This method places a byte containing the low-order eight bits of the given integer into the buffer. If the buffer is full, it is flushed, and the value `b` is placed in the newly empty buffer. If the buffer is flushed, this method blocks until `flush()` returns; otherwise this method returns immediately.

`public synchronized void write(byte b[], int off, int len) throws IOException`

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.write(byte[], int, int)`

Description

This method copies `len` bytes from `b`, starting at `off`, into the buffer. If there is enough space left in the buffer for the new data, it is copied into the buffer and the method returns immediately. Otherwise, the buffer is flushed, and the new data is written directly to the underlying stream. This is subtly different from the behavior of `write(int)`, which places new data in the buffer after a `flush()`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`FilterOutputStream`
`equals(Object)`	`Object`	`finalize()`	`Object`

BufferedReader

Name

BufferedReader

Synopsis

Class Name:

`java.io.BufferedReader`

Superclass:

`java.io.Reader`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A BufferedReader object provides a more efficient way to read just a few characters at a time from a Reader. BufferedReader objects use a buffer to store input from an associated Reader. In other words, a large number of characters are read from the underlying reader and stored in an internal buffer. A BufferedReader is more efficient than a regular Reader because reading data from memory is faster than reading it from a disk or a network. All reading is done directly from the buffer; the disk or network needs to be accessed only occasionally to fill up the buffer.

You should wrap a BufferedReader around any Reader whose read() operations may be time consuming or costly, such as a FileReader or InputStreamReader.

BufferedReader provides a way to mark a position in the stream and subsequently reset the stream to that position, using mark() and reset().

A BufferedReader is similar to a BufferedInputStream, but it operates on a stream of Java characters instead of a byte stream, which makes it easier to support internationalization.

Class Summary

```
public class java.io.BufferedReader extends java.io.Reader {
  // Constructors
  public BufferedReader(Reader in);
  public BufferedReader(Reader in, int sz);
  // Instance Methods
  public void close();
  public void mark(int readAheadLimit);
  public boolean markSupported();
  public int read();
  public int read(char[] cbuf, int off, int len);
  public String readLine();
  public boolean ready();
  public void reset();
  public long skip(long n);
}
```

Constructors

BufferedReader

public BufferedReader(Reader in)

Parameters

`in`

The reader to buffer.

Description

This constructor creates a `BufferedReader` that buffers input from the given `Reader` using a buffer with the default size of 8192 characters.

public BufferedReader(Reader in, int sz)

Parameters

`in`

The reader to buffer.

`sz`

The size of buffer to use.

Throws

`IllegalArgumentException`

If the specified size is less than 0.

Description

This constructor creates a `BufferedReader` that buffers input from the given `Reader`, using a buffer of the given size.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.close()`

Description

This method closes this `BufferedReader` and its underlying `Reader`.

mark

public void mark(int readAheadLimit) throws IOException

Parameters

`readlimit`

The maximum number of bytes that can be read before the saved position becomes invalid.

Throws

`IOException`

If the stream is closed.

Overrides

`Reader.mark(int)`

Description

This method causes the `BufferedReader` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position, and thus reread a portion of the buffer.

markSupported

public boolean markSupported()

Returns

The `boolean` value `true`.

Overrides

`Reader.markSupported()`

Description

This method returns `true` to indicate that this class supports `mark()` and `reset()`.

read

public int read() throws IOException

Returns

The next character of data, or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.read()`

Description

This method returns the next character from the buffer. If all the characters in the buffer have been read, the buffer is filled from the underlying `Reader`, and the next character is returned. If the buffer does not need to be filled, this method returns immediately. If the buffer needs to be filled, this method blocks until data is available from the underlying `Reader`, the end of the stream is reached, or an exception is thrown.

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

Offset into the character array.

`len`

Number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.read(char[], int, int)`

Description

This method reads characters from the internal buffer into the given array `cbuf`, starting at index `off` and continuing for up to `len` bytes. If there are any characters in the buffer, this method returns immediately. Otherwise the buffer needs to be filled; this method blocks until the data is available from the underlying `InputStream`, the end of the stream is reached, or an exception is thrown.

readLine

public String readLine() throws IOException

Returns

A `String` containing the line just read, or `null` if the end of the stream has been reached.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads a line of text. Lines are terminated by `"\n"`, `"\r"`, or `"\r\n"`. The line terminators are not returned with the line string.

ready

public boolean ready() throws IOException

Returns

A `boolean` value that indicates whether the stream is ready to be read.

Throws

`IOException`

If the stream is closed.

Overrides

`Reader.ready()`

Description

If there is data in the buffer, or if the underlying stream is ready, this method returns `true`. The underlying stream is ready if the next `read()` is guaranteed to not block. Note that a return value of `false` does not guarantee that the next read operation will block.

reset

public void reset() throws IOException

Throws

`IOException`

If the reader is closed, `mark()` has not been called, or the saved position has been invalidated.

Overrides

`Reader.reset()`

Description

This method sets the position of the `BufferedReader` to a position that was saved by a previous call to `mark()`. Subsequent characters read from this `BufferedReader` will begin from the saved position and continue normally.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of characters to skip.

Returns

The actual number of characters skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.skip()`

Description

This method skips `n` characters of input. If the new position of the stream is still within the data contained in the buffer, the method returns immediately. Otherwise the buffer is repeatedly filled until the requested position is available.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`read(char[])`	`Reader`
`toString()`	`Object`	`void wait()`	`Object`
`void wait(long)`	`Object`	`void wait(long, int)`	`Object`

See Also

BufferedWriter

Name

BufferedWriter

Synopsis

Class Name:

`java.io.BufferedWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `BufferedWriter` object provides a more efficient way to write just a few characters at a time to a `Writer`. `BufferedWriter` objects use a buffer to store output for an associated `Writer`. In other words, a large number of characters are stored in an internal buffer and only written when the buffer fills up or is explicitly flushed. A `BufferedWriter` is more efficient than a regular `Writer` because the data is written to memory, rather than a disk or a network. Minimizing the number of write operations to a disk or the network minimizes the cumulative overhead for these operations.

You should wrap a `BufferedWriter` around any `Writer` whose `write()` operations may be time consuming or costly, such as a `FileWriter` or a `OutputStreamWriter`.

This class is very similar to `BufferedOutputStream`, but it operates on a stream of Java characters instead of a byte stream; this makes it easier to support internationalization.

Class Summary

```
public class java.io.BufferedWriter extends java.io.Writer {
  // Constructors
  public BufferedWriter(Writer out);
  public BufferedWriter(Writer out, int size);
  // Instance Methods
  public void close();
  public void flush();
  public void newLine();
  public void write(int c);
  public void write(char[] cbuf, int off, int len);
  public void write(String s, int off, int len);
}
```

Constructors

BufferedWriter

public BufferedWriter (Writer out)

Parameters

`out`

The output stream to buffer.

Description

This constructor creates a `BufferedWriter` that acts on the specified `Writer`, using a buffer with the default size of 8192 characters.

public BufferedWriter (Writer out, int size)

Parameters

`out`

The output stream to buffer.

`size`

The size of buffer to use.

Throws

`IllegalArgumentException`

If the specified size is less than 0.

Description

This constructor creates a `BufferedWriter` that acts on the specified `Writer`, using a buffer that is `size` bytes long.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.close()`

Description

This method closes this `BufferedWriter` and its underlying `Writer`.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.flush()`

Description

This method writes the contents of the buffer to the underlying `Writer` and calls `flush()` on the underlying `Writer`. It is called automatically when the buffer fills up. You can also call it before the buffer is full. This is known as "flushing" the buffer. This method blocks until the underlying `write()` is complete.

newLine

public void newLine() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

> This method writes the newline character or characters to the stream. It uses `System.getProperty('line.separator')` to choose the newline appropriate for the run-time system. Calling this method is preferable to explicitly writing a newline character.

write

public void write(int c) throws IOException

Parameters

> `c`
>
> > The value to write.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Overrides

> `Writer.write(int)`

Description

> This method places the low-order 16 bits of the specified value into the buffer. If the buffer is full, it is flushed, and the value `c` is placed in the newly empty buffer. If the buffer is flushed, this method blocks while the data is written; otherwise this method returns immediately.

`public void write(char[] cbuf, int off, int len) throws IOException`

Parameters

> `cbuf`
>
> > An array of characters to write.

`off`

An offset into the character array.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(char[], int, int)`

Description

This method copies `len` characters from `cbuf`, starting at `off`, into the buffer. If there is enough space left in the buffer for the new data, it is copied into the buffer, and the method returns immediately. Otherwise, the buffer is filled and flushed repeatedly until all the new data has been copied into the buffer.

public void write(String s, int off, int len) throws IOException

Parameters

`s`

The string to be written.

`off`

An offset into the string.

`len`

The number of characters to write.

Throws

`IOException`

If an I/O error occurs.

Overrides

`Writer.write(String, int, int)`

Description

This method copies `len` characters from `s`, starting at `off`, into the buffer. If there is enough space left in the buffer for the new data, it is copied into the buffer and the method returns immediately. Otherwise, the buffer is filled and flushed repeatedly until all the new data has been copied into the buffer.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`	`write(char[])`	`Writer`
`write(String)`	`Writer`

ByteArrayInputStream

ByteArrayInputStream

Name

ByteArrayInputStream

Synopsis

Class Name:

    java.io.ByteArrayInputStream

Superclass:

    java.io.InputStream

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `ByteArrayInputStream` is a stream whose data comes from a byte array. None of the methods of this class throw an `IOException` because the data comes from an array instead of an actual I/O device. This class does not support the ability to mark a position in the stream. A call to `reset()`, however, does position the stream at the beginning of the byte array.

The position of the end of the stream depends on the constructor used. If the `ByteArrayInputStream(byte[] buf)` constructor is used, the end of the stream is the end of the byte array. If the `ByteArrayInputStream(byte[] buf, int offset, int length)` constructor is used, the end of the stream is reached at the index given by `offset+length`.

Class Summary

```
public class java.io.ByteArrayInputStream extends java.io.InputStream {
  // Variables
  protected byte[] buf;
  protected int count;
  protected int pos;
  // Constructors
  public ByteArrayInputStream(byte[] buf);
  public ByteArrayInputStream(byte[] buf, int offset, int length);
  // Instance Methods
  public synchronized int available();
  public synchronized int read();
  public synchronized int read(byte[] b, int off, int len);
  public synchronized void reset();
  public synchronized long skip(long n);
}
```

Variables

buf

protected byte[] buf

Description

> The buffer represented by this stream.

count

protected int count

Description

A placeholder that marks the end of the data this `ByteArrayInputStream` represents.

pos

protected int pos

Description

The current position in the buffer.

Constructors

ByteArrayInputStream

public ByteArrayInputStream(byte[] buf)

Parameters

`buf`

The stream source.

Description

This constructor creates a `ByteArrayInputStream` object that uses the given array of bytes as its data source. The data is not copied, so changes made to the array affect the data the `ByteArrayInputStream` returns.

public ByteArrayInputStream(byte[] buf, int offset, int length)

Parameters

`buf`

The stream source.

`offset`

An index into the buffer where the stream should begin.

`length`

The number of bytes to read.

Description

This constructor creates a `ByteArrayInputStream` that uses, as its data source, `length` bytes in a given array of bytes, starting at `offset` bytes from the beginning of the array. The data is not copied, so changes made to the array affect the data the `ByteArrayInputStream` returns.

Instance Methods

available

public synchronized int available()

Returns

The number of bytes remaining to be read in the array.

Overrides

`InputStream.available()`

Description

This method returns the number of bytes remaining to be read in the byte array.

read

public synchronized int read()

Returns

The next byte or `-1` if the end of the stream is encountered.

Overrides

`InputStream.read()`

Description

This method returns the next byte in the array.

public synchronized int read(byte[] b, int off, int len)

Parameters

`b`

An array to read bytes into.

`off`

An offset into `b`.

`len`

The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of the stream is encountered.

Overrides

`InputStream.read(byte[], int, int)`

Description

This method copies up to `len` bytes from its internal byte array into the given array `b`, starting at index `off`.

reset

public synchronized void reset()

Overrides

`InputStream.reset()`

Description

This method resets the position of the input stream to the beginning of the byte array. If you specified an offset into the array, you might expect this method to reset the position to where you first started reading from the stream, but that is not the case.

skip

public synchronized long skip(long n)

Parameters

`n`

The number of bytes to skip.

Returns

The number of bytes skipped.

Overrides

`InputStream.skip()`

Description

This method skips `n` bytes of input. If you try to skip past the end of the array, the stream is positioned at the end of the array.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`InputStream`
`equals (Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`mark(int)`	`InputStream`	`markSupported ()`	`InputStream`
`notify()`	`Object`	`notifyAll()`	`Object`
`read(byte[])`	`InputStream`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

BufferedWriter BOOK INDEX ByteArrayOutputStream

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ByteArrayOutputStream

Name

ByteArrayOutputStream

Synopsis

Class Name:

`java.io.ByteArrayOutputStream`

Superclass:

`java.io.FilterOutputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `ByteArrayOutputStream` is a stream whose data is written to an internal byte array. None of the methods of this class throws an `IOException` because the data is written to an array instead of an actual I/O device.

The data for a `ByteArrayOutputStream` can be sent to another `OutputStream` using the `writeTo()` method. A copy of the array can be obtained using the `toCharArray()` method.

Class Summary

```
public class java.io.ByteArrayOutputStream extends java.io.OutputStream {
  // Variables
  protected byte[] buf;
  protected int count;

  // Constructors
  public ByteArrayOutputStream();
  public ByteArrayOutputStream(int size);
  // Instance Methods
  public synchronized void reset();
  public int size( );
  public synchronized byte[] toByteArray();
  public String toString();
  public String toString(int hibyte);            // Deprecated in 1.1
  public String toString(String enc);            // New in 1.1
  public synchronized void write(int b);
  public synchronized void write(byte[] b, int off, int len);
  public synchronized void writeTo(OutputStream out);
}
```

Variables

buf

protected byte[] buf

Description

The buffer that holds data for this stream.

count

protected int count

Description

A placeholder that marks the end of the data in the buffer.

Constructors

ByteArrayOutputStream

public ByteArrayOutputStream()

Description

This constructor creates a `ByteArrayOutputStream` with an internal buffer that has a default size of 32 bytes. The buffer grows automatically as data is written to the stream.

public ByteArrayOutputStream(int size)

Parameters

`size`

The initial buffer size.

Description

This constructor creates a `ByteArrayOutputStream` with an internal buffer that has a size of `size` bytes. The buffer grows automatically as data is written to the stream.

Instance Methods

reset

public synchronized void reset()

Description

This method discards the current contents of the buffer and resets the position of the stream to zero. Subsequent data is written starting at the beginning of the array.

size

public int size()

Description

> This method returns the number of bytes currently stored in this object's internal buffer. It is a count of the number of bytes that have been written to the stream.

toByteArray

public synchronized byte[] toByteArray()

Returns

> A copy of the data that has been written to this `ByteArrayOutputStream`.

Description

> This method copies the data in the internal array and returns a reference to the copy. The returned array is as long as the data that has been written to the stream, i.e., the same as `size()`.

toString

public String toString()

Returns

> A copy of the data that has been written to this `ByteArrayOutputStream`.

Overrides

> `Object.toString()`

Description

> This method returns a reference to a `String` object that contains a copy of the bytes currently stored in this object's internal buffer. The bytes are assumed to represent characters in the encoding that is customary for the native platform, so the bytes are converted to Unicode characters based on that assumption.

public String toString(int hibyte)

Availability

Deprecated as of JDK 1.1

Parameters

`hibyte`

A value to use as the high byte of each character.

Returns

A copy of the data that has been written to this `ByteArrayOutputStream`, where each character in the string has a high byte of `hibyte` and a low byte taken from the corresponding byte in the array.

Description

This method provides a way to convert from bytes to characters. As of 1.1, it is deprecated and replaced with `toString(String)`.

`public String toString(String enc) throws UnsupportedEncodingException`

Availability

New as of JDK 1.1

Parameters

`enc`

The encoding scheme to use.

Returns

A copy of the data that has been written to this `ByteArrayOutputStream`, converted from bytes to characters via the named encoding scheme `enc`.

Throws

`UnsupportedEncodingException`

The specified encoding is not supported.

Description

This method returns a Java `String` created from the byte array of this stream. The conversion is performed according to the encoding scheme `enc`.

write

public synchronized void write(int b)

Parameters

`b`

The value to write.

Overrides

`OutputStream.write(int)`

Description

This method writes the low-order 8 bits of the given value into the internal array. If the array is full, a larger array is allocated.

public synchronized void write(byte b[], int off, int len)

Parameters

`b`

The array to copy from.

`off`

Offset into the byte array.

`len`

Number of bytes to write.

