that want custom serialization behavior simply implement `readObject()` and `writeObject()` methods to do pre- and post-processing. `Externalizable` objects, on the other hand, take complete control over reading and writing their state. This interface is intended for objects that do not even want to use the basic serialized object data format used for all `Serializable` objects. A word processor object, for example, might "externalize" itself using its own native file format.

Another advanced serialization feature is the ability to register an `ObjectInputValidation` object that can verify that an object graph has been deserialized in a consistent, valid state. Typically, the root of an object graph registers such a validation object by calling the `registerValidation()` method of the `ObjectInputStream` from its own custom `readObject()` method. Then, when the graph has been read completely, the `validateObject()` method of the `ObjectInputValidation` object is called to perform whatever validity checks are necessary.

Finally, you may notice that `ObjectOutputStream` and `ObjectInputStream` have methods like `annotateClass()`, `replaceObject()`, `resolveClass()`, and `resolveObject()`. These are intended for use by subclasses of the object streams that implement special kinds of object serialization behavior.

28.21 java.net.UnknownServiceException (JDK 1.0)

Signals an attempt to use an unsupported service of a network connection.

```
public class UnknownServiceException extends IOException {
    // Public Constructors
            public UnknownServiceException();
            public UnknownServiceException(String msg);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->UnknownServiceException

Cloneable

Name

Cloneable

Synopsis

Interface Name:

`java.lang.Cloneable`

Super-interface:

None

Immediate Sub-interfaces:

`java.text.CharacterIterator`

Implemented by:

`java.awt.GridBagConstraints`, `java.awt.Insets`,

`java.awt.image.ImageFilter`,

`java.text.BreakIterator`,

`java.text.Collator`, `java.text.DateFormat`,

`java.text.DateFormatSymbols`,

`java.text.DecimalFormatSymbols`,

`java.text.Format`, `java.text.NumberFormat`,

`java.util.BitSet`, `java.util.Calendar`,

`java.util.Date`, `java.util.Hashtable`,

`java.util.Locale`, `java.util.TimeZone`,

`java.util.Vector`

Availability:

JDK 1.0 or later

Description

The `Cloneable` interface provides no functionality; it declares no methods or variables. This interface is simply provided as a way of indicating that an object can be cloned (that is, copied). A class that is declared as implementing this interface is assumed to have overridden the `Object` class' implementation of `clone()` with an implementation that can successfully clone instances of the class. The implementation of `clone()` that is provided by the `Object` class simply throws a `CloneNotSupportedException`.

Interface Declaration

```
public interface java.lang.Cloneable {
}
```

12. Reflection

Contents:
Obtaining Class and Member Information
Invoking a Named Method

As noted in Chapter 4, *What's New in Java 1.1*, the Reflection API allows a Java program to inspect and manipulate itself. The Reflection API comprises the much-expanded `Class` class in `java.lang` and the `java.lang.reflect` package, which represents the members of a class with `Method`, `Constructor`, and `Field` objects.

Reflection can be used to obtain information about a class and its members. This is the technique that the JavaBeans "introspection" mechanism uses to determine the properties, events, and methods that are supported by a bean, for example. Reflection can also be used to manipulate objects in Java. You can use the `Field` class to query and set the values of fields, the `Method` class to invoke methods, and the `Constructor` class to create new objects. The examples in this chapter demonstrate both techniques for using the Reflection API.

12.1 Obtaining Class and Member Information

Example 12.1 shows a program that uses the `Class`, `Constructor`, `Field`, and `Method` classes to display information about a specified class. The program's output is similar to the class synopses that appear in the reference section of this book. (You might notice that the names of method arguments are not shown; argument names are not stored in class files, so they are not available through the Reflection API.)

Here is the output from using `ShowClass` on itself:

```
% java ShowClass ShowClass
public class ShowClass extends java.lang.Object {
 // Constructors
  public ShowClass();
 // Fields
 // Methods
  public static void main(java.lang.String[]);
  public static void print_class(java.lang.Class);
  public static java.lang.String typename(java.lang.Class);
  public static java.lang.String modifiers(int);
  public static void print_field(java.lang.reflect.Field);
  public static void print_method_or_constructor(java.lang.reflect.Member);
}
```

The code for this example is quite straightforward. It uses the `Class.forName()` method to dynamically load the named class, and calls various methods of `Class` object to look up the superclass, interfaces, and members of the class. The example uses `Constructor`, `Field`, and `Method` objects to obtain information about each member of the class.

Example 12.1: Obtaining Class and Member Information with the Reflection API

```
import java.lang.reflect.*;
/** A program that displays a class synopsis for the named class. */
public class ShowClass {
  /** The main method.  Print info about the named class. */
  public static void main(String[] args) throws ClassNotFoundException {
    Class c = Class.forName(args[0]);
    print_class(c);
  }
  /** Display the modifiers, name, superclass, and interfaces of a class
   *  or interface. Then go and list all constructors, fields, and methods. */
  public static void print_class(Class c)
  {
    // Print modifiers, type (class or interface), name, and superclass.
    if (c.isInterface()) {
      // The modifiers will include the "interface" keyword here...
      System.out.print(Modifier.toString(c.getModifiers()) +  c.getName());
    }
    else
      System.out.print(Modifier.toString(c.getModifiers()) + " class " +
                       c.getName() +
                       " extends " + c.getSuperclass().getName());
    // Print interfaces or super-interfaces of the class or interface.
    Class[] interfaces = c.getInterfaces();
    if ((interfaces != null) && (interfaces.length > 0)) {
      if (c.isInterface()) System.out.println(" extends ");
      else System.out.print(" implements ");
      for(int i = 0; i < interfaces.length; i++) {
        if (i > 0) System.out.print(", ");
        System.out.print(interfaces[i].getName());
      }
    }
    System.out.println(" {");            // Begin class member listing.
    // Now look up and display the members of the class.
    System.out.println(" // Constructors");
    Constructor[] constructors = c.getDeclaredConstructors();
    for(int i = 0; i < constructors.length; i++)      // Display constructors.
      print_method_or_constructor(constructors[i]);
    System.out.println(" // Fields");
    Field[] fields = c.getDeclaredFields();           // Look up fields.
    for(int i = 0; i < fields.length; i++)            // Display them.
      print_field(fields[i]);
    System.out.println(" // Methods");
    Method[] methods = c.getDeclaredMethods();        // Look up methods.
    for(int i = 0; i < methods.length; i++)           // Display them.
      print_method_or_constructor(methods[i]);
    System.out.println("}");             // End class member listing.
  }
  /** Return the name of an interface or primitive type, handling arrays. */
  public static String typename(Class t) {
    String brackets = "";
    while(t.isArray()) {
      brackets += "[]";
      t = t.getComponentType();
    }
    return t.getName() + brackets;
  }
  /** Return a string version of modifiers, handling spaces nicely. */
  public static String modifiers(int m) {
    if (m == 0) return "";
    else return Modifier.toString(m) + " ";
  }
  /** Print the modifiers, type, and name of a field. */
  public static void print_field(Field f) {
    System.out.println("  " +
                       modifiers(f.getModifiers()) +
                       typename(f.getType()) + " " + f.getName() + ";");
  }
  /** Print the modifiers, return type, name, parameter types, and exception
   *  type of a method or constructor.  Note the use of the Member interface
   *  to allow this method to work with both Method and Constructor objects. */
  public static void print_method_or_constructor(Member member) {
    Class returntype=null, parameters[], exceptions[];
    if (member instanceof Method) {
      Method m = (Method) member;
      returntype = m.getReturnType();
      parameters = m.getParameterTypes();
      exceptions = m.getExceptionTypes();
    } else {
      Constructor c = (Constructor) member;
      parameters = c.getParameterTypes();
      exceptions = c.getExceptionTypes();
    }
    System.out.print("  " + modifiers(member.getModifiers()) +
                     ((returntype!=null)? typename(returntype)+" " : "") +
                     member.getName() + "(");
    for(int i = 0; i < parameters.length; i++) {
      if (i > 0) System.out.print(", ");
      System.out.print(typename(parameters[i]));
    }
    System.out.print(")");
    if (exceptions.length > 0) System.out.print(" throws ");
    for(int i = 0; i < exceptions.length; i++) {
      if (i > 0) System.out.print(", ");
      System.out.print(typename(exceptions[i]));
    }
    System.out.println(";");
  }
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

30.5 java.util.EmptyStackException (JDK 1.0)

Signals that a `Stack` object is empty.

```
public class EmptyStackException extends RuntimeException {
    // Public Constructor
            public EmptyStackException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->EmptyStackException

30.7 java.util.EventListener (JDK 1.1)

`EventListener` is a base interface for the Java 1.1 AWT event model. This interface defines no method or constants. Its purpose is to serve as a tag to identify objects that serve as event listeners. The event listener interfaces in the `java.awt.event`, and `java.beans` packages extend this interface.

```
public interface EventListener {
}
```

Extended By:

ActionListener, AdjustmentListener, ComponentListener, ContainerListener, FocusListener, ItemListener, KeyListener, MouseListener, MouseMotionListener, PropertyChangeListener, TextListener, VetoableChangeListener, WindowListener

Passed To:

AWTEventMulticaster(), AWTEventMulticaster.addInternal(), AWTEventMulticaster.remove(), AWTEventMulticaster.removeInternal(), AWTEventMulticaster.save()

Returned By:

AWTEventMulticaster.addInternal(), AWTEventMulticaster.remove(), AWTEventMulticaster.removeInternal()

Type Of:

AWTEventMulticaster.a, AWTEventMulticaster.b

30.14 java.util.NoSuchElementException (JDK 1.0)

Signals that there are no elements in an object (such as a `Vector`) or that there are no more elements in an object (such as an `Enumeration`).

```
public class NoSuchElementException extends RuntimeException {
    // Public Constructors
            public NoSuchElementException();
            public NoSuchElementException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->NoSuchElementException

30.25 java.util.TooManyListenersException (JDK 1.1)

An exception of this type signals that an AWT component or Java bean may only have one `EventListener` object registered for some specific type of event. That is, it signals that a particular event is a "unicast" event rather than a "multicast" event.

This exception type serves a formal purpose in the AWT and JavaBeans event model. Its presence in the `throws` clause of an `EventListener` registration method (even if the method never actually throws the exception) signals that an event is a unicast event.

```
public class TooManyListenersException extends Exception {
    // Public Constructors
            public TooManyListenersException();
            public TooManyListenersException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->TooManyListenersException

10. Java Beans

Contents:

The JavaBeans API provides a framework for defining reusable, embeddable, modular software components. The JavaBeans Specification includes the following definition of a bean: "a reusable software component that can be manipulated visually in a builder tool." As you can see, this is a rather loose definition; beans can take a variety of forms. At the simplest level, individual AWT components (in Java 1.1) are all beans, while at a much higher level, an embeddable spreadsheet application might also function as a bean. Most beans, however, will probably fall somewhere between these two extremes.

One of the goals of the JavaBeans model is interoperability with similar component frameworks. So, for example, a native Windows program can, with an appropriate bridge or wrapper object, use a Java bean as if it were a COM or ActiveX component. The details of this sort of interoperability are beyond the scope of this chapter, however.

Beans can be used at three levels, by three different categories of programmers:

- If you are developing GUI editors, application builders, or other "beanbox" tools, you need the JavaBeans API to manipulate beans within these tools. *beanbox* is the name of the sample bean manipulation program provided by Sun in its Beans Development Kit (BDK). The term is a useful one, and I'll use it to describe any kind of graphical design tool or application builder that manipulates beans.

- If you are writing actual beans, you need the JavaBeans API to write code that can be used in any conforming beanbox.
- If you are writing applications that use beans developed by other programmers, or using a beanbox tool to combine those beans into an application, you do not actually need to be familiar with the JavaBeans API. You only need to be familiar with the documentation for individual beans that you are using.

This chapter explains how to use the JavaBeans API at the second level, or in other words, it describes how to write beans. It covers the following topics:

- Basic bean concepts and terminology
- Requirements for the simplest beans
- Packaging beans in JAR files
- Providing additional information about beans with the `BeanInfo` class
- Defining property editors to allow custom editing of bean properties
- Defining bean customizers to allow customization of an entire bean
- The various naming conventions and requirements imposed by the JavaBeans model

10.1 Bean Basics

We begin our discussion of beans with some basic concepts and terminology. Any object that conforms to certain basic rules can be a bean; there is no `Bean` class that all beans are required to subclass. Many beans are AWT components, but it is also quite possible, and often useful, to write "invisible" beans that do not have an on-screen appearance. (Just because a bean does not have an on-screen appearance in a finished application does not mean that it won't be visually manipulated by a beanbox tool, however.)

A bean exports properties, events, and methods. A *property* is a piece of the bean's internal state that can be programmatically set and queried, usually through a standard pair of `get` and `set` accessor methods. A bean may generate *events* in the same way that an AWT component, such as a `Button`, generates `ActionEvent` events. The JavaBeans API uses the same event model as the Java 1.1 AWT does. See Chapter 7, *Events*, for a full discussion of this model. A bean defines an event if it provides methods for adding and removing event listener objects from a list of interested listeners for that event. Finally, the *methods* exported by a bean are simply any `public` methods defined by the bean, excluding those methods used to get and set property values and register and remove event listeners.

In addition to the regular sort of properties described above, the JavaBeans API also provides support for "indexed properties," "bound properties," and "constrained properties." An indexed property is any property that has an array value and for which the bean provides methods to get and set individual elements of the array, as well as methods to get and set the entire array. A bound property is one that sends out a notification event when its value changes, while a constrained property is one that sends out a notification event when its value changes and allows the change to be vetoed by listeners.

Because Java allows dynamic loading of classes, beanbox programs can load arbitrary beans. The beanbox tool determines the properties, events, and methods a bean supports by using an "introspection" mechanism that is based on the `java.lang.reflect` reflection mechanism for obtaining information about the members of a class. A bean can also provide an auxiliary `BeanInfo` class that provides additional information about the bean. The `BeanInfo` class provides this additional information in the form of a number of `FeatureDescriptor` objects, each one describing a single feature of the bean. `FeatureDescriptor` has a number of subclasses: `BeanDescriptor`, `PropertyDescriptor`, `IndexedPropertyDescriptor`, `EventSetDescriptor`, `MethodDescriptor`, and `ParameterDescriptor`.

One of the primary tasks of a beanbox application is to allow the user to customize a bean by setting property values. A beanbox defines "property editors" for commonly used property types, such as numbers, strings, fonts, and colors. If a bean has properties of more complicated types, however, it may need to define a `PropertyEditor` class that enables the beanbox to let the user set values for that property.

In addition, a complex bean may not be satisfied with the property-by-property customization mechanism provided by most beanboxes. Such a bean may want to define a `Customizer` class, which creates a graphical interface that allows the user to configure a bean in some useful way. A particularly complex bean may even define customizers that serve as "wizards" that guide the user step-by-step through the customization process.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

25.38 java.lang.NegativeArraySizeException (JDK 1.0)

Signals an attempt to allocate an array with fewer than zero elements.

```
public class NegativeArraySizeException extends RuntimeException {
    // Public Constructors
            public NegativeArraySizeException();
            public NegativeArraySizeException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->NegativeArraySizeException

Thrown By:

Array.newInstance()

25.2 java.lang.ArithmeticException (JDK 1.0)

A `RuntimeException` that signals an exceptional arithmetic condition, such as integer division by zero.

```
public class ArithmeticException extends RuntimeException {
    // Public Constructors
            public ArithmeticException();
            public ArithmeticException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->ArithmeticException

Thrown By:

BigDecimal.divide(), BigDecimal.setScale(), BigInteger.add(), BigInteger.clearBit(), BigInteger.divide(), BigInteger.divideAndRemainder(), BigInteger.flipBit(), BigInteger.modInverse(), BigInteger.pow(), BigInteger.remainder(), BigInteger.setBit(), BigInteger.testBit()

25.3 java.lang.ArrayIndexOutOfBoundsException (JDK 1.0)

Signals that an array index less than zero or greater than or equal to the array size has been used.

```
public class ArrayIndexOutOfBoundsException extends IndexOutOfBoundsException {
    // Public Constructors
            public ArrayIndexOutOfBoundsException();
            public ArrayIndexOutOfBoundsException(int index);
            public ArrayIndexOutOfBoundsException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException-> IndexOutOfBoundsException->ArrayIndexOutOfBoundsException

Thrown By:

Array.get(), Array.getBoolean(), Array.getByte(), Array.getChar(), Array.getDouble(), Array.getFloat(), Array.getInt(), Array.getLong(), Array.getShort(), Array.set(), Array.setBoolean(), Array.setByte(), Array.setChar(), Array.setDouble(), Array.setFloat(), Array.setInt(), Array.setLong(), Array.setShort()

25.4 java.lang.ArrayStoreException (JDK 1.0)

Signals an attempt to store the wrong type of object into an array.

```
public class ArrayStoreException extends RuntimeException {
    // Public Constructors
            public ArrayStoreException();
            public ArrayStoreException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->ArrayStoreException

25.9 java.lang.ClassCastException (JDK 1.0)

Signals an invalid cast of an object to a type of which it is not an instance.

```
public class ClassCastException extends RuntimeException {
    // Public Constructors
            public ClassCastException();
            public ClassCastException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->ClassCastException

25.10 java.lang.ClassCircularityError (JDK 1.0)

Signals that a circular dependency has been detected while performing initialization for a class.

```
public class ClassCircularityError extends LinkageError {
    // Public Constructors
            public ClassCircularityError();
            public ClassCircularityError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->ClassCircularityError

25.11 java.lang.ClassFormatError (JDK 1.0)

Signals an error in the binary format of a class file.

```
public class ClassFormatError extends LinkageError {
    // Public Constructors
            public ClassFormatError();
            public ClassFormatError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->ClassFormatError

25.13 java.lang.ClassNotFoundException (JDK 1.0)

Signals that a class to be loaded could not be found.

```
public class ClassNotFoundException extends Exception {
    // Public Constructors
            public ClassNotFoundException();
            public ClassNotFoundException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->ClassNotFoundException

Thrown By:

Beans.instantiate(), Class.forName(), ClassLoader.findSystemClass(), ClassLoader.loadClass(), Externalizable.readExternal(), ObjectInput.readObject(), ObjectInputStream.defaultReadObject(), ObjectInputStream.readObject(), ObjectInputStream.resolveClass()

25.14 java.lang.CloneNotSupportedException (JDK 1.0)

Signals that the `clone()` method has been called for an object of a class that does not implement the `Cloneable` interface.

```
public class CloneNotSupportedException extends Exception {
    // Public Constructors
            public CloneNotSupportedException();
            public CloneNotSupportedException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->CloneNotSupportedException

Thrown By:

Object.clone()

25.15 java.lang.Cloneable (JDK 1.0)

This interface defines no methods or variables, but indicates that the class that implements it may be cloned (i.e., copied) by calling the `Object` method `clone()`. Calling `clone()` for an object that does not implement this interface (and does not override `clone()` with its own implementation) causes a `CloneNotSupportedException` to be thrown.

```
public interface Cloneable {
}
```

Extended By:

CharacterIterator

Implemented By:

BitSet, BreakIterator, Calendar, Collator, Date, DateFormat, DateFormatSymbols, DecimalFormatSymbols, Format, GridBagConstraints, Hashtable, ImageFilter, Insets, Locale, NumberFormat, TimeZone, Vector

25.18 java.lang.Error (JDK 1.0)

This class forms the root of the error hierarchy in Java. Subclasses of `Error`, unlike subclasses of `Exception`, should generally not be caught, and generally cause termination of the program. Subclasses of `Error` need not be declared in the `throws` clause of a method definition.

`getMessage()` returns a message associated with the error. See `Throwable` for other methods.

```
public class Error extends Throwable {
    // Public Constructors
            public Error();
            public Error(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error

Extended By:

AWTError, LinkageError, ThreadDeath, VirtualMachineError

25.19 java.lang.Exception (JDK 1.0)

This class forms the root of the exception hierarchy in Java. An `Exception` signals an abnormal condition that must be specially handled to prevent program termination. Exceptions may be caught and handled. Exceptions that are not subclasses of `RuntimeException` must be declared in the `throws` clause of any method that can throw them.

`getMessage()` returns a message associated with the exception. See `Throwable` for other methods.

```
public class Exception extends Throwable {
    // Public Constructors
            public Exception();
            public Exception(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception

Extended By:

AWTException, ClassNotFoundException, CloneNotSupportedException, DataFormatException, IllegalAccessException, InstantiationException, InterruptedException, IntrospectionException, InvocationTargetException, IOException, NoSuchFieldException, NoSuchMethodException, ParseException, PropertyVetoException, RuntimeException, TooManyListenersException, UnsupportedFlavorException

Passed To:

WriteAbortedException()

Type Of:

WriteAbortedException.detail

25.22 java.lang.IllegalAccessError (JDK 1.0)

Signals an attempted use of a class, method, or variable that is not accessible.

```
public class IllegalAccessError extends IncompatibleClassChangeError {
    // Public Constructors
            public IllegalAccessError();
            public IllegalAccessError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->IncompatibleClassChangeError->IllegalAccessError

25.23 java.lang.IllegalAccessException (JDK 1.0)

Signals that a class or initializer is not accessible. Thrown by `Class.newInstance()`.

```
public class IllegalAccessException extends Exception {
    // Public Constructors
            public IllegalAccessException();
            public IllegalAccessException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IllegalAccessException

Thrown By:

Class.newInstance(), Constructor.newInstance(), Field.get(), Field.getBoolean(), Field.getByte(), Field.getChar(), Field.getDouble(), Field.getFloat(), Field.getInt(), Field.getLong(), Field.getShort(), Field.set(), Field.setBoolean(), Field.setByte(), Field.setChar(), Field.setDouble(), Field.setFloat(), Field.setInt(), Field.setLong(), Field.setShort(), Method.invoke()

25.24 java.lang.IllegalArgumentException (JDK 1.0)

Signals an illegal argument to a method. See subclasses `IllegalThreadStateException` and `NumberFormatException`.

```
public class IllegalArgumentException extends RuntimeException {
    // Public Constructors
            public IllegalArgumentException();
            public IllegalArgumentException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->IllegalArgumentException

Extended By:

IllegalThreadStateException, NumberFormatException

Thrown By:

Array.get(), Array.getBoolean(), Array.getByte(), Array.getChar(), Array.getDouble(), Array.getFloat(), Array.getInt(), Array.getLength(), Array.getLong(), Array.getShort(), Array.newInstance(), Array.set(), Array.setBoolean(), Array.setByte(), Array.setChar(), Array.setDouble(), Array.setFloat(), Array.setInt(), Array.setLong(), Array.setShort(), BigDecimal.divide(), BigDecimal.setScale(), BigInteger(), Constructor.newInstance(), Field.get(), Field.getBoolean(), Field.getByte(), Field.getChar(), Field.getDouble(), Field.getFloat(), Field.getInt(), Field.getLong(), Field.getShort(), Field.set(), Field.setBoolean(), Field.setByte(), Field.setChar(), Field.setDouble(), Field.setFloat(), Field.setInt(), Field.setLong(), Field.setShort(), Method.invoke(), PropertyEditor.setAsText(), PropertyEditorSupport.setAsText()

java.lang.IllegalAccessException (JDK 1.0) | BOOK INDEX | java.lang.IllegalMonitorStateException (JDK 1.0)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

25.25 java.lang.IllegalMonitorStateException (JDK 1.0)

Signals an illegal monitor state. It is thrown by the `Object` `notify()` and `wait()` methods used for thread synchronization.