Overrides

`OutputStream.write(byte[], int, int)`

Description

This method copies `len` bytes to this object's internal array from `b`, starting `oset` elements from the beginning of the supplied array `b`. If the internal array is full, a larger array is allocated.

writeTo

```
public synchronized void writeTo(OutputStream out) throws IOException
```

Parameters

`out`

The destination stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes the contents of this object's internal buffer to the given `OutputStream`. All the data that has been written to this `ByteArrayOutputStream` is written to `out`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`OutputStream`
`equals(Object)`	`Object`	`finalize()`	`Object`
`flush()`	`OutputStream`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`

`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`
`write(byte[])`	`OutputStream`

CharArrayReader

Name

CharArrayReader

Synopsis

Class Name:

```
java.io.CharArrayReader
```

Superclass:

```
java.io.Reader
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `CharArrayReader` class represents a stream whose data comes from a character array. This class is similar to `ByteArrayInputStream`, but it deals with a Java character stream rather than a byte stream. Furthermore, this class supports marking a position in the stream, which `ByteArrayInputStream` does not.

The position of the end of the stream depends on the constructor used. If the `CharArrayReader(char[] buf)` constructor is used, the end of the stream is the end of the character array. If the `CharArrayReader(char[] buf, int offset, int length)` constructor is used, the end of the stream is reached at the index given by `offset+length`.

Class Summary

```
public class java.io.CharArrayReader extends java.io.Reader {
  // Variables
  protected char[] buf;
  protected int count;
  protected int markedPos;
  protected int pos;
  // Constructors
  public CharArrayReader(char[] buf);
  public CharArrayReader(char[] buf, int offset, int length);
  // Instance Methods
  public void close();
  public void mark(int readAheadLimit);
  public boolean markSupported();
  public int read();
  public int read(char[] b, int off, int len);
  public boolean ready();
  public void reset();
  public long skip(long n);
}
```

Variables

buf

protected char[] buf

Description

The buffer represented by this reader.

count

protected int count

Description

The size of the buffer, or in other words, the length of the array.

markedPos

protected int markedPos

Description

The buffer position when `mark()` was called. If `mark()` has not been called, this variable is 0.

pos

protected int pos

Description

The current position in the buffer.

Constructors

CharArrayReader

public CharArrayReader(char[] buf)

Parameters

`buf`

The reader source.

Description

This constructor creates a `CharArrayReader` object that uses the given array of characters as its data source. The data is not copied, so changes made to the array affect the data that the `CharArrayReader` returns.

public CharArrayReader(char[] buf, int offset, int length)

Parameters

`buf`

The reader source.

`offset`

An offset into the array.

`length`

The number of bytes to read.

Description

This constructor creates a `CharArrayReader` that uses, as its data source, `length` characters in a given array of bytes, starting at `offset` characters from the beginning of the array. The data is not copied, so changes made to the array affect the data that the `CharArrayReader` returns.

Instance Methods

close

public void close()

Overrides

`Reader.close()`

Description

This method closes the reader by removing the link between this `CharArrayReader` and the array it was created with.

mark

public void mark(int readAheadLimit) throws IOException

Parameters

`readAheadLimit`

The maximum number of characters that can be read before the saved position becomes invalid.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.mark(int)`

Description

This method causes the `CharArrayReader` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position, and thus reread a portion of the buffer. Because the data for this stream comes from a `char` array, there is no limit on reading ahead, so `readAheadLimit` is ignored.

markSupported

public boolean markSupported()

Returns

The `boolean` value `true`.

Overrides

`Reader.markSupported()`

Description

This method returns `true` to indicate that this class supports `mark()` and `reset()`.

read

public int read() throws IOException

Returns

The next character or `-1` if the end of the stream is encountered.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.read()`

Description

This method returns the next character in the array.

public int read(char[] b, int off, int len) throws IOException

Parameters

`b`

An array of characters to be filled from the stream.

`off`

An offset into the character array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.read(char[], int, int)`

Description

This method copies up to `len` characters from its internal array into the given array `b`, starting at index `off`.

ready

public boolean ready() throws IOException

Returns

A `boolean` value that indicates whether the stream is ready to be read.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.ready()`

Description

If there is any data left to be read from the character array, this method returns `true`.

reset

public void reset() throws IOException

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.reset()`

Description

This method resets the position of the `CharArrayReader` to the position that was saved by calling the `mark()` method. If `mark()` has not been called, the `CharArrayReader` is reset to read from the beginning of the array.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of characters to skip.

Returns

The actual number of characters skipped.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.skip()`

Description

This method skips n characters of input. If you try to skip past the end of the array, the stream is positioned at the end of the array.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals (Object)`	`Object`

CharArrayWriter

Name

CharArrayWriter

Synopsis

Class Name:

`java.io.CharArrayWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `CharArrayWriter` class represents a stream whose data is written to an internal character array. This class is similar to `ByteArrayOutputStream`, but it operates on an array of Java characters instead of a byte array.

The data from a `CharArrayWriter` can be sent to another `Writer` using the `writeTo()` method. A copy of the array can be obtained using the `toCharArray()` method.

Class Summary

```
public class java.io.CharArrayWriter extends java.io.Writer {
  // Variables
  protected char[] buf;
  protected int count;
  // Constructors
  public CharArrayWriter();
  public CharArrayWriter(int initialSize);
  // Instance Methods
  public void close();
  public void flush();
  public void reset();
  public int size();
  public char[] toCharArray();
  public String toString();
  public void write(int c);
  public void write(char[] c, int off, int len);
  public void write(String str, int off, int len);
  public void writeTo(Writer out);
}
```

Variables

buf

protected char[] buf

Description

The buffer that holds data for this stream.

count

protected int count

Description

A placeholder that marks the end of the data in the buffer.

Constructors

CharArrayWriter

public CharArrayWriter()

Description

This constructor creates a `CharArrayWriter` with an internal buffer that has a default size of 32 characters. The buffer grows automatically as data is written to the stream.

public CharArrayWriter(int initialSize)

Parameters

`initialSize`

The initial buffer size.

Description

This constructor creates a `CharArrayWriter` with an internal buffer that has a size of `initialSize` characters. The buffer grows automatically as data is written to the stream.

Instance Methods

close

public void close()

Overrides

> `Writer.close()`

Description

> This method does nothing. For most subclasses of `Writer`, this method releases any system resources that are associated with the `Writer` object. However, the `CharArrayWriter`'s internal array may be needed for subsequent calls to `toCharArray()` or `writeTo()`. For this reason, `close()` does nothing, and the internal array is not released until the `CharArrayWriter` is garbage collected.

flush

public void flush()

Overrides

> `Writer.flush()`

Description

> This method does nothing. The `CharArrayWriter` writes data directly into its internal array; thus it is never necessary to flush the stream.

reset

public void reset()

Description

> This method discards the current contents of the buffer and resets the position of the stream to zero. Subsequent data is written starting at the beginning of the array.

size

public int size()

Description

> This method returns the number of characters currently stored in this object's internal buffer. It is a count of the number of characters that have been written to the stream.

toCharArray

public char[] toCharArray()

Returns

> A copy of the data that has been written to this `CharArrayWriter` in the form of a `char` array.

Description

> This method copies the data in the internal array and returns a reference to the copy. The returned array is as long as the data that has been written to the stream, i.e., the same as `size()`.

toString

public String toString()

Returns

> A copy of the data that has been written to this `CharArrayWriter` in the form of a `String`.

Overrides

> `Object.toString()`

Description

> This method returns a reference to a `String` object created from the characters stored in this object's internal buffer.

write

public void write(int c)

Parameters

`c`

The value to write.

Overrides

`Writer.write(int)`

Description

This method writes the low-order 16 bits of the given value into the internal array. If the array is full, a larger array is allocated.

public void write(char[] c, int off, int len)

Parameters

`c`

An array of characters to write to the stream.

`off`

An offset into the character array.

`len`

The number of characters to write.

Overrides

`Writer.write(char[], int, int)`

Description

This method copies `len` characters to this object's internal array from `c`, starting `off` elements from the beginning of the array. If the internal array is full, a larger array is allocated.

public void write(String str, int off, int len)

Parameters

`str`

A `String` to write to the stream.

`off`

An offset into the string.

`len`

The number of characters to write.

Overrides

`Writer.write(String, int, int)`

Description

This method copies `len` characters to this object's internal array from `str`, starting `off` characters from the beginning of the given string. If the internal array is full, a larger array is allocated.

writeTo

public void writeTo(Writer out) throws IOException

Parameters

`out`

The destination stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

> This method writes the contents of this object's internal buffer to the given `Writer`. All the data that has been written to this `CharArrayWriter` is written to `out`.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`

CharConversionException

Name

CharConversionException

Synopsis

Class Name:

```
java.io.CharConversionException
```

Superclass:

```
java.io.IOException
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `CharConversionException` object is thrown when a problem occurs in converting a character to a byte.

Class Summary

```
public class java.io.CharConversionException extends java.io.IOException {
  // Constructors
  public CharConversionException();
  public CharConversionException(String s);
}
```

Constructors

CharConverionException

public CharConversionException()

Description

This constructor creates a `CharConversionException` with no detail message.

public CharConversionException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `CharConversionException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`fillInStackTrace()`	`Throwable`	`finalize()`	`Object`
`getClass()`	`Object`	`getLocalizedMessage()`	`Throwable`

File

Name

File

Synopsis

Class Name:

> `java.io.File`

Superclass:

> `java.lang.Object`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> JDK 1.0 or later

Description

The `File` class provides methods to obtain information about files and directories. A `File` object encapsulates the name of a file or a directory. A `File` object can list the files in a directory, check the existence and type of a file, create new directories, and rename and delete files, among other things. However, the `File` class does not handle I/O to files. Actual reading and writing is accomplished using `RandomAccessFile`, `FileReader`, `FileWriter`, `FileInputStream`, and `FileOutputStream` objects.

The `File` class also defines some constants for the platform-specific directory and path separator characters. If you want to avoid putting system-dependent path information in your program, you may want to reference all files relative to the directory in which your program is running (i.e., the current directory). Alternatively, you can use `java.awt.FileDialog` to prompt the user for system-dependent paths.

Many of the methods in `File` throw a `SecurityException` if the application does not have sufficient privileges for the requested operation. This happens in two steps. First, `System.getSecurityManager()` is called. If a `SecurityManager` has been installed, it is queried for the appropriate permission. For example, `File.canRead()` calls `SecurityManager.canRead()`. If the application does not have permission to read the specified file, the `SecurityManager` throws a `SecurityException`, which in turn is thrown by `File.canRead()`.

Class Summary

```
public class java.io.File extends java.lang.Object
                          implements java.io.Serializable {
  // Constants
  public final static String pathSeparator;
  public final static char pathSeparatorChar;
  public final static String separator;
  public final static char separatorChar;
  // Constructors
  public File(String path);
  public File(String path, String name);
  public File(File dir, String name);
  // Instance Methods
  public boolean canRead();
  public boolean canWrite();
  public boolean delete();
  public boolean equals(Object obj);
  public boolean exists();
  public String getAbsolutePath();
  public String getCanonicalPath();              // New in 1.1
  public String getName();
  public String getParent();
  public String getPath();
  public int hashCode();
  public native boolean isAbsolute();
  public boolean isDirectory();
  public boolean isFile();
  public long lastModified();
  public long length();
  public String[] list();
  public String[] list(FilenameFilter filter);
  public boolean mkdir();
  public boolean mkdirs();
  public boolean renameTo(File dest);
  public String toString();
}
```

Constants

pathSeparator

public final static String pathSeparator

Description

> This string holds the value of `System.getProperty('path.separator')`. It contains the character that separates paths in a path list. Usually it is "`:`" or "`;`".

pathSeparatorChar

public final static char pathSeparatorChar

Description

> This variable holds the first (and only) character in `pathSeparator`.

separator

public final static String separator

Description

This string holds the value of `System.getProperty('file.separator')`. It contains the character that separates directory and filenames in a path string. Usually it is "`/`" or "`\`".

separatorChar

public final static char separatorChar

Description

This variable holds the first (and only) character in `separator`.

Constructors

File

public File(String path)

Parameters

`path`

A full pathname (i.e., a directory and filename).

Description

This constructor creates a `File` object that represents the file specified by `path`.

public File(String path, String name)

Parameters

`path`

A directory path.

name

A filename.

Description

This constructor creates a `File` object that represents the file with the specified `name` in the directory described by `path`. In other words, the full pathname is the directory, followed by the separator character, followed by the filename.

If `path` is `null`, the constructor creates a `File` that represents the file with the specified `name` in the current directory. The current directory is the directory in which the program is running.

public File(File dir, String name)

Parameters

dir

A `File` object that represents a directory.

name

A filename.

Description

This constructor creates a `File` object that represents the file with the specified `name` in the directory described by the `File` object `dir`. In other words, the full pathname is the directory represented by `dir`, followed by the separator character, followed by the filename.

If `dir` is `null`, the constructor creates a `File` that represents the file with the specified `name` in the current directory. The current directory is the directory in which the program is running.

Instance Methods

canRead

public boolean canRead()

Returns

A `boolean` value that indicates if the file is readable.

Throws

`SecurityException`

If the application does not have permission to read the `File`.

Description

This method returns `true` if `File` corresponds to an existing, readable file or directory. Otherwise it returns `false`.

canWrite

public boolean canWrite()

Returns

A `boolean` value that indicates if the file is writable.

Throws

`SecurityException`

If the application does not have permission to write to the `File`.

Description

This method returns `true` if `File` corresponds to an existing, writable file or directory. Otherwise it returns `false`.

delete

public boolean delete()

Returns

`true` if the file is deleted; otherwise `false`.

Throws

`SecurityException`

If the application does not have permission to delete the file.

Description

This method attempts to delete the file or directory associated with this `File` object. A directory is only deleted if it is empty.

equals

public boolean equals(Object obj)

Parameters

`obj`

The `Object` to be compared.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `File` that encapsulates the same pathname as this object.

exists

public boolean exists()

Returns

`true` if the file or directory exists; `false` otherwise.

Throws

`SecurityException`

If the application does not have permission to read the `File`.

Description

This method returns `true` if this `File` corresponds to an existing file or directory.

getAbsolutePath

public String getAbsolutePath()

Returns

A `String` that contains the absolute pathname.

Description

This method returns the absolute pathname of the file or directory associated with this `File`.

getCanonicalPath

public String getCanonicalPath() throws IOException

Availability

New as of JDK 1.1

Returns

A `String` that contains the canonical, or exact, pathname.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns the canonical pathname of the file or directory associated with this `File`.

getName

public String getName()

Returns

A `String` that contains the filename.

Description

This method returns the filename associated with this `File`. The string returned does not include the name of the directory.

getParent

public String getParent()

Returns

A `String` that contains the parent directory of the file, or `null` if it does not exist.

Description

This method returns the name of the parent directory of the file or directory associated with this `File`. The algorithm used returns everything in the pathname before the last separator character.

getPath

public String getPath()

Returns

A `String` that contains the pathname of the file.

Description

This method returns the full pathname associated with this `File`.

hashCode

public int hashCode()

Returns

A hashcode value for this file.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode based on the pathname associated with this `File`.

isAbsolute

public native boolean isAbsolute()

Returns

`true` if the `File` represents an absolute path; `false` otherwise.

Description

This method indicates if the `File` represents an absolute path; what constitutes an absolute path is system-dependent.

isDirectory

public boolean isDirectory()

Returns

true if the File represents a directory; false otherwise.

Throws

SecurityException

If the application does not have permission to read the File.

Description

This method returns true if this File corresponds to a directory.

isFile

public boolean isFile()

Returns

true if the File represents a normal file; false otherwise.

Throws

SecurityException

If the application does not have permission to read the File.

Description

This method returns true if this File corresponds to a normal file, as opposed to an alternative, such as a directory, a named pipe, or a device.

lastModified

public long lastModified()

Returns

The time the file was last modified, or 0L if the file does not exist.

Throws

`SecurityException`

If the application does not have permission to read the `File`.

Description

This method returns the modification time of the file or directory that corresponds to this `File`. The format of the time returned is useful for comparing modification times; it's not meant to be used for other purposes.

length

public long length()

Returns

The file length, in bytes, or `0L` if the file does not exist.

Throws

`SecurityException`

If the application does not have permission to read the `File`.

Description

This method returns the length of the file or directory that corresponds to this `File`.

list

public String[] list()

Returns

An array of the names of the files and directories contained by this `File`, or `null` if this `File` is not a directory.

Throws

`SecurityException`

If the application does not have permission to read the `File`.

Description

This method returns the contents of a directory. The current directory and the parent directory are not included in the list.

public String[] list(FilenameFilter filter)

Parameters

`filter`

A filter to use.

Returns

An array of the names of the files and directories contained by this `File` and filtered by `filter`, or `null` if this `File` is not a directory.

Throws

`SecurityException`

If the application does not have permission to read the `File`.

Description

This method returns of the contents of a directory as selected by the given `FilenameFilter` object. Specifically, a name is included if the `FilenameFilter` object's `accept()` method returns `true` for that name.

If `filter` is `null`, this method is equivalent to, but slower than, `list()`.

mkdir

public boolean mkdir()

Returns

`true` if the directory is created; `false` otherwise.

Throws

`SecurityException`

If the application does not have permission to write to the `File`.

Description

This method creates a directory with the pathname specified by this `File`.

mkdirs

public boolean mkdirs()

Returns

`true` if the directory is created; `false` otherwise.

Throws

`SecurityException`

If the application does not have permission to write to the `File`.

Description

This method creates a directory with the pathname specified by this `File`. The method also creates all the parent directories if necessary.

renameTo

public boolean renameTo(File dest)

Parameters

`dest`

A `File` that specifies the new name.

Returns

`true` if the name is changed; `false` otherwise.

Throws

`SecurityException`

If the application does not have permission to write to this `File` or the file represented by `dest`.