```
public class IllegalMonitorStateException extends RuntimeException {
    // Public Constructors
            public IllegalMonitorStateException();
            public IllegalMonitorStateException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->IllegalMonitorStateException

25.26 java.lang.IllegalStateException (JDK 1.1)

An exception of this type signals that a method has been invoked on an object that is not in an appropriate state to be able to perform the requested operation.

```
public class IllegalStateException extends RuntimeException {
    // Public Constructors
            public IllegalStateException();
            public IllegalStateException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->IllegalStateException

Extended By:

IllegalComponentStateException

25.27 java.lang.IllegalThreadStateException (JDK 1.0)

Signals that a thread is not in the appropriate state for an attempted operation to succeed.

```
public class IllegalThreadStateException extends IllegalArgumentException {
    // Public Constructors
            public IllegalThreadStateException();
            public IllegalThreadStateException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException-> IllegalArgumentException->IllegalThreadStateException

25.28 java.lang.IncompatibleClassChangeError (JDK 1.0)

This is the superclass of a group of related error types. It signals some kind of illegal use of a legal class.

```
public class IncompatibleClassChangeError extends LinkageError {
    // Public Constructors
            public IncompatibleClassChangeError();
            public IncompatibleClassChangeError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->IncompatibleClassChangeError

Extended By:

AbstractMethodError, IllegalAccessError, InstantiationError, NoSuchFieldError, NoSuchMethodError

25.29 java.lang.IndexOutOfBoundsException (JDK 1.0)

Signals that an index is out of bounds. See the subclasses `ArrayIndexOutOfBoundsException` and `StringIndexOutOfBoundsException`.

```
public class IndexOutOfBoundsException extends RuntimeException {
    // Public Constructors
            public IndexOutOfBoundsException();
            public IndexOutOfBoundsException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->IndexOutOfBoundsException

Extended By:

ArrayIndexOutOfBoundsException, StringIndexOutOfBoundsException

25.30 java.lang.InstantiationError (JDK 1.0)

Signals an attempt to instantiate an interface or abstract class.

```
public class InstantiationError extends IncompatibleClassChangeError {
    // Public Constructors
            public InstantiationError();
            public InstantiationError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->IncompatibleClassChangeError->InstantiationError

25.31 java.lang.InstantiationException (JDK 1.0)

Signals an attempt to instantiate an interface or an abstract class.

```
public class InstantiationException extends Exception {
    // Public Constructors
            public InstantiationException();
            public InstantiationException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->InstantiationException

Thrown By:

Class.newInstance(), Constructor.newInstance()

25.33 java.lang.InternalError (JDK 1.0)

Signals an internal error in the Java interpreter.

```
public class InternalError extends VirtualMachineError {
    // Public Constructors
            public InternalError();
            public InternalError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->VirtualMachineError->InternalError

25.34 java.lang.InterruptedException (JDK 1.0)

Signals that the thread has been interrupted.

```
public class InterruptedException extends Exception {
    // Public Constructors
            public InterruptedException();
            public InterruptedException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->InterruptedException

Thrown By:

EventQueue.getNextEvent(), MediaTracker.waitForAll(), MediaTracker.waitForID(), Object.wait(), PixelGrabber.grabPixels(), Process.waitFor(), Thread.join(), Thread.sleep()

25.35 java.lang.LinkageError (JDK 1.0)

The superclass of a group of errors that signal problems linking a class or resolving dependencies between classes.

```
public class LinkageError extends Error {
    // Public Constructors
            public LinkageError();
            public LinkageError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError

Extended By:

ClassCircularityError, ClassFormatError, ExceptionInInitializerError, IncompatibleClassChangeError, NoClassDefFoundError, UnsatisfiedLinkError, VerifyError

25.39 java.lang.NoClassDefFoundError (JDK 1.0)

Signals that the definition of a specified class could not be found.

```
public class NoClassDefFoundError extends LinkageError {
    // Public Constructors
            public NoClassDefFoundError();
            public NoClassDefFoundError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->NoClassDefFoundError

25.40 java.lang.NoSuchFieldError (JDK 1.0)

Signals that a specified field could not be found.

```
public class NoSuchFieldError extends IncompatibleClassChangeError {
    // Public Constructors
            public NoSuchFieldError();
            public NoSuchFieldError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->IncompatibleClassChangeError->NoSuchFieldError

25.41 java.lang.NoSuchFieldException (JDK 1.1)

This exception signals that the specified field does not exist in the specified class.

```
public class NoSuchFieldException extends Exception {
    // Public Constructors
            public NoSuchFieldException();
            public NoSuchFieldException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->NoSuchFieldException

Thrown By:

Class.getDeclaredField(), Class.getField()

25.42 java.lang.NoSuchMethodError (JDK 1.0)

Signals that a specified method could not be found.

```
public class NoSuchMethodError extends IncompatibleClassChangeError {
    // Public Constructors
            public NoSuchMethodError();
            public NoSuchMethodError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->IncompatibleClassChangeError->NoSuchMethodError

25.43 java.lang.NoSuchMethodException (JDK 1.0)

This exception signals that the specified method does not exist in the specified class.

```
public class NoSuchMethodException extends Exception {
    // Public Constructors
            public NoSuchMethodException();
            public NoSuchMethodException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->NoSuchMethodException

Thrown By:

Class.getConstructor(), Class.getDeclaredConstructor(), Class.getDeclaredMethod(), Class.getMethod()

25.44 java.lang.NullPointerException (JDK 1.0)

Signals an attempt to access a field or invoke a method of a `null` object.

```
public class NullPointerException extends RuntimeException {
    // Public Constructors
            public NullPointerException();
            public NullPointerException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->NullPointerException

25.46 java.lang.NumberFormatException (JDK 1.0)

Signals an illegal number format.

```
public class NumberFormatException extends IllegalArgumentException {
    // Public Constructors
            public NumberFormatException();
            public NumberFormatException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException-> IllegalArgumentException->NumberFormatException

Thrown By:

BigDecimal(), BigDecimal.valueOf(), BigInteger(), Byte(), Byte.decode(), Byte.parseByte(), Byte.valueOf(), Color.decode(), Double(), Double.valueOf(), Float(), Float.valueOf(), Integer(), Integer.decode(), Integer.parseInt(), Integer.valueOf(), Long(), Long.parseLong(), Long.valueOf(), Short(), Short.decode(), Short.parseShort(), Short.valueOf()

25.48 java.lang.OutOfMemoryError (JDK 1.0)

Signals that the interpreter has run out of memory (and that garbage collection is unable to free any memory).

```
public class OutOfMemoryError extends VirtualMachineError {
    // Public Constructors
            public OutOfMemoryError();
            public OutOfMemoryError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->VirtualMachineError->OutOfMemoryError

25.52 java.lang.RuntimeException (JDK 1.0)

This exception type is not used directly, but serves as a superclass of a group of run-time exceptions that need not be declared in the `throws` clause of a method definition. These exceptions need not be declared because they are run-time conditions that can generally occur in any Java method. Thus, declaring them would be unduly burdensome, and Java does not require it.

```
public class RuntimeException extends Exception {
    // Public Constructors
            public RuntimeException();
            public RuntimeException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException

Extended By:

ArithmeticException, ArrayStoreException, ClassCastException, EmptyStackException, IllegalArgumentException, IllegalMonitorStateException, IllegalStateException, IndexOutOfBoundsException, MissingResourceException, NegativeArraySizeException, NoSuchElementException, NullPointerException, SecurityException

25.53 java.lang.SecurityException (JDK 1.0)

Signals that an operation is not permitted for security reasons.

```
public class SecurityException extends RuntimeException {
    // Public Constructors
            public SecurityException();
            public SecurityException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException->SecurityException

Thrown By:

Beans.setDesignTime(), Beans.setGuiAvailable(), Class.getConstructor(), Class.getConstructors(), Class.getDeclaredClasses(), Class.getDeclaredConstructor(), Class.getDeclaredConstructors(), Class.getDeclaredField(), Class.getDeclaredFields(), Class.getDeclaredMethod(), Class.getDeclaredMethods(), Class.getField(), Class.getFields(), Class.getMethod(), Class.getMethods(), ObjectInputStream.enableResolveObject(), ObjectOutputStream.enableReplaceObject()

25.56 java.lang.StackOverflowError (JDK 1.0)

Signals that a stack overflow has occurred within the Java interpreter.

```
public class StackOverflowError extends VirtualMachineError {
    // Public Constructors
            public StackOverflowError();
            public StackOverflowError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->VirtualMachineError->StackOverflowError

25.59 java.lang.StringIndexOutOfBoundsException (JDK 1.0)

Signals that the index used to access a character of a `String` or `StringBuffer` is less than zero or is too large.

```
public class StringIndexOutOfBoundsException extends IndexOutOfBoundsException {
    // Public Constructors
            public StringIndexOutOfBoundsException();
            public StringIndexOutOfBoundsException(String s);
            public StringIndexOutOfBoundsException(int index);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->RuntimeException-> IndexOutOfBoundsException->StringIndexOutOfBoundsException

25.62 java.lang.ThreadDeath (JDK 1.0)

Signals that a thread should terminate. This error is thrown in a thread when the `Thread.stop()` method is called for that thread. This is an unusual `Error` type that simply causes a thread to be terminated, but does not print an error message or cause the interpreter to exit. You may catch `ThreadDeath` errors to do any necessary cleanup for a thread, but if you do, you must re-throw the error, so that the thread actually terminates.

```
public class ThreadDeath extends Error {
    // Default Constructor: public ThreadDeath()
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->ThreadDeath

25.65 java.lang.UnknownError (JDK 1.0)

Signals that an unknown error has occurred at the level of the Java Virtual Machine.

```
public class UnknownError extends VirtualMachineError {
    // Public Constructors
            public UnknownError();
            public UnknownError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->VirtualMachineError->UnknownError

25.66 java.lang.UnsatisfiedLinkError (JDK 1.0)

Signals that Java cannot satisfy all of the links in a class that it has loaded.

```
public class UnsatisfiedLinkError extends LinkageError {
    // Public Constructors
            public UnsatisfiedLinkError();
            public UnsatisfiedLinkError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->UnsatisfiedLinkError

25.67 java.lang.VerifyError (JDK 1.0)

Signals that a class has not passed the byte-code verification procedures.

```
public class VerifyError extends LinkageError {
    // Public Constructors
            public VerifyError();
            public VerifyError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->LinkageError->VerifyError

25.68 java.lang.VirtualMachineError (JDK 1.0)

An abstract error type that serves as superclass for a group of errors related to the Java Virtual Machine. See `InternalError`, `UnknownError`, `OutOfMemoryError`, and `StackOverflowError`.

```
public abstract class VirtualMachineError extends Error {
    // Public Constructors
            public VirtualMachineError();
            public VirtualMachineError(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Error->VirtualMachineError

Extended By:

InternalError, OutOfMemoryError, StackOverflowError, UnknownError

24.22 java.io.FileWriter (JDK 1.1)

`FileWriter` is a convenience subclass of `OutputStreamWriter` that is useful when you want to write text (as opposed to binary data) to a file. You create a `FileWriter` by specifying the file to be written to, and optionally specifying whether the data should be appended to the end of an existing file instead of overwriting that file.

The `FileWriter` class creates an internal `FileOutputStream` to write bytes to the specified file, and uses the functionality of its superclass, `OutputStreamWriter`, to convert the Unicode characters written to the stream characters into bytes using the default encoding of the default locale. (If you want to use an encoding other than the default, you cannot use `FileWriter`; in that case you must create your own `OutputStreamWriter` and `FileOutputStream`.)

Because `FileWriter` is a trivial subclass of `OutputStreamWriter`, it does not define any methods of its own, but simply inherits them from its superclass.

```
public class FileWriter extends OutputStreamWriter {
    // Public Constructors
            public FileWriter(String fileName) throws IOException;
            public FileWriter(String fileName, boolean append) throws IOException;
            public FileWriter(File file) throws IOException;
            public FileWriter(FileDescriptor fd);
}
```

Hierarchy:

Object->Writer->OutputStreamWriter->FileWriter

28.14 java.net.ProtocolException (JDK 1.0)

Signals a protocol error in the `Socket` class.

```
public class ProtocolException extends IOException {
    // Public Constructors
            public ProtocolException(String host);
            public ProtocolException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ProtocolException

Thrown By:

HttpURLConnection.setRequestMethod()

28.17 java.net.SocketException (JDK 1.0)

Signals an exceptional condition while using a socket.

```
public class SocketException extends IOException {
    // Public Constructors
            public SocketException(String msg);
            public SocketException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->SocketException

Extended By:

BindException, ConnectException, NoRouteToHostException

Thrown By:

DatagramSocket(), DatagramSocket.getSoTimeout(), DatagramSocket.setSoTimeout(), DatagramSocketImpl.bind(), DatagramSocketImpl.create(), DatagramSocketImpl.getOption(), DatagramSocketImpl.setOption(), MulticastSocket.getInterface(), MulticastSocket.setInterface(), ServerSocket.setSoTimeout(), Socket(), Socket.getSoLinger(), Socket.getSoTimeout(), Socket.getTcpNoDelay(), Socket.setSoLinger(), Socket.setSoTimeout(), Socket.setTcpNoDelay(), SocketImpl.getOption(), SocketImpl.setOption()

19.6 java.awt.datatransfer.UnsupportedFlavorException (JDK 1.1)

An exception of this type signals that a `Transferable` object could not provide data in the requested format.

```
public class UnsupportedFlavorException extends Exception {
    // Public Constructor
            public UnsupportedFlavorException(DataFlavor flavor);
}
```

Hierarchy:

`Object->Throwable(Serializable)->Exception->UnsupportedFlavorException`

Thrown By:

`StringSelection.getTransferData(), Transferable.getTransferData()`

22.13 java.awt.peer.LightweightPeer (JDK 1.1)

```
public interface LightweightPeer extends ComponentPeer {
}
```

Returned By:

Toolkit.createComponent()

22.19 java.awt.peer.PanelPeer (JDK 1.0)

```
public interface PanelPeer extends ContainerPeer {
}
```

Hierarchy:

(PanelPeer(ContainerPeer(ComponentPeer)))

Returned By:

Toolkit.createPanel()

31.6 java.util.zip.DataFormatException (JDK 1.1)

Signals that invalid or corrupt data has been encountered while uncompressing data.

```
public class DataFormatException extends Exception {
    // Public Constructors
            public DataFormatException();
            public DataFormatException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->DataFormatException

Thrown By:

Inflater.inflate()

31.14 java.util.zip.ZipException (JDK 1.1)

Signals that an error has occurred in reading or writing a ZIP file.

```
public class ZipException extends IOException {
    // Public Constructors
            public ZipException();
            public ZipException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ZipException

Thrown By:

ZipFile()

24.9 java.io.CharConversionException (JDK 1.1)

This exception signals an error when converting bytes to characters or vice versa.

```
public class CharConversionException extends IOException {
    // Public Constructors
            public CharConversionException();
            public CharConversionException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->CharConversionException

24.14 java.io.EOFException (JDK 1.0)

An `IOException` that signals the end-of-file.

```
public class EOFException extends IOException {
    // Public Constructors
            public EOFException();
            public EOFException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->EOFException

24.19 java.io.FileNotFoundException (JDK 1.0)

An `IOException` that signals that a specified file cannot be found.

```
public class FileNotFoundException extends IOException {
    // Public Constructors
            public FileNotFoundException();
            public FileNotFoundException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->FileNotFoundException

Thrown By:

FileInputStream(), FileReader()

24.21 java.io.FileReader (JDK 1.1)

`FileReader` is a convenience subclass of `InputStreamReader` that is useful when you want to read text (as opposed to binary data) from a file. You create a `FileReader` by specifying the file to be read, in any of three possible forms. The `FileReader` constructor internally creates a `FileInputStream` to read bytes from the specified file, and uses the functionality of its superclass, `InputStreamReader`, to convert those bytes from characters in the local encoding to the Unicode characters used by Java.

Because `FileReader` is a trivial subclass of `InputStreamReader`, it does not define any `read()` methods or other methods of its own. Instead, it inherits all its methods from its superclass.

If you want to read Unicode characters from a file that uses some encoding other than the default encoding for the locale, you must explicitly create your own `InputStreamReader` to perform the byte-to-character conversion.

```
public class FileReader extends InputStreamReader {
    // Public Constructors
            public FileReader(String fileName) throws FileNotFoundException;
            public FileReader(File file) throws FileNotFoundException;
            public FileReader(FileDescriptor fd);
}
```

Hierarchy:

Object->Reader->InputStreamReader->FileReader

24.32 java.io.InvalidObjectException (JDK 1.1)

This exception should be thrown by the `validateObject()` method of an object that implements the `ObjectInputValidation` interface when a deserialized object fails an input validation test for any reason.

```
public class InvalidObjectException extends ObjectStreamException {
    // Public Constructor
            public InvalidObjectException(String reason);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException->InvalidObjectException

Thrown By:

ObjectInputStream.registerValidation(), ObjectInputValidation.validateObject()

24.33 java.io.IOException (JDK 1.0)

Signals that an exceptional condition has occurred during input or output. This class has several more specific subclasses. See `EOFException`, `FileNotFoundException`, `InterruptedIOException`, and `UTFDataFormatException`.

```
public class IOException extends Exception {
    // Public Constructors
            public IOException();
            public IOException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException

Extended By:

CharConversionException, EOFException, FileNotFoundException, InterruptedIOException, MalformedURLException, ObjectStreamException, ProtocolException, SocketException, SyncFailedException, UnknownHostException, UnknownServiceException, UnsupportedEncodingException, UTFDataFormatException, ZipException

Thrown By:

`Many methods`

java.io.InvalidObjectException (JDK 1.1) | BOOK INDEX | java.io.LineNumberInputStream (JDK 1.0; Deprecated.)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.36 java.io.NotActiveException (JDK 1.1)

This exception is thrown in several circumstances. It indicates that the invoked method was not invoked at the right time or in the correct context. Typically it means that an `ObjectOutputStream` or `ObjectInputStream` is not currently active, and therefore the requested operation could not be performed.

```
public class NotActiveException extends ObjectStreamException {
    // Public Constructors
            public NotActiveException(String reason);
            public NotActiveException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException->NotActiveException

Thrown By:

ObjectInputStream.defaultReadObject(), ObjectInputStream.registerValidation()

24.37 java.io.NotSerializableException (JDK 1.1)

This exception signals that an object could not be serialized. It is thrown when serialization is attempted on an instance of a class that does not implement the `Serializable` interface. Note that it is also thrown when an attempt is made to serialize a `Serializable` object that refers to (or "contains") an object that is not `Serializable`.

A subclass of a class that is `Serializable` can prevent itself from being serialized by throwing this exception from its `writeObject()` and/or `readObject()` methods.

```
public class NotSerializableException extends ObjectStreamException {
    // Public Constructors
            public NotSerializableException(String classname);
            public NotSerializableException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException->NotSerializableException

24.44 java.io.ObjectStreamException (JDK 1.1)

This class is the superclass of a number of more specific exception types that may be raised in the process of serializing and deserializing objects with the `ObjectOutputStream` and `ObjectInputStream` classes.

```
public abstract class ObjectStreamException extends IOException {
    // Protected Constructors
            protected ObjectStreamException(String classname);
            protected ObjectStreamException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException

Extended By:

InvalidClassException, InvalidObjectException, NotActiveException, NotSerializableException, OptionalDataException, StreamCorruptedException, WriteAbortedException

24.59 java.io.Serializable (JDK 1.1)

The `Serializable` interface defines no methods or constants. A class should implement this interface simply to indicate that it allows itself to be serialized and deserialized with `ObjectOutputStream.writeObject()` and `ObjectInputStream.readObject()`.

Objects that need special handling during serialization or deserialization may implement one or both of the following methods. Note, however, that these methods are not part of the `Serializable` interface:

```
private void writeObject(java.io.ObjectOutputStream out)
                  throws IOException
private void readObject(java.io.ObjectInputStream in)
                    throws IOException, ClassNotFoundException;
```

Typically the `writeObject()` method performs any necessary cleanup or preparation for serialization, invokes the `defaultWriteObject()` method of the `ObjectOutputStream` to serialize the non-`transient` fields of the class, and then optionally writes any additional data that are required. Similarly, the `readObject()` method typically invokes the `defaultReadObject()` method of the `ObjectInputStream`, reads any additional data written by the corresponding `writeObject()` method, and finally performs any extra initialization required by the object. The `readObject()` method may also register an `ObjectInputValidation` object to validate the object once it is completely deserialized.

```
public interface Serializable {
}
```

Extended By:

Externalizable

Implemented By:

BitSet, Boolean, BorderLayout, BreakIterator, Calendar, CardLayout, Character, CheckboxGroup, Class, Collator, Color, Component, Cursor, Date, DateFormatSymbols, DecimalFormatSymbols, Dimension, Event, EventObject, File, FlowLayout, Font, FontMetrics, Format, GridBagConstraints, GridBagLayout, GridLayout, Hashtable, InetAddress, Insets, Locale, MediaTracker, MenuComponent, MenuShortcut, Number, ObjectStreamClass, Point, Polygon, PropertyChangeSupport, Random, Rectangle, String, StringBuffer, SystemColor, Throwable, TimeZone, URL, Vector, VetoableChangeSupport

java.io.SequenceInputStream (JDK 1.0) | BOOK INDEX | java.io.StreamCorruptedException (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

24.60 java.io.StreamCorruptedException (JDK 1.1)

This exception signals that the data stream being read by an `ObjectInputStream` has been corrupted and does not contain valid serialized object data.

```
public class StreamCorruptedException extends ObjectStreamException {
    // Public Constructors
            public StreamCorruptedException(String reason);
            public StreamCorruptedException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->ObjectStreamException->StreamCorruptedException

Thrown By:

ObjectInputStream(), ObjectInputStream.readStreamHeader()

24.65 java.io.SyncFailedException (JDK 1.1)

Signals that a call to `FileDescriptor.sync()` did not complete successfully.