Description

This method changes the pathname of this `File` to the pathname specified by `dest`.

toString

public String toString()

Returns

A `String` that contains the pathname of this `File`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `File` object.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`finalize()`	`Object`

`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FileInputStream

Name

FileInputStream

Synopsis

Class Name:

```
java.io.FileInputStream
```

Superclass:

```
java.io.InputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The FileInputStream class represents a byte stream that reads data from a file. The file can be specified using a FileDescriptor, a File object, or a String that represents a pathname. All of the constructors can throw a SecurityException if the application does not have permission to read from the specified file.

FileInputStream provides a low-level interface for reading data from a file. You should wrap a FileInputStream with a DataInputStream if you need a higher-level interface that can handle reading strings and binary data. You should also think about wrapping a FileInputStream with a BufferedInputStream to increase reading efficiency.

Data must be read sequentially from a FileInputStream; you can skip forward, but you cannot move back. If you need random access to file data, use the RandomAccessFile class instead.

Class Summary

```
public class java.io.FileInputStream extends java.io.InputStream {
  // Constructors
  public FileInputStream(String name);
  public FileInputStream(File file);
  public FileInputStream(FileDescriptor fdObj);
  // Public Instance Methods
  public native int available();
  public native void close();
  public final FileDescriptor getFD();
  public native int read();
  public int read(byte[] b);
  public int read(byte[] b, int off, int len);
  public native long skip(long n);
  // Protected Instance Methods
  protected void finalize();
}
```

Constructors

FileInputStream

public FileInputStream(String name) throws FileNotFoundException

Parameters

`name`

A `String` that contains the pathname of the file to be accessed. The path must conform to the requirements of the native operating system.

Throws

`FileNotFoundException`

If the named file cannot be found.

`SecurityException`

If the application does not have permission to read the named file.

Description

This constructor creates a `FileInputStream` that gets its input from the file named by the specified `String`.

public FileInputStream(File file) throws FileNotFoundException

Parameters

`file`

The `File` to use as input.

Throws

`FileNotFoundException`

If the named file cannot be found.

`SecurityException`

If the application does not have permission to read the named file.

Description

This constructor creates a `FileInputStream` that gets its input from the file represented by the specified `File`.

public FileInputStream(FileDescriptor fdObj)

Parameters

`fdObj`

The `FileDescriptor` of the file to use as input.

Throws

`SecurityException`

If the application does not have permission to read the specified file.

`NullPointerException`

If `FileDescriptor` is `null`.

Description

This constructor creates a `FileInputStream` that gets its input from the file identified by the given `FileDescriptor`.

Public Instance Methods

available

public native int available() throws IOException

Returns

The number of bytes that can be read from the file without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.available()`

Description

This method returns the number of available bytes of data. Initially, this is the length of the file.

close

public native void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.close()`

Description

This method closes this file input stream and releases any resources used by it.

getFD

public final FileDescriptor getFD() throws IOException

Returns

The file descriptor for the file that supplies data for this stream.

Throws

`IOException`

If there is no `FileDescriptor` associated with this object.

Description

This method returns the file descriptor associated with the data source of this `FileInputStream`.

read

public native int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read()`

Description

This method reads the next byte of data from the file. The method blocks if no input is available.

public int read(byte[] b) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read(byte[])`

Description

This method reads data into the given array. The method fills the array if enough bytes are available. The method blocks until some input is available.

public int read(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read(byte[], int, int)`

Description

This method reads `len` bytes of data into the given array, starting at element `off`. The method blocks until some input is available.

skip

public native long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.skip()`

Description

This method skips `n` bytes of input in the stream.

Protected Instance Methods

finalize

protected void finalize() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Object.finalize()`

Description

This method is called when the `FileInputStream` is garbage collected to ensure that `close()` is called. If the stream has a valid file descriptor, the `close()` method is called to free the system resources used by this stream.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`mark(int)`	`InputStream`	`markSupported()`	`InputStream`
`notify()`	`Object`	`notifyAll()`	`Object`

FilenameFilter

Name

FilenameFilter

Synopsis

Interface Name:

`java.io.FilenameFilter`

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented by:

None

Availability:

JDK 1.0 or later

Description

The FilenameFilter interface is implemented by a class that wants to filter the filenames that should be included in a list of filenames. For example, the list() method of the File class can take a FilenameFilter object to filter the filenames that are listed. The java.awt.FileDialog class also uses a FilenameFilter to limit the choices that are presented to the user.

Interface Declaration

```
public abstract interface java.io.FilenameFilter {
  // Methods
  public abstract boolean accept(File dir, String name);
}
```

Methods

accept

public abstract boolean accept(File dir, String name)

Parameters

dir

The directory that contains the file.

name

The name of the file.

Returns

true if the file should be shown; false otherwise.

Description

This method returns a boolean value that indicates whether or not a file should be included in a list of filenames. The method should return true if a file should be included; otherwise it should return false. A simple filter might return true for filenames with a certain extension, like

.java. A more complex filter could check the directory name, the file's readability, and last modification time, for example.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FileOutputStream

Name

FileOutputStream

Synopsis

Class Name:

```
java.io.FileOutputStream
```

Superclass:

```
java.io.OutputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The FileOutputStream class represents a byte stream that writes data to a file. The file can be specified using a FileDescriptor, a File object, or a String that represents a pathname. All of the constructors can throw a SecurityException if the application does not have permission to write to the specified file.

FileOutputStream provides a low-level interface for writing data to a file. Wrap a FileOutputStream with a DataOutputStream or a PrintStream if you need a higher-level interface that can handle writing strings and binary data. You should also think about wrapping a FileOutputStream with a BufferedOutputStream to increase writing efficiency.

Data must be written sequentially to a FileOutputStream; you can either overwrite existing data or append data to the end of the file. If you need random access to file data, use the RandomAccessFile class instead.

Class Summary

```
public class java.io.FileOutputStream extends java.io.OutputStream {
  // Constructors
  public FileOutputStream(String name);
  public FileOutputStream(String name, boolean append);     // New in 1.1
  public FileOutputStream(File file);
  public FileOutputStream(FileDescriptor fdObj);
  // Public Instance Methods
  public native void close();
  public final FileDescriptor getFD();
  public native void write(int b);
  public void write(byte[] b);
  public void write(byte[] b, int off, int len);
  // Protected Instance Methods
  protected void finalize();
}
```

Constructors

FileOutputStream

public FileOutputStream(String name) throws IOException

Parameters

name

A `String` that contains the pathname of the file to be used for output. The path must conform to the requirements of the native operating system.

Throws

`FileNotFoundException`

If the named file cannot be found.

`SecurityException`

If the application does not have permission to write to the named file.

Description

This constructor creates a `FileOutputStream` that sends its output to the file named by the specified `String`.

`public FileOutputStream(String name, boolean append) throws IOException`

Availability

New as of JDK 1.1

Parameters

`name`

A `String` that contains the pathname of the file to be used for output. The path must conform to the requirements of the native operating system.

`append`

Specifies whether or not data is appended to the output stream.

Throws

`FileNotFoundException`

If the named file cannot be found.

`SecurityException`

If the application does not have permission to write to the named file.

Description

This constructor creates a `FileOutputStream` that sends its output to the named file. If `append` is `true`, the stream is positioned at the end of the file, and data is appended to the end of the file. Otherwise, if `append` is `false`, the stream is positioned at the beginning of the file, and any previous data is overwritten.

public FileOutputStream(File file) throws IOException

Parameters

`file`

The `File` to use as output.

Throws

`FileNotFoundException`

If the named file cannot be found.

`SecurityException`

If the application does not have permission to write to the named file.

Description

This constructor creates a `FileOutputStream` that sends its output to the file represented by the specified `File`.

public FileOutputStream(FileDescriptor fdObj)

Parameters

`fdObj`

The `FileDescriptor` of the file to use as output.

Throws

`SecurityException`

If the application does not have permission to write to the specified file.

`NullPointerException`

If `FileDescriptor` is `null`.

Description

This constructor creates a `FileOutputStream` that sends its output to the file identified by the given `FileDescriptor`.

Public Instance Methods

close

public native void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.close()`

Description

This method closes this file output stream and releases any resources used by it.

getFD

public final FileDescriptor getFD() throws IOException

Throws

`IOException`

If there is no `FileDescriptor` associated with this object.

Description

This method returns the file descriptor associated with the data source of this `FileOutputStream`.

write

public native void write(int b) throws IOException

Parameters

`b`

The value to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.write(int)`

Description

This method writes a byte containing the low-order eight bits of the given value to the output stream.

public void write(byte[] b) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.write(byte[])`

Description

This method writes the entire contents of the given array to the output stream.

public void write(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.write(byte[], int, int)`

Description

This method writes `len` bytes from the given array, starting at element `off`, to the output stream.

Protected Instance Methods

finalize

protected void finalize() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is called when the `FileOutputStream` is garbage-collected to ensure that `close()` is called. If the stream has a valid file descriptor, the `close()` method is called to free the system resources used by this stream.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`flush()`	`OutputStream`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FilterInputStream

Name

FilterInputStream

Synopsis

Class Name:

`java.io.FilterInputStream`

Superclass:

`java.io.InputStream`

Immediate Subclasses:

`java.io.BufferedInputStream`,

`java.io.DataInputStream`,

`java.io.LineNumberInputStream`,

`java.io.PushbackInputStream`,

`java.util.zip.CheckedInputStream`,

java.util.zip.InflaterInputStream

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The FilterInputStream class is the superclass of all of the input stream classes that filter input. Each of the subclasses of FilterInputStream works by wrapping an existing input stream, called the *underlying input stream*, and providing additional functionality. The methods of FilterInputStream simply override the methods of InputStream with versions that call the corresponding methods of the underlying stream.

FilterInputStream cannot be instantiated directly; it must be subclassed. An instance of one of the subclasses of FilterInputStream is constructed with another InputStream object. The methods of a subclass of FilterInputStream should override some methods in order to extend their behavior or provide some sort of filtering.

Class Summary

```
public class java.io.FilterInputStream extends java.io.InputStream {
  // Variables
  protected InputStream in;
  // Constructors
  protected FilterInputStream(InputStream in);
  // Instance Methods
  public int available();
  public void close();
  public synchronized void mark(int readlimit);
  public boolean markSupported();
  public int read();
  public int read(byte[] b);
  public int read(byte[] b, int off, int len);
  public synchronized void reset();
  public long skip(long n);
}
```

Variables

in

protected InputStream in

Description

The underlying stream that this `FilterInputStream` wraps or filters.

Constructors

FilterInputStream

protected FilterInputStream(InputStream in)

Parameters

`in`

The input stream to filter.

Description

This constructor creates a `FilterInputStream` that gets its data from `in`.

Instance Methods

available

public int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.available()`

Description

This method calls the `available()` method of the underlying stream and returns the result.

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.close()`

Description

This method calls the `close()` method of the underlying stream, which releases any system resources associated with this object.

mark

public synchronized void mark(int readlimit)

Parameters

`readlimit`

The maximum number of bytes that can be read before the saved position becomes invalid.

Overrides

`InputStream.mark()`

Description

This method calls the `mark()` method of the underlying stream. If the underlying stream supports `mark()` and `reset()`, this method causes the `FilterInputStream` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position, and thus re-read a portion of the input.

markSupported

public boolean markSupported()

Returns

`true` if this stream supports `mark()` and `reset()`; `false` otherwise.

Overrides

`InputStream.markSupported()`

Description

This method calls the `markSupported()` method of the underlying stream and returns the result.

read

public int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read()`

Description

This method calls the `read()` method of the underlying stream and returns the result. This method blocks until some data is available, the end of the stream is detected, or an exception is thrown.

public int read(byte[] b) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read(byte[])`

Description

This method reads bytes of input to fill the given array. It does this by calling `read(b, 0, b.length)`, which allows subclasses to only override `read(byte[], int, int)` and have `read(byte[])` work automatically. The method blocks until some data is available.

public int read(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read(byte[], int, int)`

Description

This method reads up to `len` bytes of input into the given array starting at index `off`. It does this by calling the `read(byte[], int, int)` method of the underlying stream and returning the result. The method blocks until some data is available.

reset

public synchronized void reset() throws IOException

Throws

`IOException`

If there was no previous call to the `mark()` method or the saved position has been invalidated.

Overrides

`InputStream.reset()`

Description

This method calls the `reset()` method of the underlying stream. If the underlying stream supports `mark()` and `reset()`, this method sets the position of the `FilterInputStream` to a position that was saved by a previous call to `mark()`. Subsequent bytes read from this `FilterInputStream` will begin from the saved position and continue normally.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.skip()`

Description

This method skips `n` bytes of input. It calls the `skip()` method of the underlying stream.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FilterOutputStream

Name

FilterOutputStream

Synopsis

Class Name:

`java.io.FilterOutputStream`

Superclass:

`java.io.ObjectStream`

Immediate Subclasses:

`java.io.BufferedOutputStream`,

`java.io.DataOutputStream`,

`java.io.PrintStream`,

`java.util.zip.CheckedOutputStream`,

`java.util.zip.DeflaterOutputStream`

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `FilterOutputStream` class is the superclass of all of the output stream classes that filter output. Each of the subclasses of `FilterOutputStream` works by wrapping an existing output stream, called the *underlying output stream*, and providing additional functionality. The methods of `FilterOutputStream` simply override the methods of `OutputStream` with versions that call the corresponding methods of the underlying stream.

`FilterOutputStream` cannot be instantiated directly; it must be subclassed. An instance of one of the subclasses of `FilterOutputStream` is constructed with another `OutputStream` object. The methods of a subclass of `FilterOutputStream` should override some methods in order to extend their behavior or provide some sort of filtering.

Class Summary

```
public class java.io.FilterOutputStream extends java.io.OutputStream {
  // Variables
  protected OutputStream out;
  // Constructors
  public FilterOutputStream(OutputStream out);
  // Instance Methods
  public void close();
  public void flush();
  public void write(int b);
  public void write(byte[] b);
  public void write(byte[] b, int off, int len);
}
```

Variables

out

protected OutputStream out

Description

The underlying stream that this `FilterOutputStream` wraps or filters.

Constructors

FilterOutputStream

public FilterOutputStream(OutputStream out)

Parameters

`out`

The output stream to filter.

Description

This constructor creates a `FilterOutputStream` that sends its data to `out`.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.close()`

Description

This method calls the `close()` method of the underlying stream, which releases any system resources associated with this object.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.flush()`

Description

This method calls the `flush()` method of the underlying stream, which forces any bytes that may be buffered by this `FilterOutputStream` to be written to the underlying device.

write

public void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.write(int)`

Description

This method writes a byte containing the low-order eight bits of the given integer value. The method calls the `write(int)` method of the underlying stream.

public void write(byte[] b) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.write(byte[])`

Description

This method writes the bytes contained in the given array. To accomplish this, it calls `write(b, 0, b.length)`. Subclasses need override only `write(byte[], int, int)` for this method to work automatically.

public void write(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.write(byte[], int, int)`

Description

This method writes `len` bytes contained in the given array, starting at offset `off`. It does this by calling `write(int)` for each element to be written in the array. This is inefficient, so subclasses should override `write(byte[], int, int)` with a method that efficiently writes a block of data.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FilterReader

Name

FilterReader

Synopsis

Class Name:

```
java.io.FilterReader
```

Superclass:

```
java.io.Reader
```

Immediate Subclasses:

```
java.io.PushbackReader
```

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `FilterReader` class is the superclass of all of the reader classes that filter input. A subclass of `FilterReader` works by wrapping an existing reader, called the *underlying reader*, and providing additional functionality. The methods of `FilterReader` simply override the methods of `Reader` with versions that call the corresponding methods of the underlying reader.

`FilterReader` cannot be instantiated directly; it must be subclassed. An instance of a subclass of `FilterReader` is constructed with another `Reader` object. The methods of a subclass of `FilterReader` should override some methods in order to extend their behavior or provide some sort of filtering.

`FilterReader` is like `FilterInputStream`, except that it deals with a character stream instead of a byte stream.

Class Summary

```
public abstract class java.io.FilterReader extends java.io.Reader {
  // Variables
  protected Reader in;
  // Constructors
  protected FilterReader(Reader in);
  // Instance Methods
  public void close();
  public void mark(int readAheadLimit);
  public boolean markSupported();
  public int read();
  public int read(char[] cbuf, int off, int len);
  public boolean ready();
  public void reset();
  public long skip(long n);
}
```

Variables

in

protected Reader in

Description

The underlying reader that this `FilterReader` wraps or filters.

Constructors

FilterReader

protected FilterReader(Reader in)

Parameters

`in`

The input reader to filter.

Description

This constructor creates a `FilterReader` that gets data from `in`.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.close()`

Description

This method calls the `close()` method of the underlying reader, which releases any system resources associated with this object.

mark

public void mark(int readAheadLimit) throws IOException

Parameters

`readAheadLimit`

The maximum number of characters that can be read before the saved position becomes invalid.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.mark()`

Description

This method calls the `mark()` method of the underlying reader. If the underlying reader supports `mark()` and `reset()`, this method causes the `FilterReader` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position, and thus re-read a portion of the input.

markSupported

public boolean markSupported()

Returns

`true` if this reader supports `mark()` and `reset()`; `false` otherwise.

Overrides

`Reader.markSupported()`

Description

This method calls the `markSupported()` method of the underlying reader and returns the result.

read

public int read() throws IOException

Returns

The next character of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.read()`

Description

This method calls the `read()` method of the underlying reader and returns the result. The method blocks until data is available, the end of the stream is detected, or an exception is thrown.