```
public class SyncFailedException extends IOException {
    // Public Constructor
            public SyncFailedException(String desc);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->SyncFailedException

Thrown By:

FileDescriptor.sync()

24.66 java.io.UnsupportedEncodingException (JDK 1.1)

This exception signals that a requested character encoding is not supported by the current Java Virtual Machine.

```
public class UnsupportedEncodingException extends IOException {
    // Public Constructors
            public UnsupportedEncodingException();
            public UnsupportedEncodingException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->UnsupportedEncodingException

Thrown By:

ByteArrayOutputStream.toString(), InputStreamReader(), OutputStreamWriter(), String(), String.getBytes()

24.67 java.io.UTFDataFormatException (JDK 1.0)

An IOException that signals that a malformed UTF-8 string has been encountered by a class that implements the DataInput interface. UTF-8 is an ASCII-compatible "transformation format" for Unicode characters that is often used to store and transmit Unicode text.

```
public class UTFDataFormatException extends IOException {
    // Public Constructors
            public UTFDataFormatException();
            public UTFDataFormatException(String s);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->UTFDataFormatException

11. Internationalization

Contents:

Internationalization is the process of making a program flexible enough to run correctly in any locale, as discussed in Chapter 4, *What's New in Java 1.1*. The required corollary to internationalization is localization--the process of arranging for a program to run in a specific locale.

There are several distinct steps to the task of internationalization. Java 1.1 addresses these steps with several different mechanisms:

- A program must be able to read, write, and manipulate localized text. Java uses the Unicode character encoding, which by itself is a huge step towards internationalization. In addition, in Java 1.1 the `InputStreamReader` and `OutputStreamWriter` classes convert text from a locale-specific encoding to Unicode and from Unicode to a locale-specific encoding, respectively.

- A program must conform to local customs when displaying dates and times, formatting numbers, and sorting strings. Java addresses these issues with the classes in the new `java.text` package.

- A program must display all user-visible text in the local language. Translating the messages a program displays is always one of the main tasks in localizing a program. A more important task is writing the program so that all user-visible text is fetched at runtime, rather than hard-coded directly into the program. Java 1.1 facilitates this process with the `ResourceBundle` class and its subclasses in the `java.util` package.

This chapter discusses all three of these aspects of internationalization.

11.1 A Word About Locales

A locale represents a geographic, political, or cultural region. In Java 1.1, locales are represented by the `java.util.Locale` class. A locale is frequently defined by a language, which is represented by its standard lowercase two-letter code, such as en (English) or fr (French). Sometimes, however, language alone is not sufficient to uniquely specify a locale, and a country is added to the specification. A country is represented by an uppercase two-letter code. For example, the United States English locale (en_US) is distinct from the British English locale (en_GB), and the French spoken in Canada (fr_CA) is different from the French spoken in France (fr_FR). Occasionally, the scope of a locale is further narrowed with the addition of a system-dependent "variant" string.

The `Locale` class maintains a static default locale, which can be set and queried with `Locale.setDefault()` and `Locale.getDefault()`. Locale-sensitive methods in Java 1.1 typically come in two forms. One uses the default locale and the other uses a `Locale` object that is explicitly specified as an argument. A program can create and use any number of non-default `Locale` objects, although it is more common simply to rely on the default locale, which is inherited from the underlying default locale on the native platform. Locale-sensitive classes in Java often provide a method to query the list of locales that they support.

Finally, note that AWT components in Java 1.1 have a locale property, so it is possible for different components to use different locales. (Most components, however, are not locale-sensitive; they behave the same in any locale.)

23.8 java.beans.IntrospectionException (JDK 1.1)

Signals that introspection on a Java bean could not be completed. Typically this indicates a bug in the way the bean or its associated `BeanInfo` class is defined.

```
public class IntrospectionException extends Exception {
    // Public Constructor
            public IntrospectionException(String mess);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IntrospectionException

Thrown By:

EventSetDescriptor(), IndexedPropertyDescriptor(), Introspector.getBeanInfo(), PropertyDescriptor()

23.11 java.beans.ParameterDescriptor (JDK 1.1)

A `ParameterDescriptor` object is a type of `FeatureDescriptor` that describes an argument or parameter to a method of a Java bean. The `BeanInfo` class for a Java bean optionally creates `ParameterDescriptor` objects that describe the parameters of the methods that the bean exports. While the `BeanInfo` class creates and initializes `ParameterDescriptor` objects, it is typically only application builders and similar tools that use these objects to obtain information about method parameters supported by the bean.

The `ParameterDescriptor` class is a trivial subclass of `FeatureDescriptor`, and does not provide any new methods. Thus, you should use the methods of `FeatureDescriptor` to provide information about method parameters.

```
public class ParameterDescriptor extends FeatureDescriptor {
    // Default Constructor: public ParameterDescriptor()
}
```

Hierarchy:

Object->FeatureDescriptor->ParameterDescriptor

Passed To:

MethodDescriptor()

Returned By:

MethodDescriptor.getParameterDescriptors()

NEXT java.beans.PropertyChangeEvent (JDK 1.1)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

28.2 java.net.ConnectException (JDK 1.1)

This exception signals that a socket could not be connected to a remote address and port. This means that the remote host could be reached, but is not responding, perhaps because there is no process on that host that is listening on the specified port.

```
public class ConnectException extends SocketException {
    // Public Constructors
            public ConnectException(String msg);
            public ConnectException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->SocketException->ConnectException

28.11 java.net.MalformedURLException (JDK 1.0)

Signals that an unparseable URL specification has been passed to a method.

```
public class MalformedURLException extends IOException {
    // Public Constructors
            public MalformedURLException();
            public MalformedURLException(String msg);
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->MalformedURLException

Thrown By:

URL(default.htm)

28.13 java.net.NoRouteToHostException (JDK 1.1)

This exception signals that a socket could not be connected to a remote host, because the host could not be contacted. Typically this means that some link in the network between the local machine and the remote host is down, or that the host is behind a firewall.

```
public class NoRouteToHostException extends SocketException {
    // Public Constructors
            public NoRouteToHostException(String msg);
            public NoRouteToHostException();
}
```

Hierarchy:

Object->Throwable(Serializable)->Exception->IOException->SocketException->NoRouteToHostException

22.2 java.awt.peer.CanvasPeer (JDK 1.0)

```
public interface CanvasPeer extends ComponentPeer {
}
```

Returned By:

Toolkit.createCanvas()

22.10 java.awt.peer.FontPeer (JDK 1.1)

```
public interface FontPeer {
}
```

Returned By:

Font.getPeer(), Toolkit.getFontPeer()

10.9 Naming Patterns and Conventions

As we've seen, beanbox programs may rely on introspection of a bean to determine the list of properties, events, and methods it supports. In order for this to work, bean developers must follow a set of standard naming conventions, sometimes referred to as JavaBeans "design patterns." These patterns specify, for example, that the getter and setter accessor methods for a property should begin with `get` and `set`. Not all of the patterns are absolute requirements. If a bean has accessor methods with different names, it is possible to use a `PropertyDescriptor` object, specified in a `BeanInfo` class, to specify the accessor methods for the property. Note, however, that although an accessor method name is not required to follow the pattern, the method is required to have the exact type signature specified by the pattern.

This section lists the design patterns for bean properties, events, and methods. It also lists other conventions and requirements that you should keep in mind when developing beans.

Java Bean Patterns

Beans

class name:

Any

superclass:

Any

constructor:

Must have a no-argument constructor, or a serialized template file

packaging:

JAR file manifest entry specifies `Java-Bean: True`

Properties (property *p* of type *T*)

getter:

```
public T getP()
```

setter:

```
public void setP(T value)
```

Boolean Properties (property *p* of type boolean)

getter:

```
public boolean getP()
```

(boolean value)

or `public boolean is P()` setter:

```
public void setP
```

Indexed Properties (property *p* of type *T*[])

array getter:

```
public T[] getP()
```

array setter:

```
public void setP(T[] value)
```

element getter:

```
public T getP(int index)
```

element setter:

```
public void setP(int index, T value)
```

Bound Properties (property *p* of type *T*)

getter:

Same as regular property

setter:

Same as regular property

listeners:

One event listener list for all bound properties of a bean

listener registration:

```
public void addPropertyChangeListener (PropertyChangeListener l)
```

listener removal:

```
public void removePropertyChangeListener (PropertyChangeListener l)
```

Constrained Properties (property *p* of type *T*)

getter:

Same as regular property

setter:

```
public void setP(T value)
                                      throws PropertyVetoException
```

listeners:

One event listener list for all constrained properties of a bean

listener registration:

```
public void addVetoableChangeListener (VetoableChangeListener l)
```

listener removal:

```
public void removeVetoableChangeListener
            (VetoableChangeListener l)
```

Events (event named *E*)

event class name:

```
EEvent
```

listener name:

```
EListener
```

listener methods:

```
public void methodname(EEvent e)
```

listener registration:

```
public void addEListener(EListener l)
```

listener removal:

```
public void removeEListener(EListener l)
```

Unicast Events (event named *E* only one listener allowed)

listener registration:

```
public void addEListener(EListener l)
       throws TooManyListenersException
```

listener removal:

```
public void removeEListener(EListener l)
```

Methods

method name:

Any

method args:

Any; some tools only recognize no-argument methods

BeanInfo Classes (for bean *B*)

class name:

`*B*BeanInfo`

Property Editors (for properties of type *T*)

class name:

`*T*Editor`

constructor:

Must have a no-argument constructor

Property Editors (for individual properties)

class name:

Any; register via *PropertyDescriptor*

constructor:

Must have a no-argument constructor

Customizers (for bean *B*)

class name:

Any; register via *BeanDescriptor* (*BCustomizer* by convention)

superclass:

Must be a component; typically extends *Panel* *constructor:*

Must have a no-argument constructor

Documentation File (for bean *B*)

default docs:

`B.html`

localized docs:

`locale/B.html`

11.2 Unicode

Java uses the Unicode character encoding. Java 1.0 used Unicode version 1.1, while Java 1.1 has adopted the newer Unicode 2.0 standard. Unicode is a 16-bit character encoding established by the Unicode Consortium, which describes the standard as follows (see http://unicode.org):

> The Unicode Worldwide Character Standard is a character coding system designed to support the interchange, processing, and display of the written texts of the diverse languages of the modern world. In addition, it supports classical and historical texts of many written languages.
>
> In its current version (2.0), the Unicode standard contains 38,885 distinct coded characters derived from 25 supported scripts. These characters cover the principal written languages of the Americas, Europe, the Middle East, Africa, India, Asia, and Pacifica.

In the canonical form of the Unicode encoding, which is what Java `char` and `String` types use, every character occupies two bytes. The Unicode characters \u0020 to \u007E are equivalent to the ASCII and ISO8859-1 (Latin-1) characters 0x20 through 0x7E. The Unicode characters \u00A0 to \u00FF are identical to the ISO8859-1 characters 0xA0 to 0xFF. Thus there is a trivial mapping between Latin-1 and Unicode characters. A number of other portions of the Unicode encoding are based on pre-existing standards, such as ISO8859-5 (Cyrillic) and ISO8859-8 (Hebrew), though the mappings between these standards and Unicode may not be as trivial as the Latin-1 mapping.

Note that Unicode support is quite limited on many platforms. One of the difficulties with the use of Unicode is the poor availability of fonts to display all of the Unicode characters. Figure 11.1 shows the characters that are available on a typical configuration of the U.S. English Windows 95 platform. Note the special box glyph used to indicate undefined characters.

Figure 11.1: Some Unicode characters and their encodings

[Graphic: Figure 11-1]

Unicode is similar to, but not the same as, ISO 10646, the UCS (Universal Character Set) encoding. UCS is a 2- or 4-byte encoding originally intended to contain all national standard character encodings. For example, it was to include the separate Chinese, Japanese, Korean, and Vietnamese encodings for Han ideographic characters. Unicode, in contrast, "unifies" these disparate encodings into a single set of Han characters that work for all four countries. Unicode has been so successful, however, that ISO 10646 has adopted it in place of non-unified encodings. Thus, ISO 10646 is effectively Unicode, with the option of two extra bytes for expansion purposes.

Unicode is a trademark of the Unicode Consortium. Version 2.0 of the standard is defined by the book *The Unicode Standard, Version 2.0* (published by Addison-Wesley, ISBN 0-201-48345-9). Further information about the Unicode standard and the Unicode Consortium can be obtained at http://unicode.org/.

Table 11.1 provides an overview of the Unicode 2.0 encoding.

Table 11.1: Outline of the Unicode 2.0 Encoding

Start	End	Description
0000	1FFF	**Alphabets**
0000	007F	Basic Latin

FFF0	FFFF	Specials

Unicode and Local Encodings

While Java programs use Unicode text internally, Unicode is not the customary character encoding for most countries or locales. Thus, an important requirement for Java programs is to be able to convert text from the local encoding to Unicode as it is read (from a file or network, for example) and to be able to convert text from Unicode to the local encoding as it is written. In Java 1.0, this requirement is not well supported. In Java 1.1, however, the conversion can be done with the `java.io.InputStreamReader` and `java.io.OutputStreamWriter` classes, respectively. These classes load an appropriate `ByteToCharConverter` or `CharToByteConverter` class to perform the conversion. Note that these converter classes are part of the `sun.io` package and are not for public use (although an explicit conversion interface may be defined in a later release of Java).

The UTF-8 Encoding

The canonical two-bytes per character encoding is useful for the manipulation of character data and is the internal representation used throughout Java. However, because a large amount of text used by Java programs is 8-bit text, and because there are so many existing computer systems that support only 8-bit characters, the 16-bit canonical form is usually not the most efficient way to store Unicode text nor the most portable way to transmit it.

Because of this, other encodings called "transformation formats" have been developed. Java provides simple support for the UTF-8 encoding with the `DataInputStream.readUTF()` and `DataOutputStream.writeUTF()` methods. UTF-8 is a variable-width or "multi-byte" encoding format; this means that different characters require different numbers of bytes. In UTF-8, the standard ASCII characters occupy only one byte, and remain untouched by the encoding (i.e., a string of ASCII characters is a legal UTF-8 string). As a tradeoff, however, other Unicode characters occupy two or three bytes.

In UTF-8, Unicode characters between `\u0000` and `\u007F` occupy a single byte, which has a value of between `0x00` and `0x7F`, and which always has its high-order bit set to `0`. Characters between `\u0080` and `\u07FF` occupy two bytes, and characters between `\u0800` and `\uFFFF` occupy three bytes. The first byte of a two-byte character always has high-order bits `110`, and the first byte of a three-byte character always has high-order bits `1110`. Since single-byte characters always have 0 as their high-order bit, the one-, two-, and three-byte characters can easily be distinguished from each other.

The second and third bytes of two- and three-byte characters always have high-order bits `10`, which distinguishes them from one-byte characters, and also distinguishes them from the first byte of a two- or three-byte sequence. This is important because it allows a program to locate the start of a character in a multi-byte sequence.

The remaining bits in each character (i.e., the bits that are not part of one of the required high-order bit sequences) are used to encode the actual Unicode character data. In the single-byte form, there are seven bits available, suitable for encoding characters up to `\u007F`. In the two-byte form, there are 11 data bits available, which is enough to encode values to `\u07FF`, and in the three-byte form there are 16 available data bits, which is enough to encode all 16-bit Unicode characters. Table 11.2 summarizes the UTF-8 encoding.

Table 11.2: The UTF-8 Encoding

Start Character	**End Character**	**Required Data Bits**	**Binary Byte Sequence (`x` = data bits)**
\u0000	\u007F	7	0xxxxxxx
\u0080	\u07FF	11	110xxxxx 10xxxxxx
\u0800	\uFFFF	16	1110xxxx 10xxxxxx 10xxxxxx

The UTF-8 has the following desirable features:

- All ASCII characters are one-byte UTF-8 characters. A legal ASCII string is a legal UTF-8 string.
- Any non-ASCII character (i.e., any character with the high-order bit set) is part of a multi-byte

character.

- The first byte of any UTF-8 character indicates the number of additional bytes in the character.
- The first byte of a multi-byte character is easily distinguished from the subsequent bytes. Thus, it is easy to locate the start of a character from an arbitrary position in a data stream.
- It is easy to convert between UTF-8 and Unicode.
- The UTF-8 encoding is relatively compact. For text with a large percentage of ASCII characters, it is more compact than Unicode. In the worst case, a UTF-8 string is only 50% larger than the corresponding Unicode string.

Java actually uses a slightly modified form of UTF-8. The Unicode character `\u0000` is encoded using a two-byte sequence, so that an encoded Unicode string never contains null characters.

11.3 Character Encodings

Text representation has traditionally been one of the most difficult problems of internationalization. Java 1.1, however, solves this problem quite elegantly and hides the difficult issues. Java uses Unicode internally, so it can represent essentially any character in any commonly used written language. As noted above, the remaining task is to convert Unicode to and from locale-specific encodings. Java 1.1 includes quite a few internal "byte-to-char" converters and "char-to-byte" converters that handle converting locale-specific character encodings to Unicode and vice versa. While the converters themselves are not public, they are accessed through the `InputStreamReader` and `OutputStreamWriter` classes, which are two of the new character streams included in the `java.io` package.

Any program can automatically handle locale-specific encodings simply by using these new character stream classes to do their textual input and output. (And in addition to automatic encoding conversion, the program also benefits from the greatly improved efficiency of these new classes over the byte streams of Java 1.0.)

Example 11.1 shows a simple program that works with character encodings. It converts a file from one specified encoding to another by converting from the first encoding to Unicode and then from Unicode to the second encoding. Note that most of the program is taken up with the mechanics of parsing argument lists, handling exceptions, and so on. Only a few lines are required to create the `InputStreamReader` and `OutputStreamWriter` classes that perform the two halves of the conversion. Also note that exceptions are handled by calling `LocalizedError.display()`. This method is not part of the Java 1.1 API; it is a custom method shown in Example 11.6 at the end of this chapter.

Example 11.1: Working with Character Encodings

```
import java.io.*;
/** A program to convert from one character encoding to another. */
public class ConvertEncoding {
  public static void main(String[] args) {
    String from = null, to = null;
    String infile = null, outfile = null;
    for(int i = 0; i < args.length; i++) {  // Parse command-line arguments.
      if (i == args.length-1) usage();      // All legal args require another.
      if (args[i].equals("-from")) from = args[++i];
      else if (args[i].equals("-to")) to = args[++i];
      else if (args[i].equals("-in")) infile = args[++i];
      else if (args[i].equals("-out")) outfile = args[++i];
      else usage();
    }
    try { convert(infile, outfile, from, to); }  // Attempt conversion.
    catch (Exception e) {                        // Handle possible exceptions.
      LocalizedError.display(e);  // Defined at the end of this chapter.
      System.exit(1);
    }
  }
  public static void usage() {
    System.err.println("Usage: java ConvertEncoding <options>\n" +
                       "Options:\n\t-from <encoding>\n\t-to <encoding>\n\t" +
                       "-in <file>\n\t-out <file>");
    System.exit(1);
  }
  public static void convert(String infile, String outfile,
                             String from, String to)
       throws IOException, UnsupportedEncodingException
  {
    // Set up byte streams.
    InputStream in;
    if (infile != null) in = new FileInputStream(infile);
    else in = System.in;
    OutputStream out;
    if (outfile != null) out = new FileOutputStream(outfile);
    else out = System.out;
    // Use default encoding if no encoding is specified.
    if (from == null) from = System.getProperty("file.encoding");
    if (to == null) to = System.getProperty("file.encoding");
    // Set up character streams.
    Reader r = new BufferedReader(new InputStreamReader(in, from));
    Writer w = new BufferedWriter(new OutputStreamWriter(out, to));
    // Copy characters from input to output.  The InputStreamReader converts
    // from the input encoding to Unicode, and the OutputStreamWriter converts
    // from Unicode to the output encoding.  Characters that cannot be
    // represented in the output encoding are output as '?'
    char[] buffer = new char[4096];
    int len;
    while((len = r.read(buffer)) != -1)  // Read a block of input.
      w.write(buffer, 0, len);           // And write it out.
    r.close();                           // Close the input.
    w.flush();                           // Flush and close output.
    w.close();
  }
}
```

11.4 Handling Local Customs

The second problem of internationalization is the task of following local customs and conventions in areas like date and time formatting. The `java.text` package defines classes to help with this duty.

The `NumberFormat` class is used to format numbers, monetary amounts, and percentages in a locale-dependent way for display to the user. This is necessary because different locales have different conventions for number formatting. For example, in France, a comma is used as a decimal separator instead of a period, as used in many English speaking countries. A `NumberFormat` object can use the default locale or any locale you specify.

The `DateFormat` class is used to format dates and times in a locale-dependent way for display to the user. Different countries have different conventions. Should the month or day be displayed first? Should periods or colons be used to separate fields of the time? What are the names of the months in the language of the locale? A `DateFormat` object can simply use the default locale or it can use any locale you specify. The `DateFormat` class is used in conjunction with the `TimeZone` and `Calendar` classes of `java.util`. The `TimeZone` object tells the `DateFormat` what time zone the date should be interpreted in, while the `Calendar` object specifies how the date itself should be broken down into days, weeks, months, and years. Almost all locales use the standard `GregorianCalendar`.

The `Collator` class is used to compare strings in a locale-dependent way. This is necessary because different languages "alphabetize" strings in different ways (and some languages don't even use alphabets). In traditional Spanish, for example, the letters "ch" are treated as a single character that comes between "c" and "d" for the purposes of sorting. When you need to sort strings or search for a string within Unicode text, you should use a `Collator` object, either one created to work with the default locale or one created for a specified locale.

The `BreakIterator` class allows you to locate character, word, line, and sentence boundaries in a locale-dependent way. This is useful when you need to recognize such boundaries in Unicode text, as when you are implementing a word-wrapping algorithm.

Example 11.3 shows a class that uses the `NumberFormat` and `DateFormat` classes to display a hypothetical stock portfolio to the user following local conventions. The program uses various `NumberFormat` and `DateFormat` objects to format (using the `format()` method) different types of numbers and dates. These `Format` objects all operate using the default locale, but could have been created with an explicitly specified locale. Example 11.2 shows the output of this program in American, Canadian, and French locales. Note the different treatment of dates, numbers, and monetary quantities in these three locales.

Example 11.2: Dates and Numbers Formatted for Three Locales

```

Example 11.3: Formatting Dates and Numbers in an Internationalized Program

```
import java.text.*;
import java.util.Date;
/**
 * A partial implementation of a hypothetical stock portfolio class.
 * We use it only to demonstrate number and date internationalization.
 */
public class Portfolio {
  EquityPosition[] positions;
  Date lastQuoteTime = new Date();
  public void print() {
    // Obtain NumberFormat and DateFormat objects to format our data.
    NumberFormat number = NumberFormat.getInstance();
    NumberFormat price = NumberFormat.getCurrencyInstance();
    NumberFormat percent = NumberFormat.getPercentInstance();
    DateFormat shortdate = DateFormat.getDateInstance(DateFormat.SHORT);
    DateFormat fulldate = DateFormat.getDateTimeInstance(DateFormat.LONG,
                                                         DateFormat.LONG);
    // Print some introductory data.
    System.out.println("Portfolio value at " +
                       fulldate.format(lastQuoteTime) + ":");
    System.out.println("Symbol\tShares\tBought On\tAt\t" +
                       "Quote\tChange");
    // Then display the table using the format() methods of the Format objects.
    for(int i = 0; i < positions.length; i++) {
      System.out.print(positions[i].name + "\t");
      System.out.print(number.format(positions[i].shares) + "\t");
      System.out.print(shortdate.format(positions[i].purchased) + "\t");
      System.out.print(price.format(positions[i].bought) + "\t");
      System.out.print(price.format(positions[i].current) + "\t");
      double change =
        (positions[i].current - positions[i].bought)/positions[i].bought;
      System.out.println(percent.format(change));
    }
  }
  static class EquityPosition {
    String name;             // Name of the stock.
    int shares;              // Number of shares held.
    Date purchased;          // When purchased.
    double bought, current;  // Purchase price and current price (per share).
    EquityPosition(String n, int s, Date when, double then, double now) {
      name = n; shares = s; purchased = when; bought = then; current = now;
    }
  }
}

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

10.2 A Simple Bean

As noted above, the AWT components in Java 1.1 can all function as beans. When you write a custom GUI component, it is not difficult to make it function as a bean as well. Example 10.1 shows the definition of a custom component, `MultiLineLabel`, that is also a bean. This component is like the standard `Label` component, but it can display labels that contain more than one line of text.

Much of the code in this example is taken up with the mechanics of breaking the label into separate lines and measuring the size of each of those lines. From the standpoint of custom AWT components, however, the most important code is in several required methods that make any component work correctly. First, there is the `paint()` method, of course. All components (including applets) use this method to display themselves on the screen. Second, the `getPreferredSize()` and `getMinimumSize()` methods return the preferred and minimum sizes for the component. These methods must be implemented so that layout managers can correctly lay the component out. (Note, though, that for compatibility with Java 1.0, this example defines the deprecated `preferredSize()` and `minimumSize()` methods instead.)

`MultiLineLabel` extends `Canvas`, which is a blank component intended primarily for subclassing. When a component is a subclass of `Canvas`, it is typically given its own native window in the underlying window system. In Java 1.1, however, it is possible to define "lightweight" custom components by extending `Component` instead of `Canvas`. A lightweight component does not have its own native window in the underlying window system.

What makes this component a bean is that all of its properties have `get` and `set` accessor methods. Because `MultiLineLabel` does not respond to user input in any way, it does not define any events, so there are no event listener registration methods required. Although it is not a formal requirement for a bean, most beanboxes attempt to instantiate a bean by invoking its no-argument constructor. Thus, a bean should define a constructor that expects no arguments.

Example 10.1: A Custom AWT Component and JavaBean

```
package oreilly.beans.yesno;
import java.awt.*;
import java.util.*;
/**
 * A custom component that displays multiple lines of text with specified
 * margins and alignment.  In Java 1.1, we could extend Component instead
 * of Canvas, making this a more efficient "Lightweight component."
 */
public class MultiLineLabel extends Canvas {
  // User-specified attributes
  protected String label;             // The label, not broken into lines
  protected int margin_width;         // Left and right margins
  protected int margin_height;        // Top and bottom margins
  protected int alignment;            // The alignment of the text
  public static final int LEFT = 0, CENTER = 1, RIGHT = 2; // alignment values
  // Computed state values
  protected int num_lines;            // The number of lines
  protected String[] lines;           // The label, broken into lines
  protected int[] line_widths;        // How wide each line is
  protected int max_width;            // The width of the widest line
  protected int line_height;          // Total height of the font
  protected int line_ascent;          // Font height above baseline
  protected boolean measured = false; // Have the lines been measured?
  // Here are five versions of the constructor.
  public MultiLineLabel(String label, int margin_width,
                        int margin_height, int alignment) {
    this.label = label;                 // Remember all the properties.
    this.margin_width = margin_width;
    this.margin_height = margin_height;
    this.alignment = alignment;
    newLabel();                         // Break the label up into lines.
  }
  public MultiLineLabel(String label, int margin_width, int margin_height) {
    this(label, margin_width, margin_height, LEFT);
  }
  public MultiLineLabel(String label, int alignment) {
    this(label, 10, 10, alignment);
  }
  public MultiLineLabel(String label) { this(label, 10, 10, LEFT); }
  public MultiLineLabel() { this(""); }
  // Methods to set and query the various attributes of the component.
  // Note that some query methods are inherited from the superclass.
  public void setLabel(String label) {
    this.label = label;
    newLabel();               // Break the label into lines.
    measured = false;         // Note that we need to measure lines.
    repaint();                // Request a redraw.
  }
  public void setFont(Font f) {
    super.setFont(f);         // Tell our superclass about the new font.
    measured = false;         // Note that we need to remeasure lines.
    repaint();                // Request a redraw.
  }
  public void setForeground(Color c) {
    super.setForeground(c);   // Tell our superclass about the new color.
    repaint();                // Request a redraw (size is unchanged).
  }
  public void setAlignment(int a) { alignment = a; repaint(); }
  public void setMarginWidth(int mw) { margin_width = mw; repaint(); }
  public void setMarginHeight(int mh) { margin_height = mh; repaint(); }
  public String getLabel() { return label; }
  public int getAlignment() { return alignment; }
  public int getMarginWidth() { return margin_width; }
  public int getMarginHeight() { return margin_height; }
  /**
   * This method is called by a layout manager when it wants to
   * know how big we'd like to be.  In Java 1.1, getPreferredSize() is
   * the preferred version of this method.  We use this deprecated version
   * so that this component can interoperate with 1.0 components.
   */
  public Dimension preferredSize() {
    if (!measured) measure();
    return new Dimension(max_width + 2*margin_width,
                         num_lines * line_height + 2*margin_height);
  }
  /**
   * This method is called when the layout manager wants to know
   * the bare minimum amount of space we need to get by.
   * For Java 1.1, we'd use getMinimumSize().
   */
  public Dimension minimumSize() { return preferredSize(); }
  /**
   * This method draws the label (same method that applets use).
   * Note that it handles the margins and the alignment, but that
   * it doesn't have to worry about the color or font--the superclass
   * takes care of setting those in the Graphics object we're passed.
   */
  public void paint(Graphics g) {
    int x, y;
    Dimension size = this.size();  // Use getSize() in Java 1.1.
    if (!measured) measure();
    y = line_ascent + (size.height - num_lines * line_height)/2;
    for(int i = 0; i < num_lines; i++, y += line_height) {
      switch(alignment) {
      default:
      case LEFT:    x = margin_width; break;
      case CENTER:  x = (size.width - line_widths[i])/2; break;
      case RIGHT:   x = size.width - margin_width - line_widths[i]; break;
      }
      g.drawString(lines[i], x, y);
    }
  }
  /** This internal method breaks a specified label up into an array of lines.
```

```
   *  It uses the StringTokenizer utility class. */
  protected synchronized void newLabel() {
    StringTokenizer t = new StringTokenizer(label, "\n");
    num_lines = t.countTokens();
    lines = new String[num_lines];
    line_widths = new int[num_lines];
    for(int i = 0; i < num_lines; i++) lines[i] = t.nextToken();
  }
  /** This internal method figures out how big the font is, and how wide each
   *  line of the label is, and how wide the widest line is. */
  protected synchronized void measure() {
    FontMetrics fm = this.getToolkit().getFontMetrics(this.getFont());
    line_height = fm.getHeight();
    line_ascent = fm.getAscent();
    max_width = 0;
    for(int i = 0; i < num_lines; i++) {
      line_widths[i] = fm.stringWidth(lines[i]);
      if (line_widths[i] > max_width) max_width = line_widths[i];
    }
    measured = true;
  }
}
```

Packaging a Bean

To prepare a bean for use in a beanbox, you must package it up in a JAR file, along with any other classes or resource files it requires. (JAR files are "Java archives"; they were introduced in Chapter 6, *Applets*.) Because a single bean can have many auxiliary files, and because a JAR file can contain multiple beans, the manifest of the JAR file must define which of the JAR file entries are beans. You create a JAR file with `c` option to the *jar* command. When you use the `m` option in conjunction with `c`, it tells *jar* to read a partial manifest file that you specify. *jar* uses the information in your partially-specified manifest file when creating the complete manifest for the JAR file. To identify a class file as a bean, you simply add the following line to the file's manifest entry:

```
Java-Bean: True
```

So, to package up the `MultiLineLabel` class in a JAR file, you must first create a manifest "stub" file. Create a file, perhaps named *manifest.stub*, with the following contents:

```
Name: oreilly/beans/MultiLineLabel.class
Java-Bean: True
```

Note that the forward slashes in the manifest file should not be changed to backward slashes on Windows systems. The format of the JAR manifest file requires forward slashes to separate directories regardless of the platform. Having created this partial manifest file, we can now go ahead and create the JAR file:

```
% jar cfm MultiLineLabel.jar manifest.stub oreilly/beans/MultiLineLabel.class
```

(On a Windows system, you do need to replace the forward slashes with backslashes in this command line.) If this bean required any auxiliary files, we would specify them on the end of the *jar* command line, along with the class file for the bean.

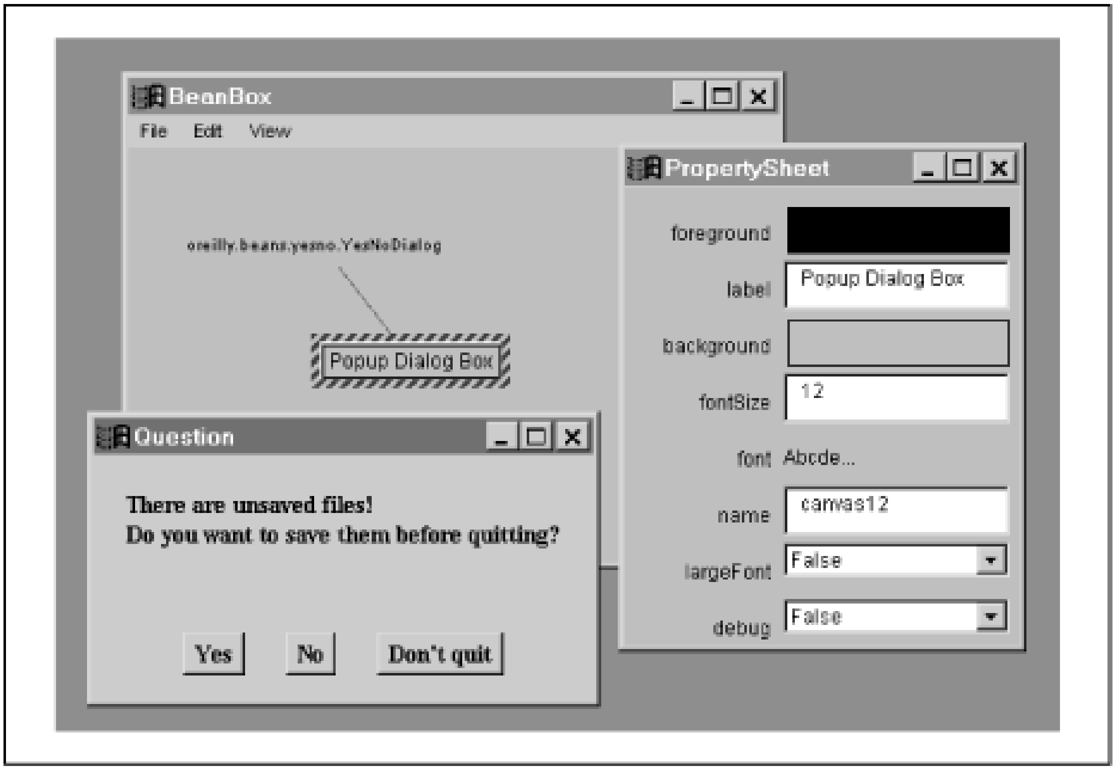
Installing a Bean

The procedure for installing a bean depends entirely upon the beanbox tool that you are using. For the *beanbox* tool shipped with the BDK, all you need to do is to copy the bean's JAR file into the *jars/* directory within the BDK directory. Once you have done this, the bean will appear on the palette of beans every time you start up the application. Alternatively, you can also load a bean's JAR file at runtime by selecting the **Load JAR** option from the **File** menu of *beanbox*.

10.3 A More Complex Bean

Example 10.2 shows another bean, `YesNoDialog`. This bean creates a dialog box that displays a simple message to the user and asks the user to respond by clicking the **Yes**, **No**, or **Cancel** button. Figure 10.1 shows the bean being manipulated in Sun's *beanbox* tool and also shows a dialog displayed by the bean.

Figure 10.1: The YesNoDialog bean in the *beanbox*



foreground
label Popup Dialog Box
background
fontSize 12
font Abcde...
name canvas12
largeFont False
debug False

There are unsaved files!
Do you want to save them before quitting?

The `YesNoDialog` bean uses a custom `AnswerEvent` type to notify `AnswerListener` objects when the user has dismissed the dialog by clicking on one of its three buttons. This new event class and listener interface are defined in the next section.

Note that `YesNoDialog` is a subclass of `Object`, not `Dialog`. This is a result of the requirement for a bean to have a no-argument constructor. Because all dialog boxes must be associated with a `Frame`, `Dialog` does not have a no-argument constructor, and this means that subclasses of `Dialog` cannot have meaningful no-argument constructors, either. As a result, `YesNoDialog` defers creation of its window and associated GUI components until it is actually popped up with the `display()` method. Another *beanbox* shortcoming is that it only recognizes methods with no arguments. [1] For this reason, the `display()` method has no arguments, and so no `Frame` can be specified through that method either. Since a parent `Frame` cannot be specified, `YesNoDialog` cannot create a `Dialog` object, and instead simulates a dialog box with a `Frame` window. An alternative would have been to define a bean property through which the required `Frame` could be specified.

> [1] The *beanbox* tool shipped with the February 1997 version of the BDK has a number of shortcomings. In part, this is due to the fact that the BDK is a new technology and not as stable or robust as the JDK. It is also because *beanbox* is intended as a test environment, not an actual programmer's tool.

Since `YesNoDialog` is not a subclass of `Component`, it has to define its own properties and accessor methods for fonts and colors; normally these would simply be inherited from `Component`. Since this bean is not a `Component` subclass, it is an "invisible" bean that does not have a graphical representation of its own. (It pops up a window when the `display()` method is called, but that is not the same as having a graphical representation that appears within another window.) Different tools treat invisible beans differently. *beanbox* simply displays the classname of invisible beans.

Notice that `YesNoDialog` does not use any classes from the `java.beans` package. One of the surprising things about beans is that they typically do not have to use any classes from this package. As we'll see in later sections, it is the auxiliary classes that are shipped with a bean that make heavy use of that package.

Example 10.2: The YesNoDialog Bean

```
package oreilly.beans.yesno;      // Put this bean in its own private package.
import java.awt.*;
import java.awt.event.*;
import java.util.*;
public class YesNoDialog {
  // Properties of the bean.
  protected String message, title;
  protected String yesLabel, noLabel, cancelLabel;
  protected int alignment;
  protected Font font = new Font("Serif", Font.PLAIN, 12);
  protected Color background = SystemColor.control;
  protected Color foreground = SystemColor.controlText;
  // Constants for the alignment property.
  public static final int LEFT = MultiLineLabel.LEFT;
  public static final int RIGHT = MultiLineLabel.RIGHT;
  public static final int CENTER = MultiLineLabel.CENTER;
  // Methods to query all of the bean properties.
  public String getMessage() { return message; }
  public String getTitle() { return title; }
  public String getYesLabel() { return yesLabel; }
  public String getNoLabel() { return noLabel; }
  public String getCancelLabel() { return cancelLabel; }
  public int getAlignment() { return alignment; }
  public Font getFont() { return font; }
  public Color getBackground() { return background; }
  public Color getForeground() { return foreground; }
  // Methods to set all of the bean properties.
  public void setMessage(String m) { message = m; }
  public void setTitle(String t) { title=t; }
  public void setYesLabel(String l) { yesLabel = l; }
  public void setNoLabel(String l) { noLabel = l; }
  public void setCancelLabel(String l) { cancelLabel = l; }
  public void setAlignment(int a) { alignment = a; }
  public void setFont(Font f) { font = f; }
  public void setBackground(Color bg) { background = bg; }
  public void setForeground(Color fg) { foreground = fg; }
  /** This field holds a list of registered ActionListeners.
   *  Vector is internally synchronized to prevent race conditions. */
  protected Vector listeners = new Vector();
  /** Register an action listener to be notified when a button is pressed. */
  public void addAnswerListener(AnswerListener l) {
    listeners.addElement(l);
  }
  /** Remove an Answer listener from our list of interested listeners. */
  public void removeAnswerListener(AnswerListener l) {
    listeners.removeElement(l);
  }
  /** Send an event to all registered listeners. */
  public void fireEvent(AnswerEvent e) {
    // Make a copy of the list and fire the events using that copy.
    // This means that listeners can be added or removed from the original
    // list in response to this event.  We ought to be able to just use an
    // enumeration for the vector, but that doesn't copy the list internally.
    Vector list = (Vector) listeners.clone();
    for(int i = 0; i < list.size(); i++) {
      AnswerListener listener = (AnswerListener)list.elementAt(i);
      switch(e.getID()) {
      case AnswerEvent.YES: listener.yes(e); break;
      case AnswerEvent.NO:  listener.no(e); break;
      case AnswerEvent.CANCEL: listener.cancel(e); break;
      }
    }
  }
  /** The no-argument bean constructor, with default property values */
  public YesNoDialog() {
    this("Question", "Your\nMessage\nHere", "Yes", "No", "Cancel", LEFT);
  }
  /** A constructor for programmers using this class "by hand". */
  public YesNoDialog(String title, String message,
                     String yesLabel, String noLabel, String cancelLabel,
                     int alignment) {
    this.title = title;
    this.message = message;
    this.yesLabel = yesLabel;
    this.noLabel = noLabel;
    this.cancelLabel = cancelLabel;
    this.alignment = alignment;
  }
  /** This method makes the bean display the dialog box. */
  public void display() {
    // Create a frame with the specified title.  It would be nice to
    // use a Dialog, but that needs to be passed a Frame argument, and
    // the BDK beanbox tool only seems to work with no-argument methods.
    final Frame frame = new Frame(title);
    // Specify a LayoutManager for it.
    frame.setLayout(new BorderLayout(15, 15));
    // Specify font and colors, if any are specified.
    if (font != null) frame.setFont(font);
    if (background != null) frame.setBackground(background);
    if (foreground != null) frame.setForeground(foreground);
    // Put the message label in the middle of the window.
    frame.add("Center", new MultiLineLabel(message, 20, 20, alignment));
    // Create an action listener for use by the buttons of the dialog.
    // When a button is pressed, this listener first closes the dialog box.
    // Then, it creates an AnswerEvent object that corresponds to the
    // button that was pressed, and sends that new event to all registered
    // listeners, using the fireEvent() method defined above.
    ActionListener listener = new ActionListener() {
      public void actionPerformed(ActionEvent e) {
        frame.dispose();     // Pop down window.
        if (listeners != null) {      // Notify any registered listeners.
          String cmd = e.getActionCommand();
          int type;
          if (cmd.equals("yes")) type = AnswerEvent.YES;
          else if (cmd.equals("no")) type = AnswerEvent.NO;
          else type = AnswerEvent.CANCEL;
          fireEvent(new AnswerEvent(YesNoDialog.this, type));
        }
      }
    };
    // Create a panel for the dialog buttons and put it at the bottom
    // of the dialog.  Specify a FlowLayout layout manager for it.
    Panel buttonbox = new Panel();
    buttonbox.setLayout(new FlowLayout(FlowLayout.CENTER, 25, 15));
    frame.add("South", buttonbox);
    // Create each specified button, specifying the action listener
    // and action command for each, and adding them to the buttonbox.
    if ((yesLabel != null) && (yesLabel.length() > 0)) {
      Button yes = new Button(yesLabel);        // Create button.
      yes.setActionCommand("yes");              // Set action command.
      yes.addActionListener(listener);          // Set listener.
      buttonbox.add(yes);                       // Add button to the panel.
    }
```

```
    if ((noLabel != null) && (noLabel.length() > 0)) {
      Button no = new Button(noLabel);
      no.setActionCommand("no");
      no.addActionListener(listener);
      buttonbox.add(no);
    }
    if ((cancelLabel != null) && (cancelLabel.length() > 0)) {
      Button cancel = new Button(cancelLabel);
      cancel.setActionCommand("cancel");
      cancel.addActionListener(listener);
      buttonbox.add(cancel);
    }
    // Finally, set the dialog to its preferred size and display it.
    frame.pack();
    frame.show();
  }
  /**
   * A main method that demonstrates how to use this class, and allows testing.
   */
  public static void main(String[] args) {
    // Create an instance of InfoDialog, with title and message specified:
    YesNoDialog d =
      new YesNoDialog("YesNoDialog Test",
                      "There are unsaved files.\n" +
                      "Do you want to save them before quitting?",
                      "Yes, save and quit",
                      "No, quit without saving",
                      "Cancel; don't quit",
                      YesNoDialog.CENTER);
    // Register an action listener for the dialog.  This one just prints
    // the results out to the console.
    d.addAnswerListener(new AnswerListener() {
      public void yes(AnswerEvent e) { System.out.println("Yes"); }
      public void no(AnswerEvent e) { System.out.println("No"); }
      public void cancel(AnswerEvent e) { System.out.println("Cancel"); }
    });
    // Now pop the dialog up.  It will pop itself down automatically.
    d.display();
  }
}
```

10.4 Custom Events

Beans can use the standard AWT event types defined in the `java.awt.event` package, but they do not have to. Our `YesNoDialog` class defines its own event type, `AnswerEvent`. Defining a new event class is really quite simple; `AnswerEvent` is shown in Example 10.3.

Example 10.3: The AnswerEvent Class