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

An offset into the array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.
Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.read(char[], int, int)`

Description

This method reads up to `len` characters of input into the given array starting at index `off`. It does this by calling the `read(char[], int, int)` method of the underlying reader and returning the result. The method blocks until some data is available.

ready

public boolean ready() throws IOException

Returns

A `boolean` value that indicates whether the reader is ready to be read.

Throws

`IOException`

If the stream is closed.

Overrides

`Reader.ready()`

Description

This method calls the `ready()` method of the underlying reader and returns the result. If the underlying stream is ready, this method returns `true`. The underlying stream is ready if the next `read()` is guaranteed not to block.

reset

public void reset() throws IOException

Throws

`IOException`

If the stream is closed, `mark()` has not been called, or the saved position has been invalidated.

Overrides

`Reader.reset()`

Description

This method calls the `reset()` method of the underlying reader. If the underlying reader supports `mark()` and `reset()`, this method sets the position of the `FilteredReader` to a position that was saved by a previous call to `mark()`. Subsequent characters read from this `FilteredReader` will begin from the saved position and continue normally.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of characters to skip.

Returns

The actual number of characters skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.skip()`

Description

This method skips `n` characters of input. It calls the `skip()` method of the underlying reader.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

FilterWriter

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FilterWriter

Name

FilterWriter

Synopsis

Class Name:

`java.io.FilterWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `FilterWriter` class is the superclass of all of the writer classes that filter output. A subclass of `FilterWriter` works by wrapping an existing writer, called the *underlying writer*, and providing additional functionality. The methods of `FilterWriter` simply override the methods of `Writer` with versions that call the corresponding methods of the underlying writer.

`FilterWriter` cannot be instantiated directly; it must be subclassed. An instance of a subclass of `FilterWriter` is constructed with another `Writer` object. The methods of a subclass of `FilterWriter` should override some methods in order to extend their behavior or provide some sort of filtering.

`FilterWriter` is like `FilterOutputStream`, except that it deals with a character stream instead of a byte stream.

Class Summary

```
public abstract class java.io.FilterWriter extends java.io.Writer {
  // Variables
  protected Writer out;
  // Constructors
  protected FilterWriter(Writer out);
  // Instance Methods
  public void close();
  public void flush();
  public void write(int c);
  public void write(char[] cbuf, int off, int len);
  public void write(String str, int off, int len);
}
```

Variables

out

protected Writer out

Description

> The underlying writer that this `FilterWriter` wraps or filters.

Constructors

FilterWriter

public FilterWriter(Writer out)

Parameters

`out`

The output writer to filter.

Description

This constructor creates a `FilterWriter` that sends data to `out`.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.close()`

Description

This method calls the `close()` method of the underlying writer, which releases any system resources associated with this object.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.flush()`

Description

This method calls the `flush()` method of the underlying writer, which forces any characters that may be buffered by this `FilterWriter` to be written to the underlying device.

write

public void write(int c) throws IOException

Parameters

`c`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(int)`

Description

This method writes a character containing the low-order 16 bits of the given integer value. It calls the `write(int)` method of the underlying writer.

`public void write(char[] cbuf, int off, int len) throws IOException`

Parameters

`cbuf`

An array of characters to write to the stream.

`off`

An offset into the array.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(char[], int, int)`

Description

This method writes `len` characters contained in the given array, starting at offset `off`. It does this by calling the `write(char[], int, int)` method of the underlying writer.

public void write(String str, int off, int len) throws IOException

Parameters

`str`

A string to write to the stream.

`off`

An offset into the string.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(String, int, int)`

Description

This method writes `len` characters contained in the given string, starting at offset `off`. It does this by calling the `write(String, int, int)` method of the underlying writer.

Inherited Methods

InputStream

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

InputStream

Name

InputStream

Synopsis

Class Name:

```
java.io.InputStream
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

```
java.io.ByteArrayInputStream,

java.io.FileInputStream,

java.io.FilterInputStream,

java.io.ObjectInputStream,

java.io.PipedInputStream,

java.io.SequenceInputStream,
```

java.io.StringBufferInputStream

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The InputStream class is an abstract class that is the superclass of all classes that represent input byte streams. InputStream defines the basic input methods that all input streams provide. A similar hierarchy of classes, based around Reader, deals with character streams instead of byte streams.

InputStream is designed so that read(byte[]) and read(byte[], int, int) both call read(). Thus, a subclass can simply override read(), and all the read methods will work. However, for efficiency sake, read(byte[], int, int) should also be overridden with a method that can read a block of data more efficiently than reading each byte separately.

InputStream also defines a mechanism for marking a position in the stream and returning to it later, via the mark() and reset() methods. Another method, markSupported(), indicates whether or not this mark-and-reset functionality is available in a particular subclass.

Class Summary

```
public abstract class java.io.InputStream extends java.lang.Object {
  // Instance Methods
  public abstract int available();
  public void close();
  public synchronized void mark(int readlimit);
  public boolean markSupported();
  public abstract int read();
  public int read(byte[] b);
  public int read(byte[] b, int off, int len);
  public synchronized void reset();
  public long skip(long n);
}
```

Instance Methods

available

public abstract int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns the number of bytes that can be read without having to wait for more data to become available, or in other words, blocking.

A subclass of `InputStream` must implement this method.

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the input stream and releases any resources associated with it.

The implementation of the `close()` method in `InputStream` does nothing; a subclass should override this method to handle cleanup for the stream.

mark

public synchronized void mark(int readlimit)

Parameters

`readlimit`

The maximum number of bytes that can be read before the saved position can become invalid.

Description

This method tells this `InputStream` object to remember its current position, so that the position can be restored by a call to the `reset()` method. The `InputStream` can read `readlimit` bytes beyond the marked position before the mark becomes invalid.

The implementation of the `mark()` method in `InputStream` does nothing; a subclass must override the method to provide the mark-and-reset functionality.

markSupported

public boolean markSupported()

Returns

`true` if this input stream supports `mark()` and `reset()`; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not this object supports mark-and-reset functionality.

The `markSupported()` method in `InputStream` always returns `false`. A subclass that implements the mark-and-reset functionality should override the method to return `true`.

read

public abstract int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads the next byte of input. The byte is returned as an integer in the range 0 to 255. The method blocks until the byte is read, the end of stream is encountered, or an exception is thrown.

A subclass of `InputStream` must implement this method.

public int read(byte[] b) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads bytes of input to fill the given array by calling `read(b, 0, b.length)`. The method blocks until some data is available.

A subclass does not usually need to override this method as it can override `read(byte[], int, int)` and have `read(byte[])` work automatically.

public int read(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads up to `len` bytes of input into the given array starting at index `off`. The method blocks until some data is available.

The implementation of this method in `InputStream` uses `read()` repeatedly to fill the array. Although it is not strictly necessary, a subclass should override this method to read a block of data more efficiently.

reset

public synchronized void reset() throws IOException

Throws

`IOException`

If there was no previous call to the `mark()` method or the saved position has been invalidated.

Description

This method restores the position of the stream to the position that was saved by a previous call to `mark()`.

The implementation of the `reset()` method in `InputStream` throws an exception to indicate that mark-and-reset functionality is not supported by default. A subclass must override the method to provide the functionality.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method skips `n` bytes of input. In other words, it moves the position of the stream forward by `n` bytes.

The implementation of the `skip()` method in `InputStream` simply calls `read(b)` where `b` is a byte array `n` bytes long. A subclass may want to override this method to implement a more efficient skipping algorithm.

Inherited Methods

InputStreamReader

Name

InputStreamReader

Synopsis

Class Name:

```
java.io.InputStreamReader
```

Superclass:

```
java.io.Reader
```

Immediate Subclasses:

```
java.io.FileReader
```

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `InputStreamReader` class is a bridge between the byte-oriented world of the `InputStream` class and the character-oriented world of the `Reader` class. The `InputStreamReader` represents a character stream, but it gets its input from an underlying byte stream. An encoding scheme is responsible for translating the bytes to Unicode characters. An `InputStreamReader` can be created using an explicit encoding scheme or a default encoding scheme.

For example, to read an ISO-8859-5 byte stream as a Unicode character stream, you can construct an `InputStreamReader` with the encoding "8859_5" as follows:

```
InputStreamReader inr = new InputStreamReader(in, "8859_5");
```

Each time you read from an `InputStreamReader` object, bytes may be read from the underlying byte stream. To improve efficiency, you may want to wrap the `InputStreamReader` in a `BufferedReader`.

Class Summary

```
public class java.io.InputStreamReader extends java.io.Reader {
  // Constructors
  public InputStreamReader(InputStream in);
  public InputStreamReader(InputStream in, String enc);
  // Instance Methods
  public void close();
  public String getEncoding();
  public int read();
  public int read(char[] cbuf, int off, int len);
  public boolean ready();
}
```

Constructors

InputStreamReader

public InputStreamReader(InputStream in)

Parameters

`in`

The input stream to use.

Description

This constructor creates an `InputStreamReader` that gets its data from `in` and translates bytes to characters using the system's default encoding scheme.

`public InputStreamReader(InputStream in, String enc) throws UnsupportedEncodingException`

Parameters

`in`

The input stream to use.

`enc`

The name of an encoding scheme.

Throws

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

This constructor creates an `InputStreamReader` that gets its data from `in` and translates bytes to characters using the given encoding scheme.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.close()`

Description

This method calls the `close()` method of the underlying input stream, which releases any system resources associated with this object.

getEncoding

public String getEncoding()

Returns

A `String` that contains the name of the character encoding scheme of this reader.

Description

This method returns the name of the character encoding scheme this `InputStreamReader` is currently using.

read

public int read() throws IOException

Returns

The next character of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.read()`

Description

This method reads a character of input. The method returns the next character that has been read and converted from the underlying byte-oriented `InputStream`. The `InputStreamReader` class uses buffering internally, so this method returns immediately unless the buffer is empty. If the buffer is empty, a new block of bytes is read from the `InputStream` and converted to characters. The method blocks until the character is read, the end of stream is encountered, or an exception is thrown.

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

An offset into the array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.read(char[], int, int)`

Description

This method reads up to `len` characters of input into the given array starting at index `off`. The `InputStreamReader` class uses buffering internally, so this method returns immediately if there is enough data in the buffer. If there is not enough data, a new block of bytes is read from the `InputStream` and converted to characters. The method blocks until some data is available.

ready

public boolean ready() throws IOException

Returns

`true` if the reader is ready to be read; `false` otherwise.

Throws

`IOException`

If the reader is closed or any other kind of I/O error occurs.

Overrides

`Reader.ready()`

Description

This method returns a `boolean` value that indicates whether or not the reader is ready to be read. If there is data available in the internal buffer or if there are bytes available to be read from the underlying byte stream, the method returns `true`. Otherwise it returns `false`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

InvalidClassException

Name

InvalidClassException

Synopsis

Class Name:

`java.io.InvalidClassException`

Superclass:

`java.io.ObjectStreamException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

An `InvalidClassException` is thrown during object serialization. It indicates that the run-time environment does not support a serialized class for one of the following reasons:

- The version of the class does not match the serial version of the class in the stream.
- The class contains unknown data types.

An `InvalidClassException` can also indicate one of these problems with the class itself:

- The class implements only one of `writeObject()` and `readObject()`.
- The class is not `public`.
- The class does not have an accessible constructor that takes no arguments.

Class Summary

```
public class java.io.InvalidClassException
             extends java.io.ObjectStreamException {
  // Variables
  public String classname;
  // Constructors
  public InvalidClassException(String reason);
  public InvalidClassException(String cname, String reason);
  // Instance Methods
  public String getMessage();
}
```

Variables

classname

public String classname

Description

> The name of the class that caused the exception.

Constructors

InvalidClassException

public InvalidClassException(String reason)

Parameters

`reason`

The reason the exception was thrown.

Description

This constructor creates an `InvalidClassException` with the specified reason string.

public InvalidClassException(String cname, String reason)

Parameters

`cname`

The name of the class.

`reason`

The reason the exception was thrown.

Description

This constructor creates an `InvalidClassException` with the specified class name and reason string.

Instance Methods

getMessage

public String getMessage()

Returns

The reason string for this exception.

Overrides

`Throwable.getMessage()`

Description

This method returns the reason string for this exception. If a class name has also been specified, it is prepended to the reason string with a semicolon.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`fillInStackTrace()`	`Throwable`	`finalize()`	`Object`
`getClass()`	`Object`	`getLocalizedMessage()`	`Throwable`

InvalidObjectException | BOOK INDEX | LineNumberInputStream

LineNumberInputStream

Name

LineNumberInputStream

Synopsis

Class Name:

```
java.io.LineNumberInputStream
```

Superclass:

```
java.io.FilterInputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

Deprecated as of JDK 1.1

Description

The `LineNumberInputStream` class is an `InputStream` that keeps track of line numbers. The line number starts at 0 and is incremented each time an end-of-line character is encountered. `LineNumberInputStream` recognizes `"\n"`, `"\r"`, or `"\r\n"` as the end of a line. Regardless of the end-of-line character it reads, `LineNumberInputStream` returns only `"\n"`. The current line number is returned by `getLineNumber()`. The `mark()` and `reset()` methods are supported, but only work if the underlying stream supports `mark()` and `reset()`.

The `LineNumberInputStream` class is deprecated as of JDK 1.1 because it does not perform any byte to character conversions. Incoming bytes are directly compared to end-of-line characters. If you are developing new code, you should use `LineNumberReader` instead.

Class Summary

```
public class java.io.LineNumberInputStream
             extends java.io.FilterInputStream {
  // Constructors
  public LineNumberInputStream(InputStream in);
  // Instance Methods
  public int available();
  public int getLineNumber();
  public void mark(int readlimit);
  public int read();
  public int read(byte[] b, int off, int len);
  public void reset();
  public void setLineNumber(int lineNumber);
  public long skip(long n);
}
```

Constructors

LineNumberInputStream

public LineNumberInputStream(InputStream in)

Parameters

`in`

The input stream to use.

Description

This constructor creates a `LineNumberInputStream` that gets its data from `in`.

Instance Methods

available

public int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.available()`

Description

This method returns the number of bytes of input that can be read without having to wait for more input to become available.

getLineNumber

public int getLineNumber()

Returns

The current line number.

Description

This method returns the current line number.

mark

public void mark(int readlimit)

Parameters

`readlimit`

The maximum number of bytes that can be read before the saved position becomes invalid.

Overrides

`FilterInputStream.mark()`

Description

This method tells the `LineNumberInputStream` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position and thus reread a portion of the input. The method calls the `mark()` method of the underlying stream, so it only works if the underlying stream supports `mark()` and `reset()`.

read

public int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read()`

Description

This method reads a byte of input from the underlying stream. If `"\n"`, `"\r"`, or `"\r\n"` is read from the stream, `"\n"` is returned. Otherwise, the byte read from the underlying stream is returned verbatim. The method blocks until the byte is read, the end of stream is encountered, or an exception is thrown.

public int read(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read(byte[], int, int)`

Description

This method reads up to `len` bytes of input into the given array starting at index `off`. If `"\n"`, `"\r"`, or `"\r\n"` is read from the stream, `"\n"` is returned. The method does this by repeatedly calling `read()`, which is not efficient, especially if the underlying stream is not buffered. The method blocks until some data is available.

reset

public void reset() throws IOException

Throws

`IOException`

If there was no previous call to this `FilterInputStream`'s `mark()` method or the saved position has been invalidated.

Overrides

`FilterInputStream.reset()`

Description

This method calls the `reset()` method of the underlying stream. If the underlying stream supports `mark()` and `reset()`, this method sets the position of the stream to a position that was saved by a previous call to `mark()`. Subsequent bytes read from this stream will begin from the saved position and continue normally. The method also restores the line number to its correct value for the mark location. The method only works if the underlying stream supports `mark()` and `reset()`.

setLineNumber

public void setLineNumber(int lineNumber)

Parameters

`lineNumber`

The new line number.

Description

This method sets the current line number of the `LineNumberInputStream`. The method does not change the position of the stream.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.skip()`

Description

This method skips `n` bytes of input. Note that since `LineNumberInputStream` returns `"\r\n"` as a single character, `"\n"`, this method may skip over more bytes than you expect.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`FilterInputStream`
`equals(Object)`	`Object`	`finalize()`	`Object`

`getClass()`	`Object`	`hashCode()`	`Object`
`markSupported()`	`FilterInputStream`	`notify()`	`Object`
`notifyAll()`	`Object`	`read(byte[])`	`FilterInputStream`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

LineNumberReader

Name

LineNumberReader

Synopsis

Class Name:

`java.io.LineNumberReader`

Superclass:

`java.io.BufferedReader`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `LineNumberReader` class is a `BufferedReader` that keeps track of line numbers. The line number starts at 0 and is incremented each time an end-of-line character is encountered. `LineNumberReader` recognizes `"\n"`, `"\r"`, or `"\r\n"` as the end of a line. Regardless of the end-of-line character it reads, `ReaderInputStream` returns only `"\n"`. The current line number is returned by `getLineNumber()`.

The `LineNumberReader` class is the JDK 1.1 replacement for `LineNumberInputStream`. Not only does it correctly handle byte to character conversions (via `Reader`), it implements `read(byte[], int, int)` and `skip()` more efficiently than its predecessor.