```
package oreilly.beans.yesno;
public class AnswerEvent extends java.util.EventObject {
  protected int id;
  public static final int YES = 0, NO = 1, CANCEL = 2;
  public AnswerEvent(Object source, int id) {
    super(source);
    this.id = id;
  }
  public int getID() { return id; }
}
```

Along with the `AnswerEvent` class, `YesNoDialog` also defines a new type of event listener interface, `ActionListener`, that defines the methods that must be implemented by any object that wants to receive notification from a `YesNoDialog`. The definition of `AnswerListener` is shown in Example 10.4.

Example 10.4: The AnswerListener Interface

```
package oreilly.beans.yesno;
public interface AnswerListener extends java.util.EventListener {
  public void yes(AnswerEvent e);
  public void no(AnswerEvent e);
  public void cancel(AnswerEvent e);
}
```

Specifying Bean Information

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

10.5 Specifying Bean Information

The `YesNoDialog` class itself and the `AnswerEvent` and `AnswerListener` classes it relies on are all a required part of our bean. When an application that uses the bean is shipped, it has to include all three of these class files. There are other kinds of classes, however, that are often bundled with a bean that are not intended for use by the application developer. These classes are used by the beanbox tool that manipulates the bean. The bean class itself does not refer to any of these auxiliary beanbox classes so that it is not dependent on them and they do not have to be shipped with the bean in finished products.

The first of these optional, auxiliary classes is a `BeanInfo` class. As explained earlier, a beanbox discovers the properties, events, and methods exported by a bean through "introspection" based on the Java Reflection API. A bean developer who wants to provide additional information about a bean, or who wants to refine the (somewhat rough) information available through introspection, should define a class that implements the `BeanInfo` interface to provide that information. A `BeanInfo` class typically subclasses `SimpleBeanInfo`, which provides a no-op implementation of the `BeanInfo` interface. When you only want to override one or two methods, it is easier to subclass `SimpleBeanInfo` than to implement `BeanInfo` directly. Beanbox tools rely on a naming convention in order to find the `BeanInfo` class for a given bean: a `BeanInfo` class should have the same name as the bean, with the string "BeanInfo" appended. Example 10.5 shows an implementation of the `YesNoDialogBeanInfo` class.

This `BeanInfo` class specifies a number of pieces of information for our bean:

- An icon that can be used to represent the bean.
- A `BeanDescriptor` object, which includes a reference to a `Customizer` class for the bean. We'll see an implementation of this class later in the chapter.
- A list of the supported properties of the bean, along with a short description of each one. Some beanbox tools (but not Sun's *beanbox*) display these strings to the user in some useful way.
- A method that returns the most commonly customized property of the bean--this is called the "default" property.
- References to `PropertyEditor` classes for two of the properties. We'll see implementations of these property editor classes later in the chapter.
- A list of the methods supported by the bean, again with a short description of each one.

Besides specifying this information, a `BeanInfo` class can also provide information about the events it generates and specify a default event. The various `FeatureDescriptor` objects used to provide information about such things as properties and methods can also include other information not provided by `YesNoDialogBeanInfo`, such as a localized display name that is distinct from the programmatic name.

Example 10.5: The YesNoDialogBeanInfo Class

```
package oreilly.beans.yesno;
import java.beans.*;
import java.lang.reflect.*;
import java.awt.*;

    }
  }
}
```

10.6 Defining a Simple Property Editor

A bean can also provide an auxiliary `PropertyEditor` for use by a beanbox tool. `PropertyEditor` is a flexible interface that allows a bean to tell a beanbox how to display and edit the values of certain types of properties.

A beanbox tool always provides simple property editors for common property types, such as strings, numbers, fonts, and colors. If your bean has properties of a non-standard type, you should register a property editor for that type. The easiest way to "register" a property editor is through a simple naming convention. If your type is defined by the class *X*, the editor for it should be defined in the class `XEditor`. Alternately, you can register a property editor by calling the `PropertyEditorManager.registerEditor()` method, probably from the constructor of your `BeanInfo` class. If you call this method from the bean itself, the bean then depends on the property editor class, so the editor has to be bundled with the bean in applications.

In our `YesNoDialog` example, we don't define any new data types, but we still have two individual properties that need custom editors. In this case, we register the property editors for individual properties by specifying them in the `PropertyDescriptor` objects returned by the `getPropertyDescriptors()` method of our `BeanInfo` class.

The `PropertyEditor` interface can seem confusing at first. Its methods allow you to define three techniques for displaying the value of a property and two techniques for allowing the user to edit the value of a property. The value of a property can be displayed:

- As a string. If you define the `getAsText()` method, a beanbox can convert a property to a string and display that string to the user.
- As an enumerated value. If a property can only take on a value from a fixed set of values, you can define the `getTags()` method to allow a beanbox to display a dropdown menu of allowed values for the property.
- In a graphical display. If you define `paintValue()`, a beanbox can ask the property editor to display the value using some natural graphical format, such as a color swatch for colors. You also need to define `isPaintable()` to specify that a graphical format is supported.

The two editing techniques are:

- *String editing*. If you define the `setAsText()` method, a beanbox knows it can simply have the user type a value into a text field and pass that value to `setAsText()`. If your property editor defines `getTags()`, it should also define `setAsText()` so that a beanbox can set the property value using the individual tag values.

- *Custom editing*. If your property editor defines `getCustomEditor()`, a beanbox can call it to obtain some kind of AWT component that can be displayed in a dialog box and serve as a custom editor for the property. You also need to define `supportsCustomEditor()` to specify that custom editing is supported.

The `setValue()` method of a `PropertyEditor` is called to specify the current value of the property. It is this value that should be converted to a string or graphical representation by `getAsText()` or `paintValue()`.

A property editor is required to maintain a list of event listeners that are interested in changes to the value of the property. The `addPropertyChangeListener()` and `removePropertyChangeListener()` methods are standard event listener registration and removal methods. When a property editor changes the value of a property, either through `setAsText()` or through a custom editor, it must send a `PropertyChangeEvent` to all registered listeners.

`PropertyEditor` defines the `getJavaInitializationString()` for use by beanbox tools that generate Java code. This method should return a fragment of Java code that can be used to initialize a variable to the current property value.

Finally, a class that implements the `PropertyEditor` interface must have a no-argument constructor, so that it can be dynamically loaded and instantiated by a beanbox.

Most property editors can be much simpler than this detailed description would suggest. In many cases, you can subclass `PropertyEditorSupport` instead of implementing the `PropertyEditor` interface directly. This useful class provides no-op implementations of most `PropertyEditor` methods. It also implements the methods for adding and removing event listeners.

A property that has an enumerated value requires a simple property editor. The `alignment` property of the `YesNoDialog` bean is an example of this common type of property. The property is defined as an `int`, but it has only three legal values, defined by the constants `LEFT`, `CENTER`, and `RIGHT`. By default, a beanbox only knows that the property is an `int`, so it displays the property as a number and allows the user to enter any integer as a property value. Instead, we would like the beanbox to display one of the strings "left," "center," or "right" as the value, and allow the user to choose from these values when setting the property. This can be done with the `getTags()` and `setAsText()` methods of a property editor, as shown in Example 10.6.

This example creates the `YesNoDialogAlignmentEditor` class, which is registered as a `PropertyEditor` for the `alignment` property by the `YesNoDialogBeanInfo` class shown in Example 10.5 . The property editor subclasses `PropertyEditorSupport`, so it is relatively short. Notice that it passes `Integer` objects in the calls to `setValue()` that are made from the `setAsText()` method. You need to use wrapper objects for any primitive-type properties. The use of the `Integer` class is also apparent in the definition of `getJavaInitializationString()`. The `setValue()` method of `ProperyEditorSupport` handles notifying registered `PropertyChangeListener` objects about changes in the value of the property, so this simple property editor does not need to be aware of the existence of such listeners.

Example 10.6: The YesNoDialogAlignmentEditor Class

```
package oreilly.beans.yesno;
import java.beans.*;
import java.awt.*;
public class YesNoDialogAlignmentEditor extends PropertyEditorSupport {
  // These two methods allow the property to be edited in a dropdown list.
  // Return the list of value names for the enumerated type.
  public String[] getTags() {
    return new String[] { "left", "center", "right" };
  }
  // Convert each of those value names into the actual value.
  public void setAsText(String s) {
    if (s.equals("left")) setValue(new Integer(YesNoDialog.LEFT));
    else if (s.equals("center")) setValue(new Integer(YesNoDialog.CENTER));
    else if (s.equals("right")) setValue(new Integer(YesNoDialog.RIGHT));
    else throw new IllegalArgumentException(s);
  }
  // This is an important method for code generation.
  public String getJavaInitializationString() {
    switch(((Number)getValue()).intValue()) {
    default:
    case YesNoDialog.LEFT:   return "oreilly.beans.yesno.YesNoDialog.LEFT";
    case YesNoDialog.CENTER: return "oreilly.beans.yesno.YesNoDialog.CENTER";
    case YesNoDialog.RIGHT:  return "oreilly.beans.yesno.YesNoDialog.RIGHT";
    }
  }
}
```

10.7 Defining a Complex Property Editor

There is another `YesNoDialog` property value that requires a property editor. The `message` property of `YesNoDialog` can specify a multi-line message to be displayed in the dialog. This property requires a property editor because the *beanbox* program does not distinguish between single-line and multi-line string types and the `TextField` objects it uses for text input do not allow the user to enter multiple lines of text. For this reason, we define the `YesNoDialogMessageEditor` class and register it with the `PropertyDescriptor` for the message property, as shown in Example 10.5.

Example 10.7 shows the definition of this property editor. This is a more complex editor that supports the creation of a custom editor component and graphical display of the value. Note that this example implements `PropertyEditor` directly. `getCustomEditor()` returns an editor component for multi-line strings. Figure 10.2 shows this custom editor placed within a dialog box created by the *beanbox* program. Note that the **Done** button in this figure is part of the *beanbox* dialog, not part of the property editor itself.

Figure 10.2: A custom property editor dialog

[Graphic: Figure 10-2]

The `paintValue()` method is responsible for displaying the value of the `message` property. This multi-line value does not typically fit in the small rectangle of screen space allowed for the property, so `paintValue()` displays instructions for popping up the custom editor, which allows the user to inspect and edit the property value. (This example relies on the click-to-edit behavior of the *beanbox* program; this `paintValue()` method may not make sense when the bean is used in other beanbox tools.)

Example 10.7: The YesNoDialogMessageEditor Class

```
package oreilly.beans.yesno;
import java.beans.*;
import java.awt.*;
import java.awt.event.*;
/**
 * This class is a custom editor for the message property of the
 * YesNoDialog bean.  It is necessary because the default editor for
 * properties of type String does not allow multi-line strings to be entered.
 */
public class YesNoDialogMessageEditor implements PropertyEditor {
  protected String value;  // The value we will be editing.
  public void setValue(Object o) {  value = (String) o; }
  public Object getValue() { return value; }
  public void setAsText(String s) { value = s; }
  public String getAsText() { return value; }
  public String[] getTags() { return null; }  // not enumerated; no tags
  // Say that we allow custom editing.
  public boolean supportsCustomEditor() { return true; }
  // Return the custom editor.  This just creates and returns a TextArea
  // to edit the multi-line text.  But it also registers a listener on the
  // text area to update the value as the user types and to fire the
  // property change events that property editors are required to fire.
  public Component getCustomEditor() {
    final TextArea t = new TextArea(value);
    t.setSize(300, 150); // TextArea doesn't have a preferred size, so set one.
    t.addTextListener(new TextListener() {
      public void textValueChanged(TextEvent e) {
        value = t.getText();
        listeners.firePropertyChange(null, null, null);
      }
    });
    return t;
  }
  // Visual display of the value, for use with the custom editor.
  // Just print some instructions and hope they fit in the box.
  // This could be more sophisticated.
  public boolean isPaintable() { return true; }
  public void paintValue(Graphics g, Rectangle r) {
    g.setClip(r);
    g.drawString("Click to edit...", r.x+5, r.y+15);
  }
  // Important method for code generators.  Note that it
  // ought to add any necessary escape sequences.
  public String getJavaInitializationString() { return "\"" + value + "\""; }
  // This code uses the PropertyChangeSupport class to maintain a list of
  // listeners interested in the edits we make to the value.
  protected PropertyChangeSupport listeners = new PropertyChangeSupport(this);
  public void addPropertyChangeListener(PropertyChangeListener l) {
    listeners.addPropertyChangeListener(l);
  }
  public void removePropertyChangeListener(PropertyChangeListener l) {
    listeners.removePropertyChangeListener(l);
  }
}
```

Defining a Simple Property Editor BOOK INDEX Defining a Bean Customizer

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

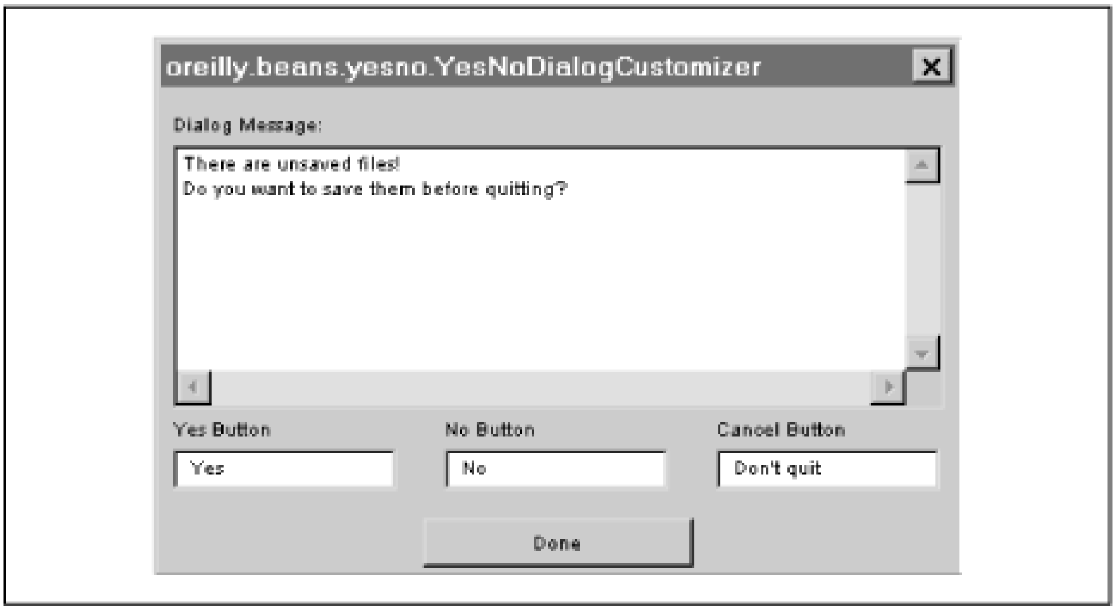
10.8 Defining a Bean Customizer

A bean may want to provide some way for the user of a beanbox program to customize its properties other than by setting them one at a time. A bean can do this by creating a `Customizer` class for itself, and registering the customizer class with the `BeanDescriptor` object returned by its `BeanInfo` class, as we saw in Example 10.5.

A customizer must be some kind of AWT component that is suitable for display in a dialog box created by the beanbox. Therefore, a customizer class is typically a subclass of `Panel`. In addition, a customizer must implement the `Customizer` interface. This interface consists of methods for adding and removing property change event listeners and a `setObject()` method that the beanbox calls to tell the customizer what bean object it is customizing. Whenever the user makes a change to the bean through the customizer, the customizer should send a `PropertyChangeEvent` to any interested listeners. Finally, like a property editor, a customizer must have a no-argument constructor, so it can easily be instantiated by a beanbox.

Example 10.8 shows a customizer for our `YesNoDialog` bean. This customizer displays a panel that has the same layout as a `YesNoDialog`, but it substitutes a `TextArea` object for the message display and three `TextField` objects for the three buttons that the dialog can display. These text entry areas allow the user to enter values for the `message`, `yesLabel`, `noLabel`, and `cancelLabel` properties. Figure 10.3 shows this customizer panel displayed within a dialog box created by the *beanbox* program. Again, note that the **Done** button is part of the *beanbox* dialog, not part of the customizer itself.

Figure 10.3: The customizer dialog for the YesNoDialog bean



Dialog Message:

There are unsaved files!
Do you want to save them before quitting?

Yes Button: Yes

No Button: No

Cancel Button: Don't quit

Example 10.8: The YesNoDialogCustomizer Class

```
package oreilly.beans.yesno;
import java.awt.*;
import java.awt.event.*;
import java.beans.*;
/**
 * This class is a customizer for the YesNoDialog bean.  It displays a
 * TextArea and three TextFields where the user can enter the dialog message
 * and the labels for each of the three buttons.  It does not allow the
 * dialog title or other resources to be set.
 */
public class YesNoDialogCustomizer extends Panel
                                   implements Customizer, TextListener
{
  protected YesNoDialog bean;                 // The bean being customized.
  protected TextComponent message, fields[];  // Components used by customizer
  // Default constructor: YesNoDialogCustomizer() { super(); }
  // The bean box calls this method to tell us what object to customize.
  // This method will always be called before the customizer is displayed,
  // so it is safe to create the customizer GUI here.
  public void setObject(Object o) {
    bean = (YesNoDialog)o;   // Save the object we're customizing.
    // Put a label at the top of the panel.
    this.setLayout(new BorderLayout());
    this.add(new Label("Enter the message to appear in the dialog:"), "North");
    // And a big text area below it for entering the dialog message.
    message = new TextArea(bean.getMessage());
    message.addTextListener(this);
    // TextAreas don't know how big they want to be.  You must tell them.
    message.setSize(400, 200);
    this.add(message, "Center");
    // Then add a row of textfields for entering the button labels.
    Panel buttonbox = new Panel();                       // The row container.
    buttonbox.setLayout(new GridLayout(1, 0, 25, 10)); // Equally spaced items.
    this.add(buttonbox, "South");                        // Put row on bottom.
    // Now go create three TextFields to put in this row.  But actually
    // position a Label above each, so create a container for each
    // TextField+Label combination.
    fields = new TextComponent[3];             // Array of TextFields.
    String[] labels = new String[] {           // Labels for each.
      "Yes Button Label", "No Button Label", "Cancel Button Label"};
    String[] values = new String[] {           // Initial values of each.
      bean.getYesLabel(), bean.getNoLabel(), bean.getCancelLabel()};
    for(int i = 0; i < 3; i++) {
      Panel p = new Panel();                   // Create a container.
      p.setLayout(new BorderLayout());         // Give it a BorderLayout.
      p.add(new Label(labels[i]), "North");    // Put a label on the top.
      fields[i] = new TextField(values[i]);    // Create the text field.
      p.add(fields[i], "Center");              // Put it below the label.
      fields[i].addTextListener(this);         // Set the event listener.
      buttonbox.add(p);                        // Add container to row.
    }
  }
  // Add some space around the outside of the panel.
  public Insets getInsets() { return new Insets(10, 10, 10, 10); }
  // This is the method defined by the TextListener interface.  Whenever the
  // user types a character in the TextArea or TextFields, this will get
  // called.  It updates the appropriate property of the bean and fires a
  // property changed event, as all customizers are required to do.
  // Note that we are not required to fire an event for every keystroke.
  // Instead we could include an "Apply" button that would make all the
  // changes at once, with a single property changed event.
  public void textValueChanged(TextEvent e) {
    TextComponent t = (TextComponent)e.getSource();
    String s = t.getText();
    if (t == message) bean.setMessage(s);
    else if (t == fields[0]) bean.setYesLabel(s);
    else if (t == fields[1]) bean.setNoLabel(s);
    else if (t == fields[2]) bean.setCancelLabel(s);
    listeners.firePropertyChange(null, null, null);
  }
  // This code uses the PropertyChangeSupport class to maintain a list of
  // listeners interested in the edits we make to the bean.
  protected PropertyChangeSupport listeners = new PropertyChangeSupport(this);
  public void addPropertyChangeListener(PropertyChangeListener l) {
    listeners.addPropertyChangeListener(l);
  }
  public void removePropertyChangeListener(PropertyChangeListener l) {
    listeners.removePropertyChangeListener(l);
  }
```

```
}
```

3.6 Subclasses and Inheritance

The `Circle` class we've defined is good for abstract mathematical manipulation. For some applications this is exactly what we need. For other applications, we want to be able to manipulate circles *and* draw them on the screen. This means we need a new class, `GraphicCircle`, that has all the functionality of `Circle`, but also has the ability to be drawn.

We want to implement `GraphicCircle` so that it can make use of the code we've already written for `Circle`. One way to do that is the following:

```
public class GraphicCircle {
    // Here is the mathematical circle.
    public Circle c;
    // Here are the old methods.
    public double area() { return c.area(); }
    public double circumference() { return c.circumference(); }
    // The new graphic variables and methods go here.
    public Color outline, fill;
    public void draw(DrawWindow dw) { /* code omitted */ }
}
```

This approach would work, but it is not particularly elegant. The problem is that we have to write stubs for methods like `area()` and `circumference()` that have nothing to do with drawing circles. It would be nice if we didn't have to do this.

Extending a Class

In fact, we don't have to do it this way. Java allows us to define `GraphicCircle` as an extension, or *subclass* of `Circle`. Example 3.10 shows how. Note that this example assumes we have two other classes of objects defined: `Color`, which represents a color, and `DrawWindow`, a class that has the window into which drawing is done and that defines the primitive methods to do the drawing.

Example 3.10: Subclassing a Class

```
public class GraphicCircle extends Circle {
    // We automatically inherit the variables and methods of
    // Circle, so we only have to put the new stuff here.
    // We've omitted the GraphicCircle constructor, for now.
    Color outline, fill;
    public void draw(DrawWindow dw) {
        dw.drawCircle(x, y, r, outline, fill);
    }
}
```

The `extends` keyword tells Java that `GraphicCircle` is a subclass of `Circle`, and that it *inherits* the fields and methods of that class. [7] The definition of the `draw()` method shows variable inheritance--this method uses the `Circle` variables `x`, `y`, and `r` as if they were defined right in `GraphicCircle` itself.

> [7] Except for `private` fields and methods. We'll discuss `private` members of a class later. C++ programmers should note that `extends` is the Java equivalent of the `:` operator in C++--both indicate the superclass of a class.

`GraphicCircle` also inherits the methods of `Circle`. Thus, if we have a `GraphicCircle` object referred to by variable `gc`, we can say:

```
double area = gc.area();
```

This works just as if the `area()` method were defined in `GraphicCircle` itself.

Another feature of subclassing is that every `GraphicCircle` object is also a perfectly legal `Circle` object. Thus, if `gc` refers to a `GraphicCircle` object, we can assign it to a `Circle` variable, and we can forget all about its extra graphic capabilities: `Circle c = gc;`.

Final Classes

When a class is declared with the `final` modifier, it means that it cannot be extended or subclassed. `java.lang.System` is an example of a `final` class. Declaring a class `final` prevents unwanted extensions to the class. But it also allows the compiler to make some optimizations when invoking the methods of a class. We'll explore this in more detail when we talk about method overriding later in this chapter.

Superclasses, Object, and the Class Hierarchy

In our example, `GraphicCircle` is a subclass of `Circle`. We can also say that `Circle` is the *superclass* of `GraphicCircle`. The superclass of a class is specified in its `extends` clause:

```
public class GraphicCircle extends Circle { ... }
```

Every class you define has a superclass. If you do not specify the superclass with an `extends` clause, the superclass is the class `Object`. `Object` is a special class for a couple of reasons:

- It is the only class that does not have a superclass.

- The methods defined by `Object` can be called by any Java object.

Because every class has a superclass, classes in Java form a *class hierarchy*, which can be represented as a tree with `Object` at its root. Figure 3.1 shows a class hierarchy diagram which includes our `Circle` and `GraphicCircle` classes, as well as some of the standard classes from the Java API.

Figure 3.1: A class hierarchy diagram

[Graphic: Figure 3-1]

The complete class hierarchy for the Java API is diagrammed in the figures of Part V, *API Quick Reference*.

Subclass Constructors

In Example 3.10 we left out the constructor method for our new `GraphicCircle` class. Let's implement that now. Here's one way:

```
public GraphicCircle(double x, double y, double r,
                                Color outline, Color fill)
{
    this.x = x;
    this.y = y;
    this.r = r;
    this.outline = outline;
    this.fill = fill;
}
```

This constructor relies on the fact that `GraphicCircle` inherits all the variables of `Circle` and simply initializes those variables itself. But this duplicates the code of the `Circle` constructor, and if `Circle` did more elaborate initialization, it could become quite wasteful. Furthermore, if the `Circle` class had internal `private` fields (discussed later), we wouldn't be able to initialize them like this. What we need is a way of calling a `Circle` constructor from within our `GraphicCircle` constructor. Example 3.11 shows how we can do this.

Example 3.11: Invoking a Superclass's Constructor

```
public GraphicCircle(double x, double y, double r,
                                Color outline, Color fill)
{
    super(x, y, r);
    this.outline = outline;
    this.fill = fill;
}
```

`super` is a reserved word in Java. One of its uses is that shown in the example--to invoke the constructor method of a superclass. Its use is analogous to the use of the `this` keyword to invoke one constructor method of a class from within another. Using `super` to invoke a constructor is subject to the same restrictions as using `this` to invoke a constructor:

- `super` may only be used in this way within a constructor method.
- The call to the superclass constructor must appear as the first statement within the constructor method. It must appear even before variable declarations.

Constructor Chaining

When you define a class, Java guarantees that the class's constructor method is called whenever an instance of that class is created. It also guarantees that the constructor is called when an instance of any subclass is created. In order to guarantee this second point, Java must ensure that every constructor method calls its superclass constructor method. If the first statement in a constructor is not an explicit call to a constructor of the superclass with the `super` keyword, then Java implicitly inserts the call `super()`--that is, it calls the superclass constructor with no arguments. If the superclass does not have a constructor that takes no arguments, this causes a compilation error.

There is one exception to the rule that Java invokes `super()` implicitly if you do not do so explicitly. If the first line of a constructor, `C1`, uses the `this()` syntax to invoke another constructor, `C2`, of the class, Java relies on `C2` to invoke the superclass constructor, and does not insert a call to `super()` into `C1`. Of course, if `C2` itself uses `this()` to invoke a third constructor, `C2` does not call `super()` either, but somewhere along the chain, a constructor either explicitly or implicitly invokes the superclass constructor, which is what is required.

Consider what happens when we create a new instance of the `GraphicCircle` class. First, the `GraphicCircle` constructor shown in Example 3.11 is invoked. This constructor explicitly invokes a `Circle` constructor and that `Circle` constructor implicitly calls `super()` to invoke the constructor of its superclass, `Object`. The body of the `Object` constructor runs first, followed by the body of the `Circle` constructor, and finally followed by the body of the `GraphicCircle` constructor.

What this all means is that constructor calls are "chained"--any time an object is created, a sequence of constructor methods are invoked, from subclass to superclass on up to `Object` at the root of the class hierarchy. Because a superclass constructor is always invoked as the first statement of its subclass constructor, the body of the `Object` constructor always runs first, followed by the body of its subclass, and on down the class hierarchy to the class that is being instantiated.

The Default Constructor

There is one missing piece in the description of constructor chaining above. If a constructor does not invoke a superclass constructor, Java does so implicitly. But what if a class is declared without any constructor at all? In this case, Java implicitly adds a constructor to the class. This default constructor does nothing but invoke the superclass constructor.

For example, if we did not declare a constructor for the `GraphicCircle` class, Java would have implicitly inserted this constructor:

```
public GraphicCircle() { super(); }
```

Note that if the superclass, `Circle()`, did not declare a no-argument constructor, then this automatically inserted default constructor would cause a compilation error. If a class does not define a no-argument constructor, then all of its subclasses must define constructors that explicitly invoke the superclass constructor with the necessary arguments.

It can be confusing when Java implicitly calls a constructor or inserts a constructor definition into a class--something is happening that does not appear in your code! Therefore, it is good coding style, whenever you rely on an implicit superclass constructor call or on a default constructor, to insert a comment noting this fact. Your comments might look like those in the following example:

```
class A {
    int i;
    public A() {
        // Implicit call to super(); here.
        i = 3;
    }
}
class B extends A {
    // Default constructor: public B() { super(); }
}
```

If a class does not declare any constructor, it is given a `publicly` constructor by default. Classes that do not want to be publically instantiated, should declare a `protected` constructor to prevent the insertion of this `public` constructor. Classes that never want to be instantiated at all should define a `private` constructor.

Finalizer Chaining?

You might assume that since Java chains constructor methods that it also automatically chains the finalizer methods for an object. In other words, you may think that the finalizer method of a class automatically invokes the finalizer of its superclass. In fact, Java does *not* do this. In practice, finalizer methods are relatively rare, and the need for finalizer chaining rarely arises. If a class `B` with a finalizer method is a subclass of a class `A` with its own finalizer method, then `B`'s finalizer should be sure to invoke `A`'s finalizer, explicitly creating a chain of finalizers. This is a little tricky, since finalizers always have the same name (`finalize()`), and we haven't yet learned how to invoke a method in the superclass when that method is also defined in the subclass. We'll return to the issue of finalizer chaining when we learn how.

Shadowed Variables

Suppose that our `GraphicCircle` class has a new variable that specifies the resolution, in dots per inch, of the `DrawWindow` object in which it is going to be drawn. And further, suppose that it names that new variable `r`:

```
public class GraphicCircle extends Circle {
    Color outline, fill;
    float r;  // New variable.  Resolution in dots-per-inch.
    public GraphicCircle(double x, double y, double rad, Color o, Color f) {
        super(x, y, rad); outline = o; fill = f;
    }
    public void setResolution(float resolution) { r = resolution; }
    public void draw(DrawWindow dw) { dw.drawCircle(x, y, r, outline, fill); }
}
```

Now, with this resolution variable declared, when we use the variable `r` in the `GraphicCircle` class, we are no longer referring to the radius of the circle. The resolution variable `r` in `GraphicCircle` *shadows* the radius variable `r` in `Circle`. [8]

> [8] This is a contrived example, of course--we could simply rename the variable and avoid the issue. Typically we would rename the variable: variable shadowing is a necessary part of Java syntax, but is not a useful programming technique. Your code will be easier to understand if you avoid shadowed variables.

So, how can we refer to the radius variable defined in the `Circle` class when we need it? Recall that using a variable, such as `r`, in the class in which it is defined is shorthand for:

```
this.r  // Refers to the GraphicCircle resolution variable.
```

As you might guess, you can refer to a variable `r` defined in the superclass like this:

```
super.r  // Refers to the Circle radius variable.
```

Another way you can do this is to cast `this` to the appropriate class and then access the variable:

```
((Circle) this).r
```

This cast is exactly what the `super` keyword does when used like this. You can use this casting technique when you need to refer to a shadowed variable defined in a class that is not the immediate superclass. For example, if `C` is a subclass of `B`, which is a subclass of `A`, and class `C` shadows a variable `x` that is also defined in classes `A` and `B`, then you can refer to these different variables from class `C` as follows:

```
x                // Variable x in class C.
this.x           // Variable x in class C.
```

```
super.x           // Variable x in class B.
((B)this).x       // Variable x in class B.
((A)this).x       // Variable x in class A.
super.super.x     // Illegal; does not refer to x in class A.
```

Note that you cannot refer to a shadowed variable `x` in the superclass of a superclass with `super.super.x`. Java does not recognize this syntax.

Shadowed Methods?

Just as a variable defined in one class can shadow a variable with the same name in a superclass, you might expect that a method in one class could shadow a method with the same name (and same arguments) in a superclass. In a sense, they do: "shadowed" methods are called overridden methods. But method overriding is significantly different than variable shadowing; it is discussed in the sections that follow.

3.7 Overriding Methods

When a class defines a method using the same name, return type, and arguments as a method in its superclass, the method in the class *overrides* the method in the superclass. When the method is invoked for an object of the class, it is the new definition of the method that is called, not the superclass' old definition.

Method overriding is an important and useful technique in object-oriented programming. Suppose we define a subclass `Ellipse` of our `Circle` class. [9] Then it would be important for `Ellipse` to override the `area()` and `circumference()` methods of `Circle`. `Ellipse` would have to implement new versions of these functions because the formulas that apply to circles don't work for ellipses.

> [9] This is admittedly a strange thing to do, since, mathematically, a circle is a kind of ellipse, and it is customary to derive a more specific class from a more general one. Nevertheless, it is a useful example here.

Before we go any further with the discussion of method overriding, be sure that you understand the difference between method overriding and method overloading, which we discussed earlier. As you probably recall, method overloading refers to the practice of defining multiple methods (in the same class) with the same name but with differing argument lists. This is very different from method overriding, and it is important not to get them confused!

Overriding Is Not Shadowing

Although Java treats the variables and methods of a class analogously in many ways, method overriding is not like variable shadowing at all: You can refer to shadowed variables simply by casting an object to the appropriate type. You cannot invoke overridden methods with this technique, however. Example 3.12 illustrates this crucial difference.

Example 3.12: Method Overriding versus Variable Shadowing

```
class A {
    int i = 1;
    int f() { return i; }
}
class B extends A {
    int i = 2;                              // Shadows variable i in class A.
    int f() { return -i; }                  // Overrides method f in class A.
}
public class override_test {
    public static void main(String args[]) {
        B b = new B();
        System.out.println(b.i);     // Refers to B.i; prints 2.
        System.out.println(b.f());   // Refers to B.f(); prints -2.
        A a = (A) b;                 // Cast b to an instance of class A.
        System.out.println(a.i);     // Now refers to A.i; prints 1;
        System.out.println(a.f());   // Still refers to B.f(); prints -2;
    }
}
```

While this difference between method overriding and variable shadowing may seem surprising at first, a little thought makes the purpose clear. Suppose we have a bunch of `Circle` and `Ellipse` (a subclass of `Circle`) objects that we are manipulating. To keep track of the circles and ellipses, we store them in an array of type `Circle[]`, casting all the `Ellipse` objects to `Circle` objects before we store them. Then, when we loop through the elements of this array, we don't have to know or care whether the element is actually a `Circle` or an `Ellipse`. What we do care very much about, however, is that the correct value is computed when we invoke the `area()` method of any element of the array. That is, we don't want to use the formula for the area of a circle when the object is actually an ellipse!

Seen in this context, it is not surprising at all that method overriding is handled differently by Java than variable shadowing.

final Methods

If a method is declared `final`, it means that the method declaration is the "final" one--that it cannot be overridden. `static` methods and `private` methods (which we haven't learned about yet) cannot be overridden either, nor can the methods of a `final` class. If a method cannot be overridden, the compiler may perform certain optimizations on it, as we'll see below.

Dynamic Method Lookup

If we have an array of `Circle` and `Ellipse` objects, how does the compiler know to call the `Circle area()` method or the `Ellipse area()` method for any given item in the array? The compiler does not know this; it can't. The compiler knows that it does not know, however, and produces code that uses "dynamic method lookup" at run-time. When the interpreter runs the code, it looks up the appropriate `area()` method to call for each of the objects. That is, when the interpreter interprets the expression s.area(), it dynamically looks for an area() method associated with the particular object referred to by the variable s. It does not simply use the area() method that is statically associated with the type of the variable s. [10]

[10] C++ programmers should note that dynamic method lookup is what C++ does for virtual functions. An important difference between Java and C++ is that Java does not have a virtual keyword; methods in Java are "virtual" by default.

Dynamic method lookup is fast, but it is not as fast as invoking a method directly. Fortunately, there are a number of cases in which Java does not need to use dynamic method lookup. static methods cannot be overridden, so they are always invoked directly. private methods (which we haven't learned about yet) are not inherited by subclasses and so cannot be overridden by subclasses; this means the Java compiler can safely invoke them without dynamic method lookup as well. final methods are invoked directly for the same reason: they cannot be overridden. Finally, when a method of a final class is invoked through an instance of the class or a subclass of it, then it, too, can be invoked without the overhead of dynamic lookup. These static, final, and private methods that can be invoked directly are also candidates for inlining--i.e., if the methods are short, the compiler may simply insert the method body into the code rather than inserting a call to the method.

Invoking an Overridden Method

We've seen the important differences between method overriding and variable shadowing. Nevertheless, the Java syntax for invoking an overridden method is very similar to the syntax for accessing a shadowed variable: both use the super keyword. Example 3.13 illustrates this.

Example 3.13: Invoking an Overridden Method

```
class A {
    int i = 1;
    int f() { return i; }        // A very simple method.
}
class B extends A {
    int i;                       // This variable shadows i in A.
    int f() {                    // This method overrides f() in A.
        i = super.i + 1;         // It retrieves A.i this way.
        return super.f() + i;    // And it invokes A.f() this way.
    }
}
```

Recall that when you use super to refer to a shadowed variable, it is the same as casting this to the superclass type and accessing the variable through that. On the other hand, using super to invoke an overridden method is not the same as casting this. In this case, super has the special purpose of turning off dynamic method lookup and invoking the specific method that the superclass defines or inherits.

In Example 3.13 we use `super` to invoke an overridden method that is actually defined in the immediate superclass. `super` also works perfectly well to invoke overridden methods that are defined further up the class hierarchy. This is because the overridden method is inherited by the immediate superclass, and so the `super` syntax does in fact refer to the correct method.

To make this more concrete, suppose class `A` defines method `f`, and that `B` is a subclass of `A`, and that `C` is a subclass of `B` that overrides method `f`. Then you can still use:

```
super.f()
```

to invoke the overridden method from within class `C`. This is because class `B` inherits method `f` from class `A`. If classes `A`, `B`, and `C` all define method `f`, however, then calling `super.f()` in class `C` invokes class `B`'s definition of the method. In this case, there is no way to invoke `A.f()` from within class `C`. `super.super.f()` is not legal Java syntax!

It is important to note that `super` can only be used to invoke overridden methods from within the class that does the overriding. With our `Circle` and `Ellipse` classes, for example, there is no way to write a program (with or without `super`) that invokes the `Circle` `area()` method on an object of type `Ellipse`. The only way to do this is to use `super` in a method within the `Ellipse` class.

Finally, note that this form of `super` does not have to occur in the first statement in a method, as it does when used to invoke a superclass constructor method.

Finalizer Chaining Revisited

Now that we've discussed method overriding and how to invoke an overridden method, we can return to the issue of the finalizer method that we left dangling earlier on.

In Java, constructor methods are automatically chained, but finalizer methods are not. If you define a `finalize()` method to free resources allocated by your class, you may be overriding a `finalize()` method in a superclass that frees resources allocated by that class. If your finalizer method does not invoke the superclass finalizer, the superclass finalizer never gets called, and resources are not deallocated when they should be.

To prevent this, you should be sure to invoke the superclass `finalize()` method. The best time to do this is usually after your `finalize()` method has done all of its deallocation. It is a good idea to add the following call:

```
super.finalize();
```

as the last line of all your finalizer methods. You should do this even if you know that none of your class's superclasses have finalizer methods, because future implementations of the class may include one.

3.8 Data Hiding and Encapsulation

We started this chapter by describing a class as "a collection of data and methods." One of the important object-oriented techniques that we haven't discussed so far is hiding the data within the class, and making it available only through the methods. This technique is often known as *encapsulation*, because it seals the class's data (and internal methods) safely inside the "capsule" of the class, where it can be accessed only by trusted users--i.e., by the methods of the class.

Why would you want to do this? The most important reason is to hide the internal implementation details of your class. If you prevent programmers from relying on those details, then you can safely modify the implementation without worrying that you will break existing code that uses the class.

Another reason for encapsulation is to protect your class against accidental or willful stupidity. A class often contains a number of variables that are interdependent and must be in a consistent state. If you allow a programmer (this may be you yourself) to manipulate those variables directly, she may change one variable without changing important related variables, thus leaving the class in an inconsistent state. If, instead, she had to call a method to change the variable, that method can be sure to do everything necessary to keep the state consistent.

Here's another way to think about encapsulation: When all of a class's variables are hidden, the class's methods define the only possible operations that can be performed on objects of that class. Once you have carefully tested and debugged your methods, you can be confident that the class will work as expected. On the other hand, if all the variables can be directly manipulated, the number of possibilities you have to test becomes unmanageable.

There are other reasons to hide data, too:

- Internal variables that are visible externally to the class just clutter up your class's API. Keeping visible variables to a minimum keeps your class tidy and elegant.
- If a variable is visible in your class, you have to document it. Save time by hiding it instead!

Visibility Modifiers

In most of our examples so far, you've probably noticed the `public` keyword being used. When applied to a class, it means that the class is visible everywhere. When applied to a method or variable, it means that the method or variable is visible everywhere.

To hide variables (or methods, for that matter) you just have to declare them `private`:

```
public class Laundromat {       // People can use this class.
    private Laundry[] dirty;    // They can't see this internal variable,
    public void wash() { ... }  // but they can use these public methods
    public void dry() { ... }   // to manipulate the internal variable.
}
```

A `private` field of a class is visible only in methods defined within that class. (Or, in Java 1.1, in classes defined within the class.) Similarly, a `private` method may only be invoked by methods within the class (or methods of classes within the class). Private members are not visible within subclasses, and are *not* inherited by subclasses as other members are. [11] Of course, non-`private` methods that invoke `private` methods internally are inherited and may be invoked by subclasses.

> [11] Every object does, of course, have its own copy of all fields of all superclasses, including the `private` fields. The methods defined by the object can never refer to or use the `private` fields of superclasses, however, and so we say that those fields are not inherited.

Besides `public` and `private`, Java has two other visibility levels: `protected` and the default visibility level, "package visibility," which applies if none of the `public`, `private`, and `protected` keywords are used.

A `protected` member of a class is visible within the class where it is defined, of course, and within all subclasses of the class, and also within all classes that are in the same package as that class. You should use `protected` visibility when you want to hide fields and methods from code that uses your class, but want those fields and methods to be fully accessible to code that extends your class.

The default package visibility is more restrictive than `protected`, but less restrictive than `private`. If a class member is not declared with any of the `public`, `private`, or `protected` keywords, then it is visible only within the class that defines it and within classes that are part of the same package. It is not visible to subclasses unless those subclasses are part of the same package.

A note about packages: A package is a group of related and possibly cooperating classes. All non-`private` members of all classes in the package are visible to all other classes in the package. This is okay because the classes are assumed to know about, and trust, each other. [12] The only time difficulty arises is when you write programs without a `package` statement. These classes are thrown into a default package with other `package`-less classes, and all their non-`private` members are visible throughout the package. (The default package usually consists of all classes in the current working directory.)

> [12] If you're a C++ programmer, you can say that classes within the same package are `friend`-ly to each other.

There is an important point to make about subclass access to `protected` members. A subclass inherits the `protected` members of its superclass, but it can only access those members through instances of itself, not directly in instances of the superclass. Suppose, for example, that `A`, `B`, and `C` are `public` classes, each defined in a different package, and that `a`, `b`, and `c` are instances of those classes. Let `B` be a subclass of `A`, and `C` be a subclass of `B`. Now, if `A` has a `protected` field `x`, then the class B inherits that field, and its methods can use `this.x`, `b.x` and `c.x`. But it cannot access `a.x`. Similarly, if `A` has a `protected` method `f()`, then the methods of class `B` can invoke `this.f()`, `b.f()`, and `c.f()`, but they cannot invoke `a.f()`.

Table 3.1 shows the circumstances under which class members of the various visibility types are accessible to other classes.

Table 3.1: Class Member Accessibility

Accessible to:	**public**	**protected**	**package**	**private**
Same class	yes	yes	yes	yes
Class in same package	yes	yes	yes	no
Subclass in different package	yes	yes	no	no
Non-subclass, different package	yes	no	no	no

The details of member visibility in Java can become quite confusing. Here are some simple rules of thumb for using visibility modifiers:

- Use `public` only for methods and constants that form part of the public API of the class. Certain very important or very frequently used fields may also be `public`, but it is common practice to make fields non-`public` and encapsulate them with `public` accessor methods.

- Use `protected` for fields and methods that aren't necessary to use the class, but that may be of interest to anyone creating a subclass as part of a different package.

- Use the default package visibility for fields and methods that you want to be hidden outside of the package, but which you want cooperating classes within the same package to have access to.

- Use `private` for fields and methods that are only used inside the class and should be hidden everywhere else.

Note that you can't take advantage of package visibility unless you use the `package` statement to group your related classes into packages. See Chapter 13, *Java Syntax*, *Java Syntax*, for a table that summarizes the Java visibility modifiers and other modifiers.

Data Access Methods

In the `Circle` example we've been using, we've declared the circle position and radius to be `public` fields. In fact, the `Circle` class is one where it may well make sense to keep those visible--it is a simple enough class, with no dependencies between the variables.

On the other hand, suppose we wanted to impose a maximum radius on objects of the `Circle` class. Then it would be better to hide the `r` variable so that it could not be set directly. Instead of a visible `r` variable, we'd implement a `setRadius()` method that verifies that the specified radius isn't too large and then sets the `r` variable internally. Example 3.14 shows how we might implement `Circle` with encapsulated data and a restriction on radius size. For convenience, we use `protected` fields for the radius and position variables. This means that subclasses of

`Circle`, or cooperating classes within the `shapes` package are able to access these variables directly. To any other classes, however, the variables are hidden. Also, note the `private` constant and method used to check whether a specified radius is legal. And finally, notice the `public` methods that allow you to set and query the values of the instance variables.

Example 3.14: Hiding Variables in the Circle Class