Class Summary

```
public class java.io.LineNumberReader extends java.io.BufferedReader {
  // Constructors
  public LineNumberReader(Reader in);
  public LineNumberReader(Reader in, int sz);
  // Instance Methods
  public int getLineNumber();
  public void mark(int readAheadLimit);
  public int read();
  public int read(char[] cbuf, int off, int len);
  public String readLine();
  public void reset();
  public void setLineNumber(int lineNumber);
  public long skip(long n);
}
```

Constructors

LineNumberReader

public LineNumberReader(Reader in)

Parameters

`in`

The reader to use.

Description

This constructor creates a `LineNumberReader` that gets its data from `in` and uses a default sized buffer. The default buffer size for `BufferedReader` is 8192 characters.

public LineNumberReader(Reader in, int sz)

Parameters

`in`

The reader to use.

`sz`

The buffer size.

Description

This constructor creates a `LineNumberReader` that gets its data from `in` and uses a buffer of the given size.

Instance Methods

getLineNumber

public int getLineNumber()

Returns

The current line number.

Description

This method returns the current line number.

mark

public void mark(int readAheadLimit) throws IOException

Parameters

`readAheadLimit`

The maximum number of characters that can be read before the saved position becomes invalid.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`BufferedReader.mark()`

Description

This method causes the `LineNumberReader` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position and thus reread a portion of the input.

read

public int read() throws IOException

Returns

The next character of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`BufferedReader.read()`

Description

This method reads a character of input from the underlying reader. If `"\n"`, `"\r"`, or `"\r\n"` is read from the stream, `"\n"` is returned. Otherwise the character read from the underlying `BufferedReader` is returned verbatim. The method blocks until it reads the character, the end of stream is encountered, or an exception is thrown.

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

An offset into the array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`BufferedReader.read(char[], int, int)`

Description

This method reads up to `len` characters of input into the given array starting at index `off`. This method, unlike `read()`, returns end-of-line characters exactly as they come from the underlying `BufferedReader`. The method blocks until data is available.

readLine

public String readLine() throws IOException

Returns

A `String` containing the line just read, or `null` if the end of the stream has been reached.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`BufferedReader.readLine()`

Description

This method reads a line of text. Lines are terminated by `"\n"`, `"\r"`, or `"\r\n"`. The line terminators are not returned with the line string.

reset

public void reset() throws IOException

Throws

`IOException`

If the reader is closed, `mark()` has not been called, or the saved position has been invalidated.

Overrides

`BufferedReader.reset()`

Description

This method sets the position of the reader to a position that was saved by a previous call to `mark()`. Subsequent characters read from this reader will begin from the saved position and continue normally. The method also restores the line number to its correct value for the mark location.

setLineNumber

public void setLineNumber(int lineNumber)

Parameters

`lineNumber`

The new line number.

Description

This method sets the current line number of the `LineNumberReader`. The method does not change the position of the reader.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of characters to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`BufferedReader.skip()`

Description

This method skips `n` characters of input.

NotActiveException

Synopsis

Class Name:

java.io.NotActiveException

Superclass:

java.io.ObjectStreamException

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `NotActiveException` is thrown to indicate that an inappropriate method is being called when serialization or deserialization is not in progress.

Class Summary

```
public class java.io.NotActiveException
             extends java.io.ObjectStreamException {
  // Constructors
  public NotActiveException();
  public NotActiveException(String reason);
}
```

Constructors

NotActiveException

public NotActiveException()

Description

This constructor creates a `NotActiveException` with no detail message.

public NotActiveException(String reason)

Parameters

`reason`

The detail message.

Description

This constructor creates a `NotActiveException` with the specified detail message.

ObjectInput

Name

ObjectInput

Synopsis

Interface Name:

`java.io.ObjectInput`

Super-interface:

`java.io.DataInput`

Immediate Sub-interfaces:

None

Implemented By:

`java.io.ObjectInputStream`

Availability:

New as of JDK 1.1

Description

The `ObjectInput` interface extends the `DataInput` interface for object serialization. While `DataInput` defines methods for reading primitive types from a stream, `ObjectInput` defines methods for reading objects and arrays of bytes.

Interface Declaration

```
public abstract interface java.io.ObjectInput extends java.io.DataInput {
  // Methods
  public abstract int available();
  public abstract void close();
  public abstract int read();
  public abstract int read(byte[] b);
  public abstract int read(byte[] b, int off, int len);
  public abstract Object readObject();
  public abstract long skip(long n);
}
```

Methods

available

public abstract int available() throws IOException

Returns

> The number of bytes that can be read without blocking.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

> This method returns the number of bytes that can be read from the stream without accessing a physical device, like a disk or a network.

close

public abstract void close() throws IOException

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

This method closes the stream and releases any system resources associated with it.

read

public abstract int read() throws IOException

Returns

The `next byte` of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns the next byte of data from the stream. The method blocks until the byte is read, the end of stream is detected, or an exception is thrown.

public abstract int read(byte[] b) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads bytes from the stream to fill the given array. The method blocks until some data is available.

`public abstract int read(byte[] b, int off, int len) throws IOException`

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads up to `len` bytes of input into the given array starting at index `off`. The method blocks until some data is available.

readObject

`public abstract Object readObject() throws ClassNotFoundException, IOException`

Returns

An `Object` that has been deserialized from the stream.

Throws

`ClassNotFoundException`

If the class of the serialized object cannot be found in the run-time environment.

`IOException`

If any kind of I/O error occurs.

Description

This method reads and returns an object instance from the stream; in other words, it deserializes an object from the stream. The class that implements this interface determines exactly how the object is to be read.

skip

public abstract long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method skips `n` bytes of input.

Inherited Methods

`DataInput`, `ObjectInputStream`

ObjectInputStream

Name

ObjectInputStream

Synopsis

Class Name:

`java.io.ObjectInputStream`

Superclass:

`java.io.InputStream`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.ObjectInput`

Availability:

New as of JDK 1.1

Description

The `ObjectInputStream` class can read both primitive types and object instances from an underlying `InputStream`. The objects and other data must have been written by an `ObjectOutputStream`. These two classes can provide persistent storage of objects when they are used in conjunction with `FileInputStream` and `FileOutputStream`. The classes can also be used with socket streams to pass objects across the network.

Only objects that are instances of classes that implement the `Serializable` or `Externalizable` interfaces can be deserialized from an input stream. The default deserialization mechanism is implemented by `readObject()`. When an object is deserialized, the non-`static` and non-`transient` fields of the object are restored to the values they had when the object was serialized, including any other objects referenced by the object (except for those objects that do not implement the `Serializable` interface themselves). Graphs of objects are restored using a reference sharing mechanism. New object instances are always allocated during the deserialization process, to prevent existing objects from being overwritten. Deserialized objects are returned as instances of type `Object`, so they should be cast to the appropriate type. Strings and arrays are objects in Java, so they are treated as objects during deserialization.

For example, the following code opens a file called *color.ser* and reads a `Color` object:

```
FileInputStream fileIn;
ObjectInputStream in;
Color color;
try {
    fileIn = new FileInputStream("color.ser");
    in = new ObjectInputStream(fileIn);
    color = (Color)in.readObject();
    in.close();
}
catch (Exception e) {
    System.out.println("Error reading: " + e);
}
```

Classes that have `transient` instance variables may require special handling to reconstruct the values of these variables when objects are deserialized. Special handling may also be necessary to correctly deserialize objects that were serialized with a different version of their class than is in use when they are deserialized. Classes that require special handling during serialization and deserialization must implement the following methods (with these exact signatures):

```
private void readObject(ObjectOutputStream stream)
             throws IOException, ClassNotFoundException
private void writeObject(ObjectOutputStream stream) throws IOException
```

The `writeObject()` method is responsible for writing the state of the object for the particular class so that it can be restored by `readObject()`. The `readObject()` method registers an object validation callback by calling `registerValidation()` as its first action. The `readObject()` method doesn't need to handle reading the state for the object's superclass or any of its subclasses except in the case where the superclass doesn't itself implement the `Serializable` interface. In this case, the nonserializable class must have a no-argument constructor that can be called to initialize its fields, and it is the responsibility of the subclass to restore the state of its superclass.

A class that inherits the implementation of `Serializable` prevents itself from being serialized by defining `readObject()` and `writeObject()` methods that throw `NotSerializableException` objects.

If a class needs complete control over the contents and formatting of the serialized form of its objects, it should implement the `Externalizable` interface.

Class Summary

```
public class java.io.ObjectInputStream extends java.io.InputStream
             implements java.io.ObjectInput {
  // Constructors
  public ObjectInputStream(InputStream in);
  // Public Instance Methods
  public int available();
  public void close();
  public final void defaultReadObject();
  public int read();
  public int read(byte[] data, int offset, int length);
  public boolean readBoolean();
  public byte readByte();
  public char readChar();
  public double readDouble();
  public float readFloat();
  public void readFully(byte[] data);
  public void readFully(byte[] data, int offset, int size);
  public int readInt();
  public String readLine();
  public long readLong();
  public final Object readObject();
  public short readShort();
  public int readUnsignedByte();
  public int readUnsignedShort();
  public String readUTF();
  public synchronized void
         registerValidation(ObjectInputValidation obj, int prio);
  public int skipBytes(int len);
  // Protected Instance Methods
  protected final boolean enableResolveObject(boolean enable);
  protected void readStreamHeader();
  protected Class resolveClass(ObjectStreamClass v);
  protected Object resolveObject(Object obj);
}
```

Constructors

ObjectInputStream

`public ObjectInputStream(InputStream in) throws IOException, StreamCorruptedException`

Parameters

`in`

The underlying input stream.

Throws

`IOException`

If any kind of I/O error occurs.

`StreamCorruptedException`

If the stream header is not correct.

Description

This constructor creates an `ObjectInputStream` that reads from the given input stream. The constructor attempts to read the stream header, which consists of a magic number and a version number, and if something goes wrong, an appropriate exception is thrown. If all of the bytes of the stream header are not available, the constructor does not return until they become available.

Public Instance Methods

available

public int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectInput.available()`

Overrides

`InputStream.available()`

Description

This method returns the number of bytes that can be read without having to wait for more data to become available.

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectInput.close()`

Overrides

`InputStream.close()`

Description

This method closes the stream and releases any system resources that are associated with it.

defaultReadObject

`public final void defaultReadObject() throws IOException, ClassNotFoundException, NotActiveException`

Throws

`IOException`

If any kind of I/O error occurs.

`ClassNotFoundException`

If the class of the object being read cannot be found.

`NotActiveException`

If serialization is not active.

Description

This method reads the fields of the current object that are not `static` and not `transient`. The method can only be called from the `private` `readObject()` method of an object that is being deserialized; it throws a `NotActiveException` if it is called at any other time. This method implements the default deserialization mechanism.

read

public int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectInput.read()`

Overrides

`InputStream.read()`

Description

This method reads the next byte from the stream. The method blocks until some data is available, the end of the stream is detected, or an exception is thrown.

`public int read(byte[] data, int offset, int length) throws IOException`

Parameters

`data`

Array of bytes to be filled from the stream.

`offset`

An offset into the byte array.

`length`

The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectInput.read(byte[], int, int)`

Overrides

`InputStream.read(byte[], int, int)`

Description

This method reads up to `length` bytes of input into the given array starting at index `offset`. The method blocks until there is some input available.

readBoolean

public boolean readBoolean() throws IOException

Returns

The `boolean` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readBoolean()`

Description

This method reads a byte as a `boolean` value from the underlying input stream. A byte that contains a zero is read as `false`. A byte that contains any other value is read as `true`. The method blocks until the byte is read, the end of the stream is encountered, or an exception is thrown.

readByte

public byte readByte() throws IOException

Returns

The `byte` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readByte()`

Description

This method reads a signed 8-bit value, a `byte`, from the underlying input stream. The method blocks until the byte is read, the end of the stream is encountered, or an exception is thrown.

readChar

public char readChar() throws IOException

Returns

The `char` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readChar()`

Description

This method reads a 16-bit Unicode character from the stream. The method reads two bytes from the underlying input stream and then creates a `char` value using the first byte read as the most significant byte. The method blocks until the two bytes are read, the end of the stream is encountered, or an exception is thrown.

readDouble

public double readDouble() throws IOException

Returns

The `double` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readDouble()`

Description

This method reads a 64-bit `double` quantity from the stream. The method reads a `long` value from the underlying input stream as if using the `readLong()` method. The `long` value is then converted to a `double` using the `longBitsToDouble()` method in `Double`. The method blocks until the necessary eight bytes are read, the end of the stream is encountered, or an exception is thrown.

readFloat

public float readFloat() throws IOException

Returns

The `float` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readFloat()`

Description

This method reads a 32-bit `float` quantity from the stream. The method reads an `int` value from the underlying input stream as if using the `readInt()` method. The `int` value is then converted to a `float` using the `intBitsToFloat()` method in `Float`. The method blocks until the necessary four bytes are read, the end of the stream is encountered, or an exception is thrown.

readFully

public void readFully(byte[] b) throws IOException

Parameters

`b`

The array to fill.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readFully(byte[])`

Description

This method reads bytes into the given array `b` until the array is full. The method reads repeatedly from the underlying stream to fill the array. The method blocks until all of the bytes are read, the end of the stream is encountered, or an exception is thrown.

`public void readFully(byte[] data, int offset, int size) throws IOException`

Parameters

`data`

The array to fill.

`offset`

An offset into the array.

`length`

The number of bytes to read.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readFully(byte[], int, int)`

Description

This method reads `len` bytes into the given array, starting at offset `off`. The method reads repeatedly from the underlying stream to fill the array. The method blocks until all of the bytes are read, the end of the stream is encountered, or an exception is thrown.

readInt

public int readInt() throws IOException

Returns

The `int` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readInt()`

Description

This method reads a signed 32-bit `int` quantity from the stream. The method reads four bytes from the underlying input stream and then creates an `int` quantity, using the first byte read as the most significant byte. The method blocks until the four bytes are read, the end of the stream is encountered, or an exception is thrown.

readLine

public String readLine() throws IOException

Returns

A `String` that contains the line read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other I/O error occurs.

Implements

`DataInput.readLine()`

Description

This method reads the next line of text from the stream. The method reads bytes of data from the underlying input stream until it encounters a line terminator. A line terminator is a carriage return (`"\r"`), a newline character (`"\n"`), a carriage return immediately followed by a newline character, or the end of the stream. The method blocks until a line terminator is read, the end of the stream is encountered, or an exception is thrown. Note that this method calls the `readLine()` method of `DataInputStream`, which is deprecated in 1.1.

readLong

public long readLong() throws IOException

Returns

The `long` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readLong()`

Description

This method reads a signed 64-bit `long` quantity from the stream. The method reads eight bytes from the underlying input stream and then creates a `long` quantity, using the first byte read as the most significant byte. The method blocks until the eight bytes are read, the end of the stream is encountered, or an exception is thrown.

readObject

`public final Object readObject() throws OptionalDataException, ClassNotFoundException, IOException`

Returns

An `Object` that has been deserialized from the stream.

Throws

`ClassNotFoundException`

If the object being deserialized has an unrecognized class.

`InvalidClassException`

If there is a problem with the class of the deserialized object.

`StreamCorruptedException`

If the stream serialization information is not correct.

`OptionalDataException`

If the stream contains primitive data instead of an object.

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectInput.readObject()`

Description

This method deserializes an object from the stream and returns a reference to the object. The non-`static` and non-`transient` fields of the object are restored to the values they had when the object was serialized. If the object contains references to other objects, these objects are also deserialized (as long as they implement the `Serializable` interface). Graphs of objects are restored using a reference-sharing mechanism. New object instances are always allocated during the deserialization process, to prevent existing objects from being overwritten. Deserialized objects are returned as instances of type `Object`, so they should be cast to the appropriate type.

Once an object has been completely restored (i.e., all of its fields and any objects it references have been restored), any object validation callbacks for the object or any of the objects it references are called in an order based on their priority. An object validation callback is registered by the `private` `readObject()` method for an object.

readShort

public short readShort() throws IOException

Returns

> The `short` value read from the stream.

Throws

> `EOFException`
>
> > If the end of the file is encountered.
>
> `IOException`
>
> > If any other kind of I/O error occurs.

Implements

> `DataInput.readShort()`

Description

> This method reads a signed 16-bit `short` quantity from the stream. The method reads two bytes from the underlying input stream and then creates a `short` quantity, using the first byte read as the most significant byte. The method blocks until the two bytes are read, the end of the stream is encountered, or an exception is thrown.

readUnsignedByte

public int readUnsignedByte() throws IOException

Returns

> The unsigned `byte` value read from the stream.

Throws

> `EOFException`
>
> > If the end of the file is encountered.
>
> `IOException`
>
> > If any other kind of I/O error occurs.

Implements

> `DataInput.readUnsignedByte()`

Description

This method reads an unsigned 8-bit quantity from the stream. The method reads a byte from the underlying input stream and returns that byte. The method blocks until the byte is read, the end of the stream is encountered, or an exception is thrown.

readUnsignedShort

public int readUnsignedShort() throws IOException

Returns

The unsigned `short` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readUnsignedShort()`

Description

This method reads an unsigned 16-bit quantity from the stream. The method reads two bytes from the underlying input stream and creates an unsigned `short` quantity using the first byte read as the most significant byte. The method blocks until the two bytes are read, the end of the stream is encountered, or an exception is thrown.

readUTF

public String readUTF() throws IOException

Returns

The `String` read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

`UTFDataFormatException`

If the bytes do not represent a valid UTF-8 encoding.

Implements

`DataInput.readUTF()`

Description

This method reads a UTF-8 encoded string from the stream. See the description of `DataInputStream.readUTF(DataInput)` for more information.

registerValidation

`public synchronized void registerValidation( ObjectInputValidation obj, int prio) throws NotActiveException, InvalidObjectException`

Parameters

`obj`

The object requesting validation.

`prio`

The priority of the validation callback; use zero as a default.

Throws

`NotActiveException`

If `serialization` is not active.

`InvalidObjectException`

If `obj` is `null`.

Description

This method may be called from an object's `private readObject()` method to register a validation callback. An object performs internal validation by implementing the `ObjectInputValidation` interface and registering itself with the `ObjectInputStream` via this function. When `ObjectInputStream` has completely deserialized an object (i.e., restored all of its fields and any objects it references), the stream calls `ObjectInputValidation.validateObject()` for every object that has an object validation callback. Objects that register with higher priority values get validated before objects that register with lower priority values. Within a priority value, the callbacks are not processed in any particular order.

skipBytes

public int skipBytes(int len) throws IOException

Parameters

`len`

The number of bytes to skip.

Returns

The actual number of skipped bytes.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind I/O error occurs.

Implements

`DataInput.skipBytes()`

Description

This method skips over `n` bytes in the underlying input stream. The method blocks until all of the bytes are skipped, the end of the stream is encountered, or an exception is thrown.

Protected Instance Methods

enableResolveObject

```
protected final boolean enableResolveObject(boolean enable) throws SecurityException
```

Parameters

`enable`

A `boolean` value that specifies whether or not object replacement is enabled.

Returns

`true` if object replacement was previously enabled; `false` otherwise.

Throws

`SecurityException`

If `enable` is `true` and `getClassLoader()` called on the class of the stream does not return `null`.

Description

This method determines if a trusted subclass of `ObjectInputStream` is allowed to replace deserialized objects. If the method is called with `true`, object replacement is enabled. Each time an object is deserialized, `resolveObject()` is called to give the `ObjectInputStream` a chance to replace the object. A trusted stream is one whose class has no `ClassLoader`.

readStreamHeader

`protected void readStreamHeader() throws IOException, StreamCorruptedException`

Throws

`StreamCorruptedException`

If the stream header is not correct.

`IOException`

If any kind of I/O error occurs.

Description

This method attempts to read the stream header, which consists of a magic number and a version number. If something goes wrong, an appropriate exception is thrown. This method is called by the constructor for `ObjectInputStream` and is the source of the exceptions it throws. If you subclass `ObjectInputStream`, you can override this method to provide your own stream header checking.

resolveClass

`protected Class resolveClass(ObjectStreamClass v) throws IOException, ClassNotFoundException`

Parameters

`v`

The `ObjectStreamClass` to be resolved.

Returns

The `Class` that corresponds to the given `ObjectStreamClass`.

Throws

`ClassNotFoundException`

If the class of the given `ObjectStreamClass` cannot be found.

`IOException`

If any kind of I/O error occurs.

Description

This method attempts to find the `Class` object that corresponds to the supplied `ObjectStreamClass`. When a object is deserialized, its class information is read into an `ObjectStreamClass` object, which is then resolved to a `Class` if possible. Subclasses of `ObjectInputStream` can override this method to allow classes to be fetched from alternate sources. The version of the `ObjectStreamClass` and the `Class` must match.

resolveObject

protected Object resolveObject(Object obj) throws IOException

Parameters

`obj`

The object to be replaced.

Returns

A replacement for the given object.

Throws

`IOException`

If any kind of I/O error occurs.

Description

If object replacement is enabled for this `ObjectInputStream` (see `enableResolveObject()`), this method is called with each deserialized object to give the stream a chance to replace the object. In `ObjectInputStream`, this method simply returns the object that was passed to it. Subclasses can override this method to provide more useful functionality.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`mark()`	`InputStream`
`markSupported()`	`InputStream`	`notify()`	`Object`

ObjectOutput

Name

ObjectOutput

Synopsis

Interface Name:

`java.io.ObjectOutput`

Super-interface:

`java.io.DataOutput`

Immediate Sub-interfaces:

None

Implemented By:

`java.io.ObjectOutputStream`

Availability:

New as of JDK 1.1

Description

The `ObjectOutput` interface extends the `DataOutput` interface for object serialization. While

`DataOutput` defines methods for reading primitive types from a stream, `ObjectOutput` defines methods for writing objects and arrays of bytes.

Interface Declaration

```
public abstract interface java.io.ObjectOutput extends java.io.DataOutput {
  // Methods
  public abstract void close();
  public abstract void flush();
  public abstract void write(int b);
  public abstract void write(byte[] b);
  public abstract void write(byte[] b, int off, int len);
  public abstract void writeObject(Object obj);
}
```

Methods

close

public abstract void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the stream and releases any system resources associated with it.

flush

public abstract void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

If the stream uses a buffer, this method forces any bytes that may be buffered by the output stream to be written to the underlying physical device.

write

public abstract void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`DataOutput.write(int)`

Description

This method writes the lowest eight bits of the given integer `b` to the stream.

public abstract void write(byte[] b) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`DataOutput.write(byte[])`

Description

This method writes all of the 8-bit bytes in the given array to the stream.

`public abstract void write(byte[] b, int off, int len) throws IOException`

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`DataOutput.write(byte[], int, int)`

Description

This method writes `len` bytes from the given array, starting `off` elements from the beginning of the array, to the stream.

writeObject

public abstract void writeObject(Object obj) throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes the given object to the stream, or in other words, it serializes an object to the stream. The class that implements this interface determines how the object is written.

Inherited Methods

Method	Inherited From	Method	Inherited From
`writeBoolean(boolean)`	`DataOutput`	`writeByte(int)`	`DataOutput`
`writeBytes(String)`	`DataOutput`	`writeChar(int)`	`DataOutput`
`writeChars(String)`	`DataOutput`	`writeDouble(double)`	`DataOutput`
`writeFloat(float)`	`DataOutput`	`writeInt(int)`	`DataOutput`
`writeLong(long)`	`DataOutput`	`writeShort(int)`	`DataOutput`
`writeUTF(String)`	`DataOutput`

ObjectOutputStream

Name

ObjectOutputStream

Synopsis

Class Name:

`java.io.ObjectOutputStream`

Superclass:

`java.io.OutputStream`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.ObjectOutput`

Availability:

New as of JDK 1.1

Description

The `ObjectOutputStream` class can write both primitive types and object instances to an underlying `OutputStream`. The objects and other data can then be read by an `ObjectInputStream`. These two classes provide persistent storage of objects when they are used in conjunction with `FileInputStream` and `FileOutputStream`. The classes can also be used with socket streams to pass objects across the network.

Only objects that are instances of classes that implement the `Serializable` or `Externalizable` interfaces can be serialized to an output stream. The default serialization mechanism is implemented by `writeObject()`. When an object is serialized, the class of the object is encoded, along with the class name, the signature of the class, the values of the non-`static` and non-`transient` fields of the object, including any other objects referenced by the object (except those that do not implement the `Serializable` interface themselves). Multiple references to the same object are encoded using a reference sharing mechanism, so that a graph of the object can be restored appropriately. Strings and arrays are objects in Java, so they are treated as objects during serialization.

For example, the following code opens a file called *color.ser* and writes out a `Color` object:

```
FileOutputStream fileOut;
ObjectOutputStream out;
try {
    fileOut = new FileOutputStream("color.ser");
    out = new ObjectOutputStream(fileOut);
    out.writeObject(Color.blue);
    out.close();
}
catch (IOException e) {
    System.out.println("Error writing: " + e);
}
```

Classes that require special handling during serialization and deserialization must implement the following methods (with these exact signatures):

```
private void readObject(ObjectOutputStream stream)
             throws IOException, ClassNotFoundException
private void writeObject(ObjectOutputStream stream) throws IOException
```

The `writeObject()` method is responsible for writing the state of the object for the particular class so that it can be restored by `readObject()`. The `writeObject()` method does not need to handle writing the state for the object's superclass or any of its subclasses except in the case where the superclass does not itself implement the `Serializable` interface. In this case, the nonserializable class must have a no-argument constructor that can be called to initialize its fields, and it is the responsibility of the subclass to save the state of its superclass.

A class that inherits the implementation of `Serializable` prevents itself from being serialized by defining `readObject()` and `writeObject()` methods that throw `NotSerializableException` objects.

If a class needs complete control over the contents and formatting of the serialized form of its objects, it should implement the `Externalizable` interface.

Class Summary

```
public class java.io.ObjectOutputStream extends java.io.OutputStream
             implements java.io.ObjectOutput {
  // Constructors
  public ObjectOutputStream(OutputStream out);
  // Instance Methods
  public void close();
  public final void defaultWriteObject();
  public void flush();
  public void reset();
  public void write(int data);
  public void write(byte[] b);
  public void write(byte[] b, int off, int len);
  public void writeBoolean(boolean data);
  public void writeByte(int data);
  public void writeBytes(String data);
  public void writeChar(int data);
  public void writeChars(String data);
  public void writeDouble(double data);
  public void writeFloat(float data);
  public void writeInt(int data);
  public void writeLong(long data);
  public final void writeObject(Object obj);
  public void writeShort(int data);
  public void writeUTF(String data);
  // Protected Instance Methods
  protected void annotateClass(Class cl);
  protected void drain();
  protected final boolean enableReplaceObject(boolean enable);
  protected Object replaceObject(Object obj);
  protected void writeStreamHeader();
}
```

Constructors

ObjectOutputStream

public ObjectOutputStream(OutputStream out) throws IOException

Parameters

`out`

The underlying output stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This constructor creates an `ObjectOutputStream` that writes to the given output stream. The constructor writes the stream header, which consists of a magic number and version number, in preparation for serialization.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectOutput.close()`

Overrides

`OutputStream.close()`

Description

This method closes the stream and releases any system resources that are associated with it.

defaultWriteObject

public final void defaultWriteObject() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

`NotActiveException`

If serialization is not active.

Description

This method writes the fields of the object that are not `static` or `transient`. The method can only be called from the `private` `writeObject()` method of an object that is being serialized; it throws a `NotActiveException` if it is called at any other time. This method implements the default serialization mechanism.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectOutput.flush()`

Overrides

`OutputStream.flush()`

Description

This method takes any buffered output and forces it to be written to the underlying stream.

reset

public void reset() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method sets the state of the `ObjectOutputStream` to the same state as when it was created. As objects are serialized to the stream, the `ObjectOutputStream` remembers which ones are already serialized. If the program requests that already serialized objects be written again, the `ObjectOutputStream` just writes out a reference to the previous object. Calling `reset()` causes the `ObjectOutputStream` to forget what it has done before, so all subsequent objects are fully serialized.

write

public void write(int data) throws IOException

Parameters

`data`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectOutput.write(int)`

Overrides

`OutputStream.write(int)`

Description

This method writes the lowest eight bits of `b` to the underlying stream as a `byte`.

public void write(byte[] b) throws IOException

Parameters

`b`

An array of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectOutput.write(byte[])`

Overrides

`OutputStream.write(byte[])`

Description

This method writes the given array of bytes to the underlying stream.

public void write(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectOutput.write(byte[], int, int)`

Overrides

`OutputStream.write(byte[], int, int)`

Description

This method writes `len` bytes from the given array, starting `off` elements from the beginning of the array, to the underlying stream.

writeBoolean

public void writeBoolean(boolean data) throws IOException

Parameters

`data`

The `boolean` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeBoolean()`

Description

If `data` is `true`, this method writes a byte that contains the value `1` to the underlying stream. If `data` is `false`, the method writes a byte that contains the value 0.

writeByte

public void writeByte(int data) throws IOException

Parameters

`data`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeByte()`

Description

This method writes an 8-bit `byte` to the underlying stream, using the lowest eight bits of the given integer `data`.

writeBytes

public void writeBytes(String data) throws IOException

Parameters

`data`

The `String` to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeBytes()`

Description

This method writes the characters in the given `String` to the underlying stream as a sequence of 8-bit bytes. The high-order bytes of the characters in the string are ignored.

writeChar

public void writeChar(int data) throws IOException

Parameters

`data`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeChar()`

Description

This method writes a 16-bit `char` to the underlying stream, using the lowest two bytes of the given integer `data`.

writeChars

public void writeChars(String data) throws IOException

Parameters

`data`

The `String` to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeChars()`

Description

This method writes the characters in the given `String` object to the underlying stream as a sequence of 16-bit characters.

writeDouble

public void writeDouble(double data) throws IOException

Parameters

`data`

The `double` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeDouble()`

Description

This method writes a 64-bit `double` to the underlying stream. The `double` value is converted to a `long` using `doubleToLongBits()` of `Double`; the `long` value is then written to the underlying stream as eight bytes with the highest byte first.

writeFloat

public void writeFloat(float data) throws IOException

Parameters

`data`

The `float` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeFloat()`

Description

This method writes a 32-bit `float` to the underlying stream. The `float` value is converted to a `int` using `floatToIntBits()` of `Float`; the `int` value is then written to the underlying stream as four bytes with the highest byte first.

writeInt

public void writeInt(int data) throws IOException

Parameters

`data`

The `int` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeInt()`

Description

This method writes a 32-bit `int` to the underlying stream. The value is written as four bytes with the highest byte first.

writeLong

public void writeLong(long data) throws IOException

Parameters

`data`

The `long` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeLong()`

Description

This method writes a 64-bit `long` to the underlying stream. The value is written as eight bytes with the highest byte first.

writeObject

`public final void writeObject(Object obj) throws IOException, InvalidClassException, NotSerializableException`

Parameters

`obj`

The object to be serialized.

Throws

`InvalidClassException`

If there is a problem with the class of the object.

`NotSerializableException`

If the object does not implement `Serializable` or `Externalizable`.

`IOException`

If any kind of I/O error occurs.

Implements

`ObjectOutput.writeObject()`

Description

This method serializes the given object to the stream. The class of the object is encoded, along with the class name, the signature of the class, the values of the non-`static` and non-`transient` fields of the object, including any other objects referenced by the object (except those that do not implement the `Serializable` interface themselves). Multiple references to the same object are encoded using a reference sharing mechanism, so that a graph of object can be restored appropriately.

writeShort

public void writeShort(int data) throws IOException

Parameters

`data`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeShort()`

Description

This method writes a 16-bit `short` to the underlying stream, using the lowest two bytes of the given integer `data`.

writeUTF

public void writeUTF(String data) throws IOException

Parameters

`data`

The `String` to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeUTF()`

Description

This method writes the given `String` to the underlying stream using the UTF-8 encoding. See the description of `DataOutputStream.writeUTF(String)` for more information.

Protected Instance Methods

annotateClass

protected void annotateClass(Class cl) throws IOException

Parameters

`cl`

The class to be serialized.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is called once for each unique class during serialization. The implementation in `ObjectOutputStream` does nothing; subclasses can override this method to write out more information about a class. A corresponding subclass of `ObjectInputStream` should override the `resolveClass()` method to read the extra class information.

drain

protected void drain() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is a helper method for `flush()`. It forces a write of any buffered data in the `ObjectOutputStream`, but does not call `flush()` on the underlying stream.

enableReplaceObject

```
protected final boolean enableReplaceObject(boolean enable) throws SecurityException
```

Parameters

`enable`

A `boolean` value that specifies whether or not object replacement is enabled.

Returns

`true` if object replacement was previously enabled; `false` otherwise.

Throws

`SecurityException`

If `enable` is `true` and `getClassLoader()`called on the class of the stream does not return `null`.

Description

This method determines if a trusted subclass of `ObjectOutputStream` is allowed to replace serialized objects. If the method is called with `true`, replacement is enabled. Each time an object is serialized, `replaceObject()` is called to give the `ObjectOutputStream` a chance to replace the object. A trusted stream is one whose class has no `ClassLoader`.

replaceObject

protected Object replaceObject(Object obj) throws IOException

Parameters

`obj`

The object to be replaced.

Returns

A replacement for the given object.

Throws

`IOException`

If any kind of I/O error occurs.

Description

If object replacement is enabled for this `ObjectOutputStream` (see `enableReplaceObject()`), this method is called with each object to be serialized to give the stream a chance to replace the object. In `ObjectOutputStream`, this method simply returns the object that was passed to it. Subclasses can override this method to provide more useful functionality.

writeStreamHeader

protected void writeStreamHeader() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes the serialization stream header, which consists of a magic number and a version number. This method is called by the constructor for `ObjectOutputStream`. If you subclass `ObjectOutputStream`, you can override this method to provide your own stream header.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ObjectStreamClass

Name

ObjectStreamClass

Synopsis

Class Name:

    `java.io.ObjectStreamClass`

Superclass:

    `java.lang.Object`

Immediate Subclasses:

    None

Interfaces Implemented:

    None

Availability:

    New as of JDK 1.1

Description

The `ObjectStreamClass` class represents a Java class during object serialization. When an object is deserialized, its class information is read into an `ObjectStreamClass`, which is then resolved to a `Class` if possible. An `ObjectStreamClass` instance contains the name and version information for a class.