```
package shapes;              // Specify a package for the class.
public class Circle {        // Note that the class is still public!
    protected double x, y;   // Position is hidden, but visible to subclasses.
    protected double r;      // Radius is hidden, but visible to subclasses.
    private static final double MAXR = 100.0;    // Maximum radius (constant).
    private boolean check_radius(double r) { return (r <= MAXR); }
    // Public constructors
    public Circle(double x, double y, double r) {
        this.x = x; this.y = y;
        if (check_radius(r)) this.r = r;
        else this.r = MAXR;
    }
    public Circle(double r) { this(0.0, 0.0, r); }
    public Circle() { this(0.0, 0.0, 1.0); }
    // Public data access methods
    public void moveto(double x, double y) { this.x = x; this.y = y;}
    public void move(double dx, double dy) { x += dx;  y += dy; }
    public void setRadius(double r) { this.r = (check_radius(r))?r:MAXR; }
    // Declare these trivial methods final so we don't get dynamic
    // method lookup and so that they can be inlined by the compiler.
    public final double getX() { return x; };
    public final double getY() { return y; };
    public final double getRadius() { return r; };
}
```

3.9 Abstract Classes and Interfaces

In Example 3.14 we declared our `Circle` class to be part of a package named `shapes`. Suppose we plan to implement a number of shape classes: `Rectangle`, `Square`, `Ellipse`, `Triangle`, and so on. We'll give all of these shape classes our two basic `area()` and `circumference()` methods. Now, to make it easy to work with an array of shapes, it would be helpful if all our shape classes have a common superclass, `Shape`. We want `Shape` to encapsulate whatever features all our shapes have in common. In this case, they have in common the `area()` and `circumference()` methods. But our generic `Shape` class can't actually implement these methods, since it doesn't represent any actual shape. Java handles this case with abstract methods.

Abstract Methods

Java lets us define a method without implementing it by making the method `abstract`. An `abstract` method has no body; it simply has a signature definition followed by a semicolon. [13] Here are the rules about `abstract` methods, and the `abstract` classes that contain them:

[13] An `abstract` method in Java is something like a "pure virtual function" in C++ (i.e., a virtual function that is declared `= 0`). In C++, a class that contains a pure virtual function is called an "abstract class" and may not be instantiated. The same is true of Java classes that contain `abstract` methods.

- Any class with an `abstract` method is automatically `abstract` itself, and must be declared as such.
- A class may be declared `abstract` even if it has no `abstract` methods. This prevents it from being instantiated.
- An `abstract` class cannot be instantiated.
- A subclass of an `abstract` class can be instantiated if it overrides each of the `abstract` methods of its superclass and provides an implementation (i.e., a method body) for all of them.
- If a subclass of an `abstract` class does not implement all of the `abstract` methods it inherits, that subclass is itself `abstract`.

That description of the `abstract` keyword was pretty abstract! Example 3.15 is more concrete. It shows an `abstract Shape` class and two non-`abstract` subclasses of it.

Example 3.15: An Abstract Class and Subclasses

```
public abstract class Shape {
    public abstract double area();
    public abstract double circumference();
}
class Circle extends Shape {
    protected double r;
    protected static final double PI = 3.14159265358979323846;
    public Circle() { r = 1.0; }
    public Circle(double r) { this.r = r; }
    public double area() { return PI * r * r; }
    public double circumference() { return 2 * PI * r; }
    public double getRadius() { return r; }
}
class Rectangle extends Shape {
    protected double w, h;
    public Rectangle() { w = 0.0; h = 0.0; }
    public Rectangle(double w, double h) { this.w = w;  this.h = h; }
    public double area() { return w * h; }
    public double circumference() { return 2 * (w + h); }
    public double getWidth() { return w; }
    public double getHeight() { return h; }
}
```

Note that the `abstract` methods in `Shape` have a semicolon right after their parentheses. There are no curly braces, and no method body is defined. Using the classes defined in Example 3.15, we can now write code like this:

```
Shape[] shapes = new Shape[3];          // Create an array to hold shapes.
shapes[0] = new Circle(2.0);            // Fill in the array...
shapes[1] = new Rectangle(1.0, 3.0);
shapes[2] = new Rectangle(4.0, 2.0);
double total_area = 0;
for(int i = 0; i < shapes.length; i++)
    total_area += shapes[i].area();     // Compute the area of the shapes.
```

There are two important points to notice here:

- Subclasses of `Shape` can be assigned to elements of an array of `Shape`. No cast is necessary.

- You can invoke the `area()` and `circumference()` methods for `Shape` objects, even though `Shape` does not define a body for these methods, because `Shape` declared them `abstract`. If `Shape` did not declare them at all, the code would cause a compilation error.

Interfaces

Let's extend our `shapes` package further. Suppose we now want to implement a number of shapes that can be drawn on the screen. We could define an abstract `DrawableShape` class, and then implement various subclasses of it, such as `DrawableCircle`, `DrawableRectangle`, and so on. This would work fine.

But suppose we want our drawable shape types to support the `area()` and `circumference()` methods. We don't want to have to re-implement these methods, so we'd like to make `DrawableCircle` a subclass of `Circle`, for example, and `DrawableRectangle` a subclass of `Rectangle`. But classes in Java can only have one superclass. If `DrawableCircle` extends `Circle`, then it cannot also extend `DrawableShape`! [14]

> [14] C++ allows classes to have more than one superclass, using a technique known as "multiple inheritance." Multiple inheritance opens up a can of worms, so Java replaces it with what many believe is a more elegant solution.

Java's solution to this problem is called an *interface*. An interface looks a lot like an abstract class, except that it uses the keyword `interface` instead of the words `abstract` and `class`. Example 3.16 shows an interface named `Drawable`.

Example 3.16: An Interface Definition

```
public interface Drawable {
    public void setColor(Color c);
    public void setPosition(double x, double y);
    public void draw(DrawWindow dw);
}
```

While an `abstract` class may define some `abstract` methods and some non-`abstract` methods, all the methods defined within an interface are implicitly `abstract`. We've omitted the `abstract` keyword in this example, but it is perfectly legal to use it if you want to belabor the abstractness of interface methods. A further restriction on interfaces is that any variables declared in an interface must be `static` and `final`--that is, they must be constants.

So what can we do with an interface? Just as a class `extends` its superclass, it also optionally `implements` an interface. `implements` is a Java keyword that can appear in a class declaration following the `extends` clause. `implements` should be followed by the name of the interface that the class implements. In order to implement an interface, a class must first declare the interface in an `implements` clause, and then it must provide an implementation (i.e., a body) for all of the `abstract` methods of the interface. [15]

> [15] This is the real difference between multiple inheritance in C++ and interfaces in Java. In C++, a class can inherit method implementations from more than one superclass. In Java, a class can inherit actual implementations only from one superclass. It can inherit additional `abstract` methods from interfaces, but it must provide its own implementation of those methods. It is rare, however, to actually be able to use C++ multiple inheritance to inherit useful, non-trivial implementations from more than one class. The elegance and simplicity of Java's interface more than compensate for the inability to inherit implementations from more than one class.

Example 3.17 shows how we can define a `DrawableRectangle` class that extends our `Rectangle` class and implements the `Drawable` interface we defined in Example 3.16. The example assumes that a `Color` class and a `DrawWindow` class are defined elsewhere, and that `DrawWindow` knows how to convert floating-point coordinates to pixel coordinates and knows how to draw primitive shapes.

Example 3.17: Implementing an Interface

```
public class DrawableRectangle extends Rectangle implements Drawable {
    // New instance variables
    private Color c;
    private double x, y;
    // A constructor
    public DrawableRectangle(double w, double h) { super(w, h); }
    // Here are implementations of the Drawable methods.
    // We also inherit all the public methods of Rectangle.
    public void setColor(Color c) { this.c = c; }
    public void setPosition(double x, double y) { this.x = x; this.y = y; }
    public void draw(DrawWindow dw) {
        dw.drawRect(x, y, w, h, c);
    }
}
```

Using Interfaces

Suppose we implement `DrawableCircle` and `DrawableSquare` just as we implemented `DrawableRectangle` in Example 3.17. As we saw earlier, instances of these classes can be treated as instances of the abstract `Shape` class. They can also be treated as instances of the `Drawable` interface. Example 3.18 demonstrates this.

Example 3.18: Casting Objects to Their Interface Type

```
Shape[] shapes = new Shape[3];          // Create an array to hold shapes
Drawable[] drawables = new Drawable[3]; // and an array to hold drawables.
// Create some drawable shapes.
DrawableCircle dc = new DrawableCircle(1.1);
DrawableSquare ds = new DrawableSquare(2.5);
DrawableRectangle dr = new DrawableRectangle(2.3, 4.5);
// The shapes can be assigned to both arrays.
shapes[0] = dc;   drawables[0] = dc;
shapes[1] = ds;   drawables[1] = ds;
shapes[2] = dr;   drawables[2] = dr;
// Compute total area and draw the shapes by invoking
// the Shape and the Drawable abstract methods.
double total_area = 0;
for(int i = 0; i < shapes.length; i++) {
    total_area += shapes[i].area();    // Compute the area of the shapes.
    drawables[i].setPosition(i*10.0, i*10.0);
    drawables[i].draw(draw_window);    // Assume draw_window defined somewhere.
}
```

What this example demonstrates is that interfaces are data types in Java, just as classes are, and that when a class implements an interface, instances of that class can be assigned to variables of the interface type. Don't interpret this example to imply that you must assign a `DrawableRectangle` object to a `Drawable` variable before you can invoke the `draw()` method or that you must assign it to a `Shape` variable before you can invoke the `area()` method. `DrawableRectangle` defines `draw()` and inherits `area()` from its `Rectangle` superclass, and so you can always invoke these methods.

Implementing Multiple Interfaces

Suppose we wanted shapes that could be scaled to be larger or smaller. One way we could do this is by defining a `Scalable` interface and implementing subclasses of `DrawableRectangle` and the other classes. To do this, though, the new subclass would have to implement both the `Drawable` interface and the `Scalable` interface. This is no problem. You may specify a list of comma-separated interfaces in the `implements` clause of any class:

```
public class DrawableScalableRectangle extends DrawableRectangle
                implements Drawable, Scalable {
    // The methods of the Scalable interface must be implemented here.
}
```

When a class implements more than one interface, it means simply that it must provide an implementation for all of the abstract methods in all of its interfaces.

Constants in Interfaces

As we noted above, constants may appear in interface definitions. What does it mean to implement an interface that contains constants? It simply means that the class that implements the interface "inherits" the constants (in a sense) and can use them as if they were defined directly in the class. There is no need to prefix them with the name of the interface, and there is no need to provide an "implementation" of the constants:

```
class A { static final int CONSTANT1 = 3; }
interface B { static final int CONSTANT2 = 4; }
class C implements B {
    void f() {
        int i = A.CONSTANT1;  // Have to use the class name here.
        int j = CONSTANT2;    // No class name here, because we implement
    }                         // the interface that defines this constant.
}
```

When you have a set of constants used by more than one class within a package (for example, a port number and other protocol constants used by a client and server), it is convenient to define them in an interface that contains no abstract `methods`. Then, any class that wants to use those constants needs only to declare that it implements the interface.

Extending Interfaces

Interfaces can have sub-interfaces, just as classes can have subclasses. A sub-interface inherits all the abstract methods and constants of its super-interface, and may define new abstract methods and constants. Interfaces are different from classes in one very important way, however.

An interface can extend more than one interface at a time:

```
public interface Transformable extends Scalable, Rotateable, Reflectable { }
public interface DrawingObject extends Drawable, Transformable { }
public class Shape implements DrawingObject { ... }
```

An interface that extends more than one interface inherits all the abstract methods and constants from each of those interfaces, and may define its own additional abstract methods and constants. A class that implements such an interface must implement the abstract methods defined in the interface itself as well as all the abstract methods inherited from all the super-interfaces.

Marker Interfaces

Another technique that is sometimes useful is to define an interface that is entirely empty. A class can implement this interface to provide additional information about itself. The `Cloneable` interface in `java.lang` is an example of this type of "marker interface." It defines no methods, but serves simply to identify the class as one that will allow its internal state to be cloned by the `clone()` method of the `Object` class. In Java 1.1, `java.io.Serializable` is another such marker interface. You can test whether a class implements a marker interface (or any interface) using the `instanceof` operator.

3.10 C++ Features Not Found in Java

Throughout this chapter, we've noted similarities and differences between Java and C++ in footnotes. Java shares enough concepts and features with C++ to make it an easy language for C++ programmers to pick up. There are several features of C++ that have no parallel in Java, however. In general, Java does not adopt those features of C++ that make the language significantly more complicated. These omissions from Java (or simplifications of C++) are described below.

C++ supports "multiple inheritance" of method implementations from more than one superclass at a time. While this seems like a very useful feature, adding it to the language actually turns out to introduce many complexities. The Java language designers chose to avoid the added complexity by using interfaces instead. Thus, a class in Java can only inherit method implementations from a single superclass, but it can inherit method declarations from any number of interfaces. In practice, this is not any particular hardship.

C++ supports (though not yet in a very standardized way) templates that allow you, for example, to implement a `Stack` class and then instantiate it as `Stack<int>` or `Stack<double>` to produce two separate types: a stack of integers and a stack of floating-point values. Java has no such facility. However, the fact that every class in Java is a subclass of `Object` means that every object can be cast to an instance of `Object`. Thus, in Java, it is often sufficient to define a data structure (such as a `Stack` class) that operates on `Object` values--the objects can be cast back to their actual type whenever necessary.

C++ allows you to define operators that perform arbitrary operations on instances of your classes. In effect, it allows you to extend the syntax of the language. This is a nifty feature, called operator overloading, that makes for very elegant examples. In practice, however, it tends to make code hard to understand. After much debate, the Java language designers decided to omit such "operator overloading" from the language. Note, though, that the use of the `+` operator for string concatenation in Java is at least reminiscent of operator overloading.

C++ allows you to define "conversion functions" for a class that automatically invoke an appropriate constructor method when a value is assigned to a variable of that class. This is simply a syntactic shortcut (similar to overriding the assignment operator) and is not included in Java.

In C++, objects are by default manipulated by value; you must use & to specify a variable or function argument that is automatically manipulated by reference. In Java, all objects are manipulated by reference, so there is no need for this & syntax.

Abstract Classes and Interfaces BOOK INDEX Summary

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Examples From *Java in a Nutshell, Second Edition*

The Java programming examples linked below are from the book *Java in a Nutshell, Second Edition*, by David Flanagan, published by O'Reilly & Associates.

Although you can view the example source code online, by following the links below, I recommend that you download the complete set of examples so that you can work with them on your computer locally. They are available as a zip file or as a gzipped tar file.

Reporting Bugs

If you find any bugs in these examples, please send e-mail describing the bug to bookquestions@ora.com. If you have found a workaround to the problem, please include it.

Copyright

Example 1-2

Scribble.java: an applet of intermediate complexity, used as an example in the introductory chapter.

Example 2-3

throwtest.java: an application that demonstrates how to define, throw, and handle exceptions. This application doesn't do anything other than print out some text, but you might want to study it and play around with it to learn more about how exceptions work in Java. See the usage instructions in the source code.

Example 6-1

FirstApplet.java: the simplest possible applet. Displays "Hello World"

Example 6-2

SecondApplet.java: a fancier version of "Hello World"

Example 6-3

Scribble.java: a simple applet with user interaction. It allows the user to click and scribble in the window.

Example 6-4

ColorScribble.java: the scribble applet, with colors specified through applet parameters in an HTML file.

Example 6-5

Soundmap.java: An applet that displays an image, plays a sound, and demonstrates several other applet capabilities.

Example 7-1

Scribble1.java: a simple applet, using the Java 1.0 event model.

Example 7-2

Scribble2.java: the same applet, using the Java 1.1 event model.

Example 7-3

Scribble3.java: the applet using the Java 1.1 event model and inner classes.

Example 7-4

Scribble4.java: the applet using a low-level interface to the Java 1.1 event model.

Example 8-1

ScribbleFrame.java: a relatively long application that demonstrates many of the new AWT features of Java 1.1, and also demonstrates object serialization and data compression.

Example 9-2

IntList.java: a simple datatype that defines custom serialziation and de-serialization behavior for itself.

Example 10-1

MultiLineLabel.java: a custom AWT component and Java Bean that displays a specified string of text, using multiple lines, if the string contains newline characters.

Example 10-2

YesNoDialog.java: a bean that displays a dialog box.

Example 10-3

AnswerEvent.java: an event type used by the bean.

Example 10-4

AnswerListener.java: the event listener interface used by the bean

Example 10-5

YesNoDialogBeanInfo.java: a BeanInfo class for the bean.

Example 10-6

YesNoDialogAlignmentEditor.java: a property editor class for one of the bean's properties.

Example 10-7

YesNoDialogMessageEditor.java: a property editor class for another of the bean's properties.

Example 10-8

YesNoDialogCustomizer.java: a customizer class for the bean.

Example 11-1

ConvertEncoding.java: an application that converts a file from one character encoding to another.

Example 11-3

Portfolio.java: a dummy stock portfolio program that demonstrates internationalization of dates, times and numbers.

Example 11-4

SimpleMenu.java: a convenience class for simple creation of localized menus using ResourceBundles.

Example 11-5

Menus.properties Menus_en_GB.properties Menus_fr.properties: property files that specify default, British, and French resource bundles for simple menu creation.

Example 11-6

LocalizedError.java: a class that displays a localized error message fora given exception object, using the MessageFormat class.

Example 11-7

Errors.properties: a sample property file used by the previous example

Example 12-1

ShowClass.java: a program that uses the Reflection API to show the fields and methods of a class.

Example 12-2

UniversalActionListener.java: an ActionListener implementation that uses reflection to invoke a named method of an object.

// Here we define some exception types of our own.
// Exception classes generally have constructors but no data or
// other methods.  All these do is to call their superclass constructors.
class MyException extends Exception {
    public MyException() { super(); }
    public MyException(String s) { super(s); }
}
class MyOtherException extends Exception {
    public MyOtherException() { super(); }
    public MyOtherException(String s) { super(s); }
}
class MySubException extends MyException {
    public MySubException() { super(); }
    public MySubException(String s) { super(s); }
}

// This class demonstrates defining, throwing and handling exceptions.
// Try invoking it in the following ways and try to understand the
// output:
//    java throwtest
//    java throwtest one
//    java throwtest 0
//    java throwtest 1
//    java throwtest 99
//    java throwtest 2
//    java throwtest 3
public class throwtest {
    // This is the main() method.  Note that it uses two
    // catch clauses to handle two standard Java exceptions.
    public static void main(String argv[]) {
        int i;

        // First, convert our argument to an integer
        // Make sure we have an argument and that it is convertible.
        try {
            i = Integer.parseInt(argv[0]);
        }
        catch (ArrayIndexOutOfBoundsException e) { // argv is empty
            System.out.println("Must specify an argument");
            return;
        }
        catch (NumberFormatException e) { // argv[0] isn't an integer
            System.out.println("Must specify an integer argument.");
            return;
        }

        // Now, pass that integer to method a().
        a(i);
    }

    // This method invokes b(), which is declared to throw
    // one type of exception.  We handle that one exception.
    public static void a(int i) {
        try {
            b(i);
        }
        catch (MyException e) {                              // Point 1.
            // Here we handle MyException and
            // its subclass MyOtherException
            if (e instanceof MySubException)
                System.out.print("MySubException: ");
            else
                System.out.print("MyException: ");
            System.out.println(e.getMessage());
            System.out.println("Handled at point 1");
        }
    }

    // This method invokes c(), and handles one of the
    // two exception types that that method can throw.  The other
    // exception type is not handled, and is propagated up
    // and declared in this method's throws clause.
    // This method also has a finally clause to finish up
    // the work of its try clause.  Note that the finally clause
    // is executed after a local catch clause, but before a
    // a containing catch clause or one in an invoking procedure.
    public static void b(int i) throws MyException {
        int result;
        try {
            System.out.print("i = " + i);
            result = c(i);
            System.out.print(" c(i) = " + result);
        }
        catch (MyOtherException e) {                          // Point 2
            // Handle MyOtherException exceptions:
            System.out.println("MyOtherException: " + e.getMessage());
            System.out.println("Handled at point 2");
        }
        finally {
            // Terminate the output we printed above with a newline.
            System.out.print("\n");
        }
    }

    // This method computes a value or throws an exception.
    // The throws clause only lists two exceptions, because
    // one of the exceptions thrown is a subclass of another.
    public static int c(int i) throws MyException, MyOtherException {
        switch (i) {
            case 0: // processing resumes at point 1 above
                throw new MyException("input too low");
            case 1: // processing resumes at point 1 above
                throw new MySubException("input still too low");
            case 99:// processing resumes at point 2 above
                throw new MyOtherException("input too high");
            default:
                return i*i;
        }
    }
}
```

6.3 Synchronization

Every thread has a life of its own. Normally, a thread goes about its business without any regard for what other threads in the application are doing. Threads may be time-sliced, which means they can run in arbitrary spurts and bursts as directed by the operating system. On a multiprocessor system, it is even possible for many different threads to be running simultaneously on different CPUs. This section is about coordinating the activities of two or more threads, so they can work together and not collide in their use of the same address space.

Java provides a few simple structures for synchronizing the activities of threads. They are all based on the concept of *monitors*, a widely used synchronization scheme developed by C.A.R. Hoare. You don't have to know the details about how monitors work to be able to use them, but it may help you to have a picture in mind.

A monitor is essentially a lock. The lock is attached to a resource that many threads may need to access, but that should be accessed by only one thread at a time. It's not unlike a public restroom at a gas station. If the resource is not being used, the thread can acquire the lock and access the resource. By the same token, if the restroom is unlocked, you can enter and lock the door. When the thread is done, it relinquishes the lock, just as you unlock the door and leave it open for the next person. However, if another thread already has the lock for the resource, all other threads have to wait until the current thread finishes and releases the lock, just as if the restroom is locked when you arrive, you have to wait until the current occupant is done and unlocks the door.

Fortunately, Java makes the process of synchronizing access to resources quite easy. The language handles setting up and acquiring locks; all you have to do is specify which resources require locks.