Class Summary

```
public class java.io.ObjectStreamClass extends java.lang.Object
             implements java.io.Serializable {
  // Class Methods
  public static ObjectStreamClass lookup(Class cl);
  // Instance Methods
  public Class forClass();
  public String getName();
  public long getSerialVersionUID();
  public String toString();
}
```

Class Methods

lookup

public static ObjectStreamClass lookup(Class cl)

Parameters

`cl`

The `Class` to find.

Returns

An `ObjectStreamClass` that corresponds to the given `Class`.

Description

This method finds an `ObjectStreamClass` for the given `Class`. If the appropriate

ObjectStreamClass does not already exist, this method creates an ObjectStreamClass for the given Class. The method returns null if cl is not serializable.

Instance Methods

forClass

public Class forClass()

Returns

The Class that corresponds to this ObjectStreamClass.

Description

This method returns the Class in the run-time system that corresponds to this ObjectStreamClass. If there is no corresponding class, null is returned.

getName

public String getName()

Returns

The class name.

Description

This method returns the name of the class this ObjectStreamClass represents.

getSerialVersionUID

public long getSerialVersionUID()

Returns

The class version.

Description

This method returns the version of the class this `ObjectStreamClass` represents.

toString

public String toString()

Returns

`A string representation of this` object.

Overrides

`Object.toString()`

Description

This method returns a string that contains the class name and version information for this `ObjectStreamClass`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

OutputStream

Name

OutputStream

Synopsis

Class Name:

```
    java.io.OutputStream
```

Superclass:

```
    java.lang.Object
```

Immediate Subclasses:

```
    java.io.ByteArrayOutputStream,

    java.io.FileOutputStream,

    java.io.FilterOutputStream,

    java.io.ObjectOutputStream,

    java.io.PipedOutputStream
```

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `OutputStream` class is an `abstract` class that is the superclass of all classes that represent output byte streams. `OutputStream` defines the basic output methods that all output streams provide. A similar hierarchy of classes, based around `Writer`, deals with character streams instead of byte streams.

`OutputStream` is designed so that `write(byte[])` and `write(byte[], int, int)` call `write(int b)`. Thus, a subclass can simply override `write()`, and all the `write` methods will work. However, for efficiency's sake, `write(byte[], int, int)` should also be overridden with a method that can write a block of data more efficiently than writing each byte separately.

Some `OutputStream` subclasses may implement buffering to increase efficiency. `OutputStream` provides a method, `flush()`, that tells the `OutputStream` to write any buffered output to the underlying device, which may be a disk drive or a network.

Class Summary

```
public abstract class java.io.OutputStream extends java.lang.Object {
  // Instance Methods
  public void close();
  public void flush();
  public abstract void write(int b);
  public void write(byte[] b);
  public void write(byte[] b, int off, int len);
}
```

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the output stream and releases any resources associated with it.

The implementation of the `close()` method in `OutputStream` does nothing; a subclass should override this method to handle cleanup for the stream.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method forces any bytes that may be buffered by the output stream to be written.

The implementation of `flush()` in `OutputStream` does nothing; a subclass should override this method as needed.

write

public abstract void write(int b) throws IOException

Parameters

`b`

The value to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes a byte of output. The method blocks until the byte is actually written.

A subclass of `OutputStream` must implement this method.

public void write(byte[] b) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes the bytes from the given array by calling `write(b, 0, b.length)`. The method blocks until the bytes are actually written.

A subclass does not usually need to override this method, as it can override `write(byte[], int, int)` and have `write(byte[])` work automatically.

public void write(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes `len` bytes of output from the given array, starting at offset `off`. The method blocks until the bytes are actually written.

The implementation of this method in `OutputStream` uses `write(int)` repeatedly to write the bytes. Although it is not strictly necessary, a subclass should override this method to write a block of data more efficiently.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`		

See Also

`ByteArrayOutputStream`, `FileOutputStream`, `FilterOutputStream`, `IOException`, `ObjectOutputStream`, `PipedOutputStream`

OutputStreamWriter

Name

OutputStreamWriter

Synopsis

Class Name:

`java.io.OutputStreamWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

`java.io.FileWriter`

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `OutputStreamWriter` class is a bridge between the byte-oriented world of the `OutputStream` class and the character-oriented world of the `Writer` class. The `OutputStreamWriter` represents a character stream, but it sends its output to an underlying byte stream. A character encoding scheme is responsible for translating the Unicode characters to bytes. An `OutputStreamWriter` can be created using an explicit encoding scheme or a default encoding scheme.

For example, to write a Unicode character stream as an ISO-8859-5 byte stream, you can construct an `OutputStreamWriter` with the encoding `8859_5` as follows:

```
OutputStreamWriter outr = new OutputStreamWriter(out, "8859_5");
```

Each time you write to an `OutputStreamWriter` object, bytes may be written to the underlying byte stream. To improve efficiency, you may want to wrap the `OutputStreamWriter` in a `BufferedWriter`.

Class Summary

```
public class java.io.OutputStreamWriter extends java.io.Writer {
  // Constructors
  public OutputStreamWriter(OutputStream out);
  public OutputStreamWriter(OutputStream out, String enc);
  // Instance Methods
  public void close();
  public void flush();
  public String getEncoding();
  public void write(int c);
  public void write(char[] cbuf, int off, int len);
  public void write(String str, int off, int len);
}
```

Constructors

OutputStreamWriter

public OutputStreamWriter(OutputStream out)

Parameters

`out`

The output stream to use.

Description

This constructor creates an `OutputStreamWriter` that writes its data to `out` and translates characters to bytes using the system's default encoding scheme.

`public OutputStreamWriter(OutputStream out, String enc) throws UnsupportedEncodingException`

Parameters

`out`

The output stream to use.

`enc`

The name of an encoding scheme.

Throws

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

This constructor creates an `OutputStreamWriter` that writes its data to `out` and translates characters to bytes using the given encoding scheme.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.close()`

Description

This method calls the `close()` method of the underlying output stream, which releases any system resources associated with this object.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.flush()`

Description

This method writes out any buffered data in the internal buffer and calls the `flush()` method of the underlying output stream, which forces any bytes that may be buffered to be written to the underlying device.

getEncoding

public String getEncoding()

Returns

A `String` that contains the name of the character encoding scheme of this writer.

Description

This method returns the name of the character encoding scheme this `OutputStreamWriter` is currently using.

write

public void write(int c) throws IOException

Parameters

`c`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(int)`

Description

This method converts the given character to bytes using the current encoding scheme and places the converted bytes into an internal buffer. When the buffer fills up, it is written to the underlying byte stream.

`public void write(char[] cbuf, int off, int len) throws IOException`

Parameters

`cbuf`

An array of characters to write.

`off`

An offset into the character array.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(char[], int, int)`

Description

This method converts `len` characters from the array `cbuf` to bytes, starting at offset `off`, using the current encoding scheme. The method places the converted bytes into an internal buffer. When the buffer fills up, it is written to the underlying byte stream.

public void write(String str, int off, int len) throws IOException

Parameters

`str`

The string to be written.

`off`

An offset into start in the string.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(String, int, int)`

Description

This method converts `len` characters from the string `str` to bytes, starting at offset `off`, using the current encoding scheme. The method places the converted bytes into an internal buffer. When the buffer fills up, it is written to the underlying byte stream.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`	`write(char[])`	`Writer`
`write(String)`	`Writer`		

See Also

PipedInputStream

Name

PipedInputStream

Synopsis

Class Name:

`java.io.PipedInputStream`

Superclass:

`java.io.InputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `PipedInputStream` class represents half of a communication pipe; a `PipedInputStream` must be connected to a PipedOutputStream. When the two halves of a communication pipe are connected, data written to the PipedOutputStream can be read from the PipedInputStream. The communication pipe formed by a PipedInputStream and a PipedOutputStream should be used to communicate between threads. If both ends of a pipe are used by the same thread, the thread can hang.

Class Summary

```
public class java.io.PipedInputStream extends java.io.InputStream {
  // Variables
  protected byte[] buffer;                           // New in 1.1
  protected int in;                                  // New in 1.1
  protected int out;                                 // New in 1.1
  protected final static int PIPE_SIZE;              // New in 1.1
  // Constructors
  public PipedInputStream();
  public PipedInputStream(PipedOutputStream src);
  // Public Instance Methods
  public synchronized int available();               // New in 1.1
  public void close();
  public void connect(PipedOutputStream src);
  public synchronized int read();
  public synchronized int read(byte[] b, int off, int len);

  // Protected Instance Methods
  protected synchronized void receive(int b);        // New in 1.1
}
```

Variables

buffer

protected byte[] buffer

Availability

> New as of JDK 1.1

Description

> The internal data buffer. The buffer receives data from the connected PipedOutputStream and supplies data for the calls to read().

in

protected int in

Availability

New as of JDK 1.1

Description

An index into the buffer that points to the byte after the last byte of valid data. A value of `-1` indicates that the buffer is empty.

out

protected int out

Availability

New as of JDK 1.1

Description

An index into the buffer that points to the next byte that will be returned by `read()`.

PIPE_SIZE

public final static int PIPE_SIZE = 1024

Availability

New as of JDK 1.1

Description

The size of the internal data buffer. The buffer receives data from the connected `PipedOutputStream` and supplies data for the calls to `read()`.

Constructors

PipedInputStream

public PipedInputStream()

Description

This constructor creates a `PipedInputStream` that is not connected to a `PipedOutputStream`. The created object must be connected to a `PipedOutputStream` before it can be used.

public PipedInputStream(PipedOutputStream src) throws IOException

Parameters

`src`

The `PipedOutputStream` to connect.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This constructor creates a `PipedInputStream` that receives data from the given `PipedOutputStream`.

Public Instance Methods

available

public synchronized int available() throws IOException

Availability

New as of JDK 1.1

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.available()`

Description

This method returns the number of bytes that can be read without having to wait for more data to become available. More data becomes available in the `PipedInputStream` when data is written to the connected `PipedOutputStream`.

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.close()`

Description

This method closes the stream and releases the system resources that are associated with it.

connect

public void connect(PipedOutputStream src) throws IOException

Parameters

`src`

The `PipedOutputStream` to connect.

Throws

`IOException`

If another `PipedOutputStream` is already connected to this `PipedInputStream`.

Description

This method connects the given `PipedOutputStream` to this `PipedInputStream` object. If there is already a connected `PipedOutputStream`, an exception is thrown.

read

public synchronized int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If the pipe is broken. In other words, if this `PipedInputStream` is closed or if the connected `PipedOutputStream` is dead.

`InterruptedIOException`

While this method is waiting for input, if the `interrupted()` method of the thread that invoked this method is called.

Overrides

`InputStream.read()`

Description

This method returns the next byte from the pipe buffer. If the buffer is empty, the method waits until data is written to the connected `PipedOutputStream`. The method blocks until the byte is read, the end of the stream is encountered, or an exception is thrown.

`public synchronized int read(byte b[], int off, int len) throws IOException`

Parameters

`b`

An array of bytes to be filled.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If the pipe is broken. In other words, if this `PipedInputStream` is closed or if the connected `PipedOutputStream` is dead.

`InterruptedIOException`

While this method is waiting for buffer space to become available, if the `interrupted()` method of the thread that invoked this method is called.

Overrides

`InputStream.read(byte[], int, int)`

Description

This method copies bytes from the pipe buffer into the given array `b`, starting at index `off` and continuing for `len` bytes. If there is at least one byte in the buffer, the method returns as many bytes as are in the buffer (up to `len`). If the buffer is empty, the method blocks until data is written to the connected `PipedOutputStream`.

Protected Instance Methods

receive

protected synchronized void receive(int b) throws IOException

Availability

New as of JDK 1.1

Parameters

`b`

The byte being received.

Throws

`IOException`

If the pipe is broken. In other words, if this `PipedInputStream` is closed.

Description

This method is called by the connected `PipedOutputStream` object to provide the given value as a byte of input to this `PipedInputStream` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`

PipedOutputStream

Name

PipedOutputStream

Synopsis

Class Name:

`java.io.PipedOutputStream`

Superclass:

`java.io.OutputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The PipedOutputStream class represents half of a communication pipe; a PipedOutputStream must be connected to a PipedOutputStream. When the two halves of a communication pipe are connected, data written to the PipedOutputStream can be read from the PipedInputStream. The communication pipe formed by a PipedOutputStream and a PipedInputStream should be used to communicate between threads. If both ends of a pipe are used by the same thread, the thread can hang.

Class Summary

```
public class java.io.PipedOutputStream extends java.io.OutputStream {
  // Constructors
  public PipedOutputStream();
  public PipedOutputStream(PipedInputStream snk);
  // Instance Methods
  public void close();
  public void connect(PipedInputStream snk);
  public synchronized void flush();               // New in 1.1
  public void write(int b);
  public void write(byte[] b, int off, int len);
}
```

Constructors

PipedOutputStream

public PipedOutputStream()

Description

> This constructor creates a PipedOutputStream that is not connected to a PipedInputStream. The created object must be connected to a PipedInputStream before it can be used.

public PipedOutputStream(PipedInputStream snk)

Parameters

`snk`

The `PipedInputStream` to connect.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This constructor creates a `PipedOutputStream` that sends data to the given `PipedInputStream`.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`OutputStream.close()`

Description

This method closes the stream and releases the system resources that are associated with it.

connect

public void connect(PipedInputStream snk) throws IOException

Parameters

`snk`

The `PipedInputStream` to connect.

Throws

`IOException`

If another `PipedInputStream` is already connected to this `PipedOutputStream` or this `PipedOutputStream` is already connected.

Description

This method connects this `PipedOutputStream` object to the given `PipedInputStream`. If this `PipedOutputStream` or `snk` is already connected, an exception is thrown.

flush

public synchronized void flush() throws IOException

Availability

New as of JDK 1.1

Throws

`IOException`

If any kind of I/O error occurs.

`InterruptedIOException`

While this method is waiting for buffer space to become available, if the `interrupted()` method of the thread that invoked this method is called.

Overrides

`OutputStream.flush()`

Description

This method flushes the stream, which tells the connected `PipedInputStream` to notify its readers to read any available data.

write

public void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

`InterruptedIOException`

While this method is waiting for buffer space to become available, if the `interrupted()` method of the thread that invoked this method is called.

Overrides

`OutputStream.write(int)`

Description

This method writes a byte of output. The method passes the given value directly to the connected `PipedInputStream`.

public void write(byte b[], int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

`InterruptedIOException`

While this method is waiting for buffer space to become available, if the `interrupted()` method of the thread that invoked this method is called.

Overrides

`OutputStream.write(byte[], int, int)`

Description

This method writes `len` bytes of output from the given array, starting at offset `off`. The method passes the given data to the connected `PipedInputStream`.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`

`wait(long, int)`	`Object`	`write(byte[])`	`OutputStream`

PipedReader

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

PipedReader

Name

PipedReader

Synopsis

Class Name:

    `java.io.PipedReader`

Superclass:

    `java.io.Reader`

Immediate Subclasses:

    None

Interfaces Implemented:

    None

Availability:

    New as of JDK 1.1

Description

The `PipedReader` class represents half of a communication pipe; a `PipedReader` must be connected to a `PipedWriter`. When the two halves of a communication pipe are connected, data written to the `PipedWriter` can be read from the `PipedReader`. The communication pipe formed by a `PipedReader` and a `PipedWriter` should be used to communicate between threads. If both ends of a pipe are used by the same thread, the thread can hang.

The `PipedReader` class is the character-based equivalent of the byte-based `PipedInputStream`.

Class Summary

```
public class java.io.PipedReader extends java.io.Reader {
  // Constructors
  public PipedReader();
  public PipedReader(PipedWriter src);
  // Instance Methods
  public void close();
  public void connect(PipedWriter src);
  public int read(char[] cbuf, int off, int len);
}
```

Constructors

PipedReader

public PipedReader ()

Description

> This constructor creates a `PipedReader` that is not connected to a `PipedWriter`. The created object must be connected to a `PipedWriter` before it can be used.

public PipedReader(PipedWriter src) throws IOException

Parameters

> `src`

The `PipedWriter` to connect.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This constructor creates a `PipedReader` that receives data from the given `PipedWriter`.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Reader.close()`

Description

This method closes the reader and releases the system resources that are associated with it.

connect

public void connect(PipedWriter src) throws IOException

Parameters

`src`

The `PipedWriter` to connect.

Throws

`IOException`

If another `PipedWriter` is already connected to this `PipedReader`.

Description

This method connects the given `PipedWriter` to this `PipedReader` object. If there is already a connected `PipedWriter`, an exception is thrown.

read

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled.

`off`

An offset into the array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If the pipe is broken. In other words, if this `PipedReader` is closed or if the connected

PipedWriter is dead.

InterruptedIOException

While this method is waiting for input, if the interrupted() method of the thread that invoked this method is called.

Overrides

Reader.read(char[], int, int)

Description

This method copies characters from the pipe buffer into the given array cbuf, starting at index off and continuing for len characters. If there is at least one character in the buffer, the method returns as many characters as are in the buffer (up to len). If the buffer is empty, the method blocks until data is written to the connected PipedWriter.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	equals(Object)	Object
finalize()	Object	getClass()	Object
hashCode()	Object	mark(int)	Reader
markSupported()	Reader	notify()	Object
notifyAll()	Object	read()	Reader
read(char[])	Reader	reset()	Reader
skip(long)	Reader	toString()	Object
wait()	Object	wait(long)	Object
wait(long, int)	Object

PipedWriter

Synopsis

Class Name:

`java.io.PipedWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `PipedWriter` class represents half of a communication pipe; a `PipedReader` must be connected to a `PipedWriter`. When the two halves of a communication pipe are connected, data written to the `PipedWriter` can be read from the `PipedReader`. The communication pipe formed by a `PipedWriter` and a `PipedReader` should be used to communicate between threads. If both ends of a pipe are used by the same thread, the thread can hang.