Serializing Methods

The most common need for synchronization among threads in Java is to serialize their access to some resource, namely an object. In other words, synchronization makes sure only one thread at a time can perform certain activities that manipulate an object. In Java, every object has a lock associated with it. To be more specific, every class and every instance of a class has its own lock. The `synchronized` keyword marks places where a thread must acquire the lock before proceeding.

For example, say we implemented a `SpeechSynthesizer` class that contains a `say()` method. We don't want multiple threads calling `say()` at the same time or we wouldn't be able to understand anything being said. So we mark the `say()` method as synchronized, which means that a thread has to acquire the lock on the `SpeechSynthesizer` object before it can speak:

```
class SpeechSynthesizer {

    synchronized void say( String words ) {
        // Speak
    }
}
```

Because `say()` is an instance method, a thread has to acquire the lock on the particular `SpeechSynthesizer` instance it is using before it can invoke the `say()` method. When `say()` has completed, it gives up the lock, which allows the next waiting thread to acquire the lock and run the method. Note that it doesn't matter whether the thread is owned by the `SpeechSynthesizer` itself or some other object; every thread has to acquire the same lock, that of the `SpeechSynthesizer` instance. If `say()` were a class (static) method instead of an instance method, we could still mark it as synchronized. But in this case as there is no instance object involved, the lock would be on the class object itself.

Often, you want to synchronize multiple methods of the same class, so that only one of the methods modifies or examines parts of the class at a time. All static synchronized methods in a class use the same class object lock. By the same token, all instance methods in a class use the same instance object lock. In this way, Java can guarantee that only one of a set of synchronized methods is running at a time. For example, a `SpreadSheet` class might contain a number of instance variables that represent cell values, as well as some methods that manipulate the cells in a row:

```
class SpreadSheet {

    int cellA1, cellA2, cellA3;

    synchronized int sumRow() {
        return cellA1 + cellA2 + cellA3;
    }

    synchronized void setRow( int a1, int a2, int a3 ) {
        cellA1 = a1;
        cellA2 = a2;
        cellA3 = a3;
    }
...
}
```

In this example, both methods `setRow()` and `sumRow()` access the cell values. You can see that problems might arise if one thread were changing the values of the variables in `setRow()` at the same moment another thread was reading the values in `sumRow()`. To prevent this, we have marked both methods as synchronized. When threads are synchronized, only one will be run at a time. If a thread is in the middle of executing `setRow()` when another thread calls `sumRow()`, the second thread waits until the first one is done executing `setRow()` before it gets to run `sumRow()`. This synchronization allows us to preserve the consistency of the `SpreadSheet`. And the best part is that all of this locking and waiting is handled by Java; it's transparent to the programmer.

In addition to synchronizing entire methods, the `synchronized` keyword can be used in a special construct to guard arbitrary blocks of code. In this form it also takes an explicit argument that specifies the object for which it is to acquire a lock:

```
synchronized ( myObject ) {
    // Functionality that needs to be synced
    ...
    }
```

The code block above can appear in any method. When it is reached, the thread has to acquire the lock on `myObject` before proceeding. In this way, we can have methods (or parts of methods) in different classes synchronized the same as methods in the same class.

A synchronized method is, therefore, equivalent to a method with its statements synchronized on the current object. Thus:

```
synchronized void myMethod () {
    ...
}
```

is equivalent to:

```
void myMethod () {
    synchronized ( this ) {
        ...
    }
}
```

wait( ) and notify( )

With the `synchronized` keyword, we can serialize the execution of complete methods and blocks of code. The `wait()` and `notify()` methods of the `Object` class extend this capability. Every object in Java is a subclass of `Object`, so every object inherits these methods. By using `wait()` and `notify()`, a thread can give up its hold on a lock at an arbitrary point, and then wait for another thread to give it back before continuing. All of the coordinated activity still happens inside of synchronized blocks, and still only one thread is executing at a given time.

By executing `wait()` from a synchronized block, a thread gives up its hold on the lock and goes to sleep. A thread might do this if it needs to wait for something to happen in another part of the application, as you'll see shortly. Later, when the necessary event happens, the thread that is running it calls `notify()` from a block synchronized on the same object. Now the first thread wakes up and begins trying to acquire the lock again.

When the first thread manages to reacquire the lock, it continues from the point it left off. However, the thread that waited may not get the lock immediately (or perhaps ever). It depends on when the second thread eventually releases the lock, and which thread manages to snag it next. Note also, that the first thread won't wake up from the `wait()` unless another thread calls `notify()`. There is an overloaded version of `wait()`, however, that allows us to specify a timeout period. If another thread doesn't call `notify()` in the specified period, the waiting thread automatically wakes up.

Let's look at a simple scenario to see what's going on. In the following example, we'll assume there are three threads--one waiting to execute each of the three synchronized methods of the `MyThing` class. We'll call them the `waiter`, `notifier`, and `related` threads, respectively. Here's a code fragment to illustrate:

```
class MyThing {

    synchronized void waiterMethod() {
        // Do some stuff

        // Now we need to wait for notifier to do something
        wait();

        // Continue where we left off
    }

    synchronized void notifierMethod() {
        // Do some stuff

        // Notify waiter that we've done it
        notify();
        // Do more things
    }

    synchronized void relatedMethod() {
        // Do some related stuff
    }
```

Let's assume `waiter` gets through the gate first and begins executing `waiterMethod()`. The two other threads are initially blocked, trying to acquire the lock for the `MyThing` object. When `waiter` executes the `wait()` method, it relinquishes its hold on the lock and goes to sleep. Now there are now two viable threads waiting for the lock. Which thread gets it depends on several factors, including chance and the priorities of the threads. (We'll discuss thread scheduling in the next section.)

Let's say that `notifier` is the next thread to acquire the lock, so it begins to run. `waiter` continues to sleep and `related` languishes, waiting for its turn. When `notifier` executes the call to `notify()`, Java prods the `waiter` thread, effectively telling it something has changed. `waiter` then wakes up and rejoins `related` in vying for the `MyThing` lock. Note that it doesn't actually receive the lock; it just changes from saying "leave me alone" to "I want the lock."

At this point, `notifier` still owns the lock and continues to hold it until it leaves its synchronized method (or perhaps executes a `wait()` itself). When it finally completes, the other two methods get to fight over the lock. `waiter` would like to continue executing `waiterMethod()` from the point it left off, while `unrelated`, which has been patient, would like to get started. We'll let you choose your own ending for the story.

For each call to `notify()`, Java wakes up just one method that is asleep in a `wait()` call. If there are multiple threads waiting, Java picks the first thread on a first-in, first-out basis. The `Object` class also provides a `notifyAll()` call to wake up all waiting threads. In most cases, you'll probably want to use `notifyAll()` rather than `notify()`. Keep in mind that `notify()` really means "Hey, something related to this object has changed. The condition you are waiting for may have changed, so check it again." In general, there is no reason to assume only one thread at a time is interested in the change or able to act upon it. Different threads might look upon whatever has changed in different ways.

Often, our `waiter` thread is waiting for a particular condition to change and we will want to sit in a loop like the following:

```
...
while ( condition != true )
    wait();
...
```

Other synchronized threads call `notify()` or `notifyAll()` when they have modified the environment so that `waiter` can check the condition again. This is the civilized alternative to polling and sleeping, as you'll see the following example.

The Message Passer

Now we'll illustrate a classic interaction between two threads: a `Producer` and a `Consumer`. A producer thread creates messages and places them into a queue, while a consumer reads them out and displays them. To be realistic, we'll give the queue a maximum depth. And to make things really interesting, we'll have our consumer thread be lazy and run much slower than the producer. This means that `Producer` occasionally has to stop and wait for `Consumer` to catch up. The example below shows the `Producer` and `Consumer` classes.

```
import java.util.Vector;

class Producer extends Thread {
    static final int MAXQUEUE = 5;
    private Vector messages = new Vector();

    public void run() {
        try {
            while ( true ) {
                putMessage();
                sleep( 1000 );
            }
        }
        catch( InterruptedException e ) { }
    }

    private synchronized void putMessage()
        throws InterruptedException {

        while ( messages.size() == MAXQUEUE )
            wait();
        messages.addElement( new java.util.Date().toString() );
        notify();
    }

    // Called by Consumer
    public synchronized String getMessage()
        throws InterruptedException {
        notify();
        while ( messages.size() == 0 )
            wait();
        String message = (String)messages.firstElement();
        messages.removeElement( message );
        return message;
    }
}

class Consumer extends Thread {
    Producer producer;

    Consumer(Producer p) {
        producer = p;
    }

    public void run() {
        try {
            while ( true ) {
                String message = producer.getMessage();
                System.out.println("Got message: " + message);
                sleep( 2000 );
            }
        }
        catch( InterruptedException e ) { }
    }

    public static void main(String args[]) {
        Producer producer = new Producer();
        producer.start();
        new Consumer( producer ).start();
    }
}
```

For convenience, we have included a `main()` method that runs the complete example in the `Consumer` class. It creates a `Consumer` that is tied to a `Producer` and starts the two classes. You can run the example as follows:

```
% java Consumer
```

The output is the time-stamp messages created by the `Producer`:

```
Got message: Sun Dec 19 03:35:55 CST 1996
Got message: Sun Dec 19 03:35:56 CST 1996
Got message: Sun Dec 19 03:35:57 CST 1996
...
```

The time stamps initially show a spacing of one second, although they appear every two seconds. Our `Producer` runs faster than our `Consumer`. `Producer` would like to generate a new message every second, while `Consumer` gets around to reading and displaying a message only every two seconds. Can you see how long it will take the message queue to fill up? What will happen when it does?

Let's look at the code. We are using a few new tools here. `Producer` and `Consumer` are subclasses of `Thread`. It would have been a better design decision to have `Producer` and `Consumer` implement the `Runnable` interface, but we took the slightly easier path and subclassed `Thread`. You should find it fairly simple to use the other technique; you might try it as an exercise.

The `Producer` and `Consumer` classes pass messages through an instance of a `java.util.Vector` object. We haven't discussed the `Vector` class yet, but you can think of this one as a queue where we add and remove elements in first-in, first-out order. See Chapter 7, *Basic Utility Classes* for more information about the `Vector` class.

The important activity is in the synchronized methods: `putMessage()` and `getMessage()`. Although one of the methods is used by the `Producer` thread and the other by the `Consumer` thread, they both live in the `Producer` class because they have to be synchronized on the same object to work together. Here they both implicitly use the `Producer` object's lock. If the queue is empty, the `Consumer` blocks in a call in the `Producer`, waiting for another message.

Another design option would implement the `getMessage()` method in the `Consumer` class and use a synchronized code block to explicitly synchronize on the `Producer` object. In either case, synchronizing on the `Producer` is important because it allows us to have multiple `Consumer` objects that feed on the same `Producer`.

`putMessage()`'s job is to add a new message to the queue. It can't do this if the queue is already full, so it first checks the number of elements in `messages`. If there is room, it stuffs in another time stamp. If the queue is at its limit however, `putMessage()` has to wait until there's space. In this situation, `putMessage()` executes a `wait()` and relies on the consumer to call `notify()` to wake it up after a message has been read. Here we have `putMessage()` testing the condition in a loop. In this simple example, the test probably isn't necessary; we could assume that when `putMessage()` wakes up, there is a free spot. However, this test is another example of good programming practice. Before it finishes, `putMessage()` calls `notify()` itself to prod any `Consumer` that might be waiting on an empty queue.

`getMessage()` retrieves a message for the `Consumer`. It enters a loop like the `Producer`'s, waiting for the queue to have at least one element before proceeding. If the queue is empty, it executes a `wait()` and expects the producer to call `notify()` when more items are available. Notice that `getMessage()` makes its own unconditional call to `notify()`. This is a somewhat lazy way of keeping the `Producer` on its toes, so that the queue should generally be full. Alternatively, `getMessage()` might test to see if the queue had fallen below a low water mark before waking up the producer.

Now let's add another Consumer to the scenario, just to make things really interesting. Most of the necessary changes are in the Consumer class; the example below shows the code for the modified class.

```
class Consumer extends Thread {
    Producer producer;
        String name;

    Consumer(String name, Producer producer) {
        this.producer = producer;
        this.name = name;
    }

    public void run() {
        try {
            while ( true ) {
                String message = producer.getMessage();
                System.out.println(name + " got message: " + message);
                sleep( 2000 );
            }
        }
        catch( InterruptedException e ) { }
    }

    public static void main(String args[]) {
        Producer producer = new Producer();
        producer.start();

        // Start two this time
        new Consumer( "One", producer ).start();
        new Consumer( "Two", producer ).start();
    }
}
```

The Consumer constructor now takes a string name, to identify each consumer. The run() method uses this name in the call to println() to identify which consumer received the message.

The only modification to make in the Producer code is to change the call to notify() in putMessage() to a call to notifyAll(). Now, instead of the consumer and producer playing tag with the queue, we can have many players waiting on the condition of the queue to change. We might have a number of consumers waiting for a message, or we might have the producer waiting for a consumer to take a message. Whenever the condition of the queue changes, we prod all of the waiting methods to reevaluate the situation by calling `notifyAll()`. Note, however, that we don't need to change the call to `notify()` in `getMessage()`. If a `Consumer` thread is waiting for a message to appear in the queue, it's not possible for the `Producer` to be simultaneously waiting because the queue is full.

Here is some sample output when there are two consumers running, as in the `main()` method shown above:

```
One got message: Wed Mar 20 20:00:01 CST 1996
Two got message: Wed Mar 20 20:00:02 CST 1996
One got message: Wed Mar 20 20:00:03 CST 1996
Two got message: Wed Mar 20 20:00:04 CST 1996
One got message: Wed Mar 20 20:00:05 CST 1996
Two got message: Wed Mar 20 20:00:06 CST 1996
One got message: Wed Mar 20 20:00:07 CST 1996
Two got message: Wed Mar 20 20:00:08 CST 1996
...
```

We see nice, orderly alternation between the two consumers, as a result of the calls to `sleep()` in the various methods. Interesting things would happen, however, if we were to remove all of the calls to `sleep()` and let things run at full speed. The threads would compete and their behavior would depend on whether or not the system is using time slicing. On a time-sliced system, there should be a fairly random distribution between the two consumers, while on a nontime-sliced system, a single consumer could monopolize the messages. And since you're probably wondering about time slicing, let's talk about thread priority and scheduling.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

6.2 Threading Applets

Applets are embeddable Java applications that are expected to be able to start and stop themselves on command. Unlike threads, applets can be started and stopped any number of times. A Java-enabled Web browser normally starts an applet when the applet is displayed and stops it when the user moves to another page or scrolls the applet out of view. In general, we would like an applet to cease its nonessential activity when it is stopped, and resume it when started again. (See Chapter 10, *Understand the Abstract Windowing Toolkit* for a complete discussion of applets.)

In this section, we will build `UpdateApplet`, a simple base class for an `Applet` that maintains a `Thread` to automatically update its display at regular intervals. `UpdateApplet` handles the basic starting and stopping behavior for us, as shown below.

```
public class UpdateApplet extends java.applet.Applet
    implements Runnable {

    private Thread updateThread;
    int updateInterval = 1000;

    public void run() {
        while ( true ) {
            try {
                Thread.sleep( updateInterval );
            }
            catch (InterruptedException e ) { }

            repaint();
        }
    }

    public void start() {
        if ( updateThread == null ) {
            updateThread = new Thread(this);
            updateThread.start();
        }
    }

    public void stop() {
        if ( updateThread != null ) {
            updateThread.stop();
            updateThread = null;
        }
    }
}
```

UpdateApplet is a Runnable object that alternately sleeps and calls its repaint() method. It has two other public methods: start() and stop(). These are methods of the Applet class we are overriding; do not confuse them with the similarly named methods of the Thread class. These start() and stop() methods are called by the Java environment to tell the applet when it should and should not be running.

UpdateApplet illustrates an environmentally friendly way to deal with threads in a simple applet. UpdateApplet kills its thread each time the applet is stopped and recreates it if the applet is restarted. When UpdateApplet's start() method is called, we first check to make sure there is no currently executing updateThread. We then create one to begin our execution. When our applet is subsequently stopped, we kill the thread by invoking its stop() method and throw away the reference by setting it to null. Setting updateThread to null serves both to allow the garbage collector to clean up the dead Thread object, and to indicate to UpdateApplet's start() method that the thread is gone.

In truth, an Applet's start() and stop() methods are guaranteed to be called in sequence. As a result, we shouldn't have to check for the existence of updateThread in start() (it should always be null). However, it's good programming practice to perform the test. If we didn't, and for some reason stop() were to fail at its job, we might inadvertently start a lot of threads.

With UpdateApplet doing all of the work for us, we can now create the world's simplest clock applet with just a few lines of code. Figure 6.3 shows our Clock. (This might be a good one to run on your Java wrist watch.)

```
public class Clock extends UpdateApplet {
    public void paint( java.awt.Graphics g ) {
        g.drawString( new java.util.Date().toString(), 10, 25 );
    }
}
```

Figure 6.3: The clock applet

[Graphic: Figure 6-3]

The `java.util.Date().toString()` sequence simply creates a string that contains the current time; we'll see where this code comes from in Chapter 7, *Basic Utility Classes*.

Our `Clock` applet provides a good example of a simple thread; we don't mind throwing it away and subsequently rebuilding it if the user should happen to wander on and off of our Web page a few times. But what if the task that our thread handles isn't so simple? What if, for instance, we have to open a socket and establish a connection with another system? One solution is to use `Thread`'s `suspend()` and `resume()` methods, as I'll show you momentarily.

Now if you've been wondering why we've been using `stop()` to kill the thread, rather than using the `suspend()` and `resume()` methods all along, here's the explanation you've been waiting for. The problem with applets is that we have no control over how a user navigates Web pages. For example, say a user scrolls our applet out of view, and we use `suspend()` to suspend the applet. Now we have no way of ensuring that the user will bring the applet back into view before moving on to another page. And actually, the same situation would occur if the user simply moves on to another page and never comes back.

If we call `suspend()`, we'd really like to make sure we call `resume()` at a later date, or we'll end up leaving the thread hanging in permanent suspense. But we have no way of knowing if the applet will ever be restarted, so just putting a call to `resume()` in the applet's `start()` method won't work. Leaving the suspended thread around forever might not hurt us, but it's not good programming practice to be wasteful. What we need is a way to guarantee we can clean up our mess if the applet is never used again. What to do?

There is a solution for this dilemma, but in many cases, like with our simple `Clock`, it's just easier to use `stop()`, with a subsequent call to `start()` if necessary. In cases where it is expensive to set up and tear down a thread, we could make the following modifications to `UpdateApplet`:

```
public void start() {
    if ( updateThread == null ) {
        updateThread = new Thread(this);
        updateThread.start();
    }
    else
        updateThread.resume();
}

public void stop() {
    updateThread.suspend();

public void destroy() {
    if ( updateThread != null ) {
        updateThread.stop();
        updateThread = null;
    }
}
```

These modifications change `UpdateApplet` so that it suspends and restarts its `updateThread`, rather than killing and recreating it. The new `start()` method creates the thread and calls `start()` if `updateThread` is `null`; otherwise it assumes that the thread has been suspended, so it calls `resume()`. The applet's `stop()` method simply suspends the thread by calling `suspend()`.

What's new here is the `destroy()` method. This is another method that `UpdateApplet` inherits from the `Applet` class. The method is called by the Java environment when the applet is going to be removed (often from a cache). It provides a place where we can free up any resources the applet is holding. This is the perfect place to cut the suspense and clean up after our thread. In our `destroy()` method, we check to see that the thread exists, and if it does, we call `stop()` to kill it and set its reference to `null`.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.2 Vectors

The Vector class implements a variable-length array that can hold any kind of object. Like an array, the elements in a Vector are accessed with an integer index. However, unlike an array, the size of a Vector can grow and shrink as needed to accommodate a changing number of objects. Vector provides methods to add and remove elements, as well as ways to search for objects in a Vector and iterate through all of the objects.

You can create a Vector object using the constructor that takes no arguments.

```
Vector v = new Vector()
```

This constructor creates an empty Vector with an initial capacity of 10. The capacity of a Vector specifies how many objects it can contain before more space must be allocated. You can improve the performance of a Vector by setting its initial capacity to a more appropriate value when you create it. For example, if you know that you are going to be storing close to 100 objects in a Vector, you could set the initial capacity as follows:

```
Vector v = new Vector(100)
```

It can be time-consuming for a Vector to increase its capacity, so it is better to set the initial capacity based on a rough estimate of the number of objects a Vector will contain than to simply use the default capacity.

The capacity increment of a Vector specifies how much more space is allocated each time the Vector needs to increase its capacity. If you do not specify a capacity increment when you create a Vector, it uses the default value of 0, which causes the Vector to double in size every time it needs to increase its capacity. Doubling in size is a good way for a Vector to become large enough quickly when you have no idea what size it needs to be. However, if you do have a rough idea of the final size of a Vector, specifying a positive capacity increment is less wasteful of memory. For example, if you know that you will be putting 100 or so objects in a Vector, you could create it as follows:

```
Vector v = new Vector(110, 20)
```

Once you have created an empty `Vector` object, you can put object references in it using the `addElement()` and `insertElementAt()` methods. The `addElement()` method adds an element to the end of a `Vector`. The following code fragment shows the use of the `addElement()` method:

```
Vector v = new Vector();
v.addElement("abc");
v.addElement("jkl");
v.addElement("xyz");
```

The `insertElementAt()` method inserts a new element into a `Vector` before a given position, so it can be used to insert an element at any position in a `Vector` except the last. Like arrays, `Vector` objects are indexed starting at 0. Here's how to insert an object at the beginning of the `Vector` object created above:

```
v.insertElementAt("123", 0);
```

The `size()` method returns the number of elements in a `Vector` object.

After you have added some elements to a `Vector` object, you can retrieve elements with a number of different methods. For example, the `elementAt()` method fetches the object at the specified position in the `Vector`, while the `firstElement()` and `lastElement()` methods return the first and last objects in the `Vector`, respectively. Finally, the `elements()` method returns an `Enumeration` object that accesses the elements in the `Vector` object.

The `setElementAt()` method allows you to change the object stored at a specified position in the `Vector`, while the `removeElementAt()` method removes the object at a specified position from the `Vector`. The `removeElement()` method takes an object reference as an argument and removes the first element in the `Vector` that refers to the given object, if there is such an element. You can also remove all of the elements from the `Vector` using the `removeAllElements()` method.

The `Vector` class also provides some methods for searching the contents of a `Vector` object. For example, the `contains()` method returns `true` if a `Vector` contains a reference to a specified object. The `indexOf()` and `lastIndexOf()` methods return the positions of the first and last elements, respectively, in a `Vector` that match a specified object.