The `PipedWriter` class is the character-based equivalent of the byte-based `PipedOutputStream`.

Class Summary

```
public class java.io.PipedWriter extends java.io.Writer {
  // Constructors
  public PipedWriter();
  public PipedWriter(PipedReader sink);
  // Instance Methods
  public void close();
  public void connect(PipedReader sink);
  public void flush();
  public void write(char[] cbuf, int off, int len;
}
```

Constructors

PipedWriter

public PipedWriter()

Description

> This constructor creates a `PipedWriter` that is not connected to a `PipedReader`. The created object must be connected to a `PipedReader` before it can be used.

public PipedWriter(PipedReader sink)

Parameters

> `sink`

The `PipedReader` to connect.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This constructor creates a `PipedWriter` that sends data to the given `PipedReader`.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.close()`

Description

This method closes the writer and releases the system resources that are associated with it.

connect

public void connect(PipedReader sink) throws IOException

Parameters

`sink`

The `PipedReader` to connect.

Throws

`IOException`

If another `PipedReader` is already connected to this `PipedWriter` or this `PipedWriter` is already connected.

Description

This method connects this `PipedWriter` object to the given `PipedReader`. If this `PipedWriter` or `sink` is already connected, an exception is thrown.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

`InterruptedIOException`

While this method is waiting for buffer space to become available, if the `interrupted()` method of the thread that invoked this method is called.

Overrides

`Writer.flush()`

Description

This method flushes the writer, which tells the connected `PipedReader` to notify its readers to read any available data.

write

```
public void write(char[] cbuf, int off, int len) throws IOException
```

Parameters

`cbuf`

An array of characters to write to the stream.

`off`

An offset into the character array.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`Writer.write(char[], int, int)`

Description

This method writes `len` characters of output from the given array, starting at offset `off`. The method passes the given data to the connected `PipedReader`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

NEXT PrintStream

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

PrintStream

Name

PrintStream

Synopsis

Class Name:

```
java.io.PrintStream
```

Superclass:

```
java.io.FilterOutputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The PrintStream class provides support for writing string representations of primitive data types and objects to an underlying output stream. As of JDK 1.1, PrintStream uses the system's default encoding scheme to convert characters to bytes and uses the system's own specific line separator, rather than the newline character, for separating lines of text. Although this class is not officially deprecated, its constructors are, and you should use PrintWriter instead of PrintStream in new code.

Prior to JDK 1.1, PrintStream did not handle Unicode characters. Any PrintStream methods that wrote characters only wrote the low eight bits of each character. In addition, prior to JDK 1.1, PrintStream used the newline character to separate lines of text, regardless of the platform. These problems have been corrected as of JDK 1.1.

All of the methods of PrintStream that write multiple times to the underlying output stream handle synchronization internally, so that PrintStream objects are thread-safe.

A PrintStream object is often used to write to a BufferedOutputStream object. Note that you can specify that the PrintStream be flushed every time it writes the line separator or the newline character by using the constructor that takes a boolean argument.

PrintStream objects are often used to report errors. For this reason, the methods of this class do not throw exceptions. Instead, the methods catch any exceptions thrown by any downstream OutputStream objects and set an internal flag, so that the object can remember that a problem occurred. You can query the internal flag by calling the checkError() method.

Class Summary

```
public class java.io.PrintStream extends java.io.FilterOutputStream {
  // Constructors
  public PrintStream(OutputStream out);           // Deprecated in 1.1
  public PrintStream(OutputStream out,
                     boolean autoFlush);          // Deprecated in 1.1
  // Public Instance Methods
  public boolean checkError();
  public void close();
  public void flush();
  public void print(boolean b);
  public void print(char c);
  public void print(char[] s);
  public void print(double d);
  public void print(float f);
  public void print(int i);
  public void print(long l);
  public void print(String s);
  public void print(Object obj);
  public void println();
  public void println(boolean b);
  public void println(char c);
  public void println(char[] s);
  public void println(double d);
  public void println(float f);
  public void println(int i);
  public void println(long l);
  public void println(Object obj);
  public void println(String s);
  public void write(int b);
  public void write(byte[] buf, int off, int len);
  // Protected Instance Methods
  protected void setError();                      // New in 1.1
}
```

Constructors

PrintStream

public PrintStream(OutputStream out)

Availability

Deprecated as of JDK 1.1

Parameters

`out`

The output stream to use.

Description

This constructor creates a `PrintStream` object that sends output to the given `OutputStream`.

public PrintStream(OutputStream out, boolean autoflush)

Availability

Deprecated as of JDK 1.1

Parameters

`out`

The output stream to use.

`autoflush`

A `boolean` value that indicates whether or not the print stream is flushed every time a newline is output.

Description

This constructor creates a `PrintStream` object that sends output to the given `OutputStream`. If `autoflush` is `true`, every time the `PrintStream` object writes a newline character or line separator, it calls its `flush()` method. Note that this is different than with a `PrintWriter` object, which only calls its `flush()` method when a `println()` method is called.

Public Instance Methods

checkError

public boolean checkError()

Returns

`true` if any error has occurred; `false` otherwise.

Description

This method flushes any buffered output and returns `true` if any error has occurred. Once the error flag for a `PrintStream` object has been set, it is never cleared.

close

public void close()

Overrides

`FilterOutputStream.close()`

Description

This method closes this print stream and releases any resources associated with the object. The method does this by calling the `close()` method of the underlying output stream and catching any exceptions that are thrown.

flush

public void flush()

Overrides

`FilterOutputStream.flush()`

Description

This method flushes this print stream, forcing any bytes that may be buffered to be written to the underlying output stream. The method does this by calling the `flush()` method of the underlying output stream and catching any exceptions that are thrown.

print

public void print(boolean b)

Parameters

`b`

The `boolean` value to print.

Description

This method writes `"true"` to the underlying output stream if `b` is true; otherwise it writes `"false"`.

public void print(char c)

Parameters

`c`

The `char` value to print.

Description

This method writes the given character to the underlying output stream.

public void print(char[] s)

Parameters

`s`

The `char` array to print.

Description

This method writes the characters in the given array to the underlying output stream.

public void print(double d)

Parameters

`d`

The `double` value to print.

Description

This method writes a string representation of the given `double` value to the underlying output stream. The string representation is identical to the one returned by calling `Double.toString(d)`.

public void print(float f)

Parameters

`f`

The `float` value to print.

Description

This method writes a string representation of the given `float` value to the underlying output stream. The string representation is identical to the one returned by calling `Float.toString(f)`.

public void print(int i)

Parameters

`i`

The `int` value to print.

Description

This method writes a string representation of the given `int` value to the underlying output stream. The string representation is identical to the one returned by calling `Integer.toString(i)`.

public void print(long l)

Parameters

`l`

The `long` value to print.

Description

This method writes a string representation of the given `long` value to the underlying output stream. The string representation is identical to the one returned by calling `Long.toString(l)`.

public void print(Object obj)

Parameters

`obj`

The `Object` to print.

Description

This method writes the string representation of the given `Object` to the underlying output stream. The string representation is that returned by calling the `toString()` method of `Object`.

public void print(String s)

Parameters

`s`

The `String` to print.

Description

This method writes the given `String` to the underlying output stream. If `String` is `null`, the method writes `"null"`.

println

public void println()

Description

This method writes a line separator to the underlying output stream.

public void println(boolean b)

Parameters

`b`

The `boolean` value to print.

Description

This method writes `"true"` to the underlying output stream if `b` is true, otherwise it writes `"false"`. In either case, the string is followed by a line separator.

public void println(char c)

Parameters

`c`

The `char` value to print.

Description

This method writes the given character, followed by a line separator, to the underlying output stream.

public void println(char[] s)

Parameters

`s`

The `char` array to print.

Description

This method writes the characters in the given array, followed by a line separator, to the underlying output stream.

public void println(double d)

Parameters

`d`

The `double` value to print.

Description

This method writes a string representation of the given `double` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Double.toString(d)`.

public void println(float f)

Parameters

`f`

The `float` value to print.

Description

This method writes a string representation of the given `float` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Float.toString(f)`.

public void println(int i)

Parameters

`i`

The `int` value to print.

Description

This method writes a string representation of the given `int` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Integer.toString(i)`.

public void println(long l)

Parameters

`l`

The `long` value to print.

Description

This method writes a string representation of the given `long` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Long.toString(l)`.

public void println(Object obj)

Parameters

`obj`

The `Object` to print.

Description

This method writes the string representation of the given `Object`, followed by a line separator, to the underlying output stream. The string representation is that returned by calling the `toString()` method of `Object`.

public void println(String s)

Parameters

`s`

The `String` to print.

Description

This method writes the given `String`, followed by a line separator, to the underlying output stream. If `String` is `null`, the method writes `"null"` followed by a line separator.

write

public void write(int b)

Parameters

`b`

The value to write to the stream.

Overrides

`FilterOutputStream.write(int)`

Description

This method writes the lowest eight bits of `b` to the underlying stream as a byte. The method does this by calling the `write()` method of the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the byte is written.

public void write(byte b[], int off, int len)

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Overrides

`FilterOutputStream.write(byte[], int, int)`

Description

This method writes the lowest eight bits of each of `len` bytes from the given array, starting `off` elements from the beginning of the array, to the underlying output stream. The method does this by calling `write(b, off, len)` for the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the bytes are written.

Protected Instance Methods

setError

protected void setError()

Availability

New as of JDK 1.1

Description

This method sets the error state of the `PrintStream` object to `true`. Any subsequent calls to `getError()` return `true`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`

PrintWriter

Name

PrintWriter

Synopsis

Class Name:

`java.io.PrintWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `PrintWriter` class provides support for writing string representations of primitive data types and objects to an underlying output stream. `PrintWriter` uses the system's default encoding scheme to convert characters to bytes. `PrintWriter` also uses the system's own specific line separator, rather than the newline character, for separating lines of text. This line separator is equivalent to the value returned by:

```
System.getProperty("line.separator")
```

A `PrintWriter` object can be created using a `Writer` object or an `OutputStream` object as its underlying stream. When a `PrintWriter` is created using an `OutputStream`, the constructor creates the intermediate `OutputStreamWriter` that handles the conversion of characters to bytes using the default character encoding.

All of the methods of `PrintWriter` that write multiple times to the underlying output stream handle synchronization internally, so that `PrintWriter` objects are thread-safe.

A `PrintWriter` object is often used to write to a `BufferedWriter` object. Note that you can specify that the `PrintWriter` should be flushed every time a `println()` method is called by using a constructor that takes a `boolean` argument.

`PrintWriter` objects are often used to report errors. For this reason, the methods of this class do not throw exceptions. Instead, the methods catch any exceptions thrown by any downstream `OutputStream` or `Writer` objects and set an internal flag, so that the object can remember that a problem occurred. You can query the internal flag by calling the `checkError()` method.

Class Summary

```
public class java.io.PrintWriter extends java.io.Writer {
  // Constructors
  public PrintWriter(OutputStream out);
  public PrintWriter(OutputStream out, boolean autoFlush);
  public PrintWriter(Writer out);
  public PrintWriter(Writer out, boolean autoFlush);

  public void println(int i);
  public void println(long l);
  public void println(Object obj);
  public void println(String s);
  public void write(int c);
  public void write(char[] buf);
  public void write(char[] buf, int off, int len);
  public void write(String s);
  public void write(String s, int off, int len);

  // Protected Instance Methods
  protected void setError();
}
```

Constructors

PrintWriter

public PrintWriter(OutputStream out)

Parameters

`out`

The output stream to use.

Description

This constructor creates a `PrintWriter` object that sends output to the given `OutputStream`. The constructor creates the intermediate `OutputStreamWriter` that converts characters to bytes using the default character encoding.

public PrintWriter(OutputStream out, boolean autoFlush)

Parameters

`out`

The output stream to use.

`autoFlush`

A `boolean` value that indicates whether or not the print stream is flushed every time a `println()` method is called.

Description

This constructor creates a `PrintWriter` object that sends output to the given `OutputStream`. The constructor creates the intermediate `OutputStreamWriter` that converts characters to bytes using the default character encoding. If `autoFlush` is `true`, every time a `println()` method is called, the `PrintWriter` object calls its `flush()` method. This behavior is different from that of a `PrintStream` object, which calls its `flush()` method each time a line separator or newline character is written.

public PrintWriter(Writer out)

Parameters

`out`

The output stream to use.

Description

This constructor creates a `PrintWriter` object that sends output to the given `Writer`.

public PrintStream(Writer out, boolean autoFlush)

Parameters

`out`

The output stream to use.

`autoFlush`

A `boolean` value that indicates whether or not the print stream is flushed every time a `println()` method is called.

Description

This constructor creates a `PrintWriter` object that sends output to the given `Writer`. If `autoFlush` is `true`, every time a `println()` method is called, the `PrintWriter` object calls its `flush()` method. Note that this behavior is different from that of a `PrintStream` object, which calls its `flush()` method every time a newline character or line separator is written.

Public Instance Methods

checkError

public boolean checkError()

Returns

`true` if any error has occurred; `false` otherwise.

Description

This method flushes any buffered output and returns `true` if an error occurs. Once the error flag for a `PrintWriter` object is set, it's never cleared.

close

public void close()

Overrides

`Writer.close()`

Description

This method closes this print stream and releases any resources associated with the object. The method does this by calling the `close()` method of the underlying output stream and catching any exceptions that are thrown.

flush

public void flush()

Overrides

`Writer.flush()`

Description

This method flushes this print stream, forcing any bytes that may be buffered to be written to the underlying output stream. The method does this by calling the `flush()` method of the underlying output stream and catching any exceptions that are thrown.

print

public void print(boolean b)

Parameters

`b`

The `boolean` value to print.

Description

This method writes `"true"` to the underlying output stream if `b` is true; otherwise it writes `"false"`.

public void print(char c)

Parameters

`c`

The `char` value to print.

Description

This method writes the given character to the underlying output stream.

public void print(char[] s)

Parameters

`s`

The `char` array to print.

Description

This method writes the characters in the given array to the underlying output stream.

public void print(double d)

Parameters

`d`

The `double` value to print.

Description

This method writes a string representation of the given `double` value to the underlying output stream. The string representation is identical to the one returned by calling `Double.toString(d)`.

public void print(float f)

Parameters

`f`

The `float` value to print.

Description

This method writes a string representation of the given `float` value to the underlying output stream. The string representation is identical to the one returned by calling `Float.toString(f)`.

public void print(int i)

Parameters

`i`

The `int` value to print.

Description

This method writes a string representation of the given `int` value to the underlying output stream. The string representation is identical to the one returned by calling `Integer.toString(i)`.

public void print(long l)

Parameters

`l`

The `long` value to print.

Description

This method writes a string representation of the given `long` value to the underlying output stream. The string representation is identical to the one returned by calling `Long.toString(l)`.

public void print(Object obj)

Parameters

`obj`

The `Object` to print.

Description

> This method writes the string representation of the given `Object` to the underlying output stream. The string representation is that returned by calling the `toString()` method of `Object`.

public void print(String s)

Parameters

> `s`
>
> > The `String` to print.

Description

> This method writes the given `String` to the underlying output stream. If `String` is `null`, the method writes `"null"`.

println

public void println()

Description

> This method writes a line separator to the underlying output stream.

public void println(boolean b)

Parameters

> `b`
>
> > The `boolean` value to print.

Description

> This method writes `"true"` to the underlying output stream if `b` is true, otherwise it writes `"false"`. In either case, the string is followed by a line separator.

public void println(char c)

Parameters

`c`

The `char` value to print.

Description

This method writes the given character, followed by a line separator, to the underlying output stream.

public void println(char[] s)

Parameters

`s`

The `char` array to print.

Description

This method writes the characters in the given array, followed by a line separator, to the underlying output stream.

public void println(double d)

Parameters

`d`

The `double` value to print.

Description

This method writes a string representation of the given `double` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Double.toString(d)`.

public void println(float f)

Parameters

`f`

The `float` value to print.

Description

This method writes a string representation of the given `float` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Float.toString(f)`.

public void println(int i)

Parameters

`i`

The `int` value to print.

Description

This method writes a string representation of the given `int` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Integer.toString(i)`.

public void println(long l)

Parameters

`l`

The `long` value to print.

Description

This method writes a string representation of the given `long` value, followed by a line separator, to the underlying output stream. The string representation is identical to the one returned by calling `Long.toString(l)`.

public void println(Object obj)

Parameters

`obj`

The `Object` to print.

Description

This method writes the string representation of the given `Object`, followed by a line separator, to the underlying output stream. The string representation is that returned by calling the `toString()` method of `Object`.

public void println(String s)

Parameters

`s`

The `String` to print.

Description

This method writes the given `String`, followed by a line separator, to the underlying output stream. If `String` is `null`, the method writes `"null"` followed by a line separator.

write

public void write(int c)

Parameters

`c`

The value to write to the stream.

Overrides

`Writer.write(int)`

Description

This method writes the character specified by the lowest two bytes of the given integer `c` to the underlying stream. The method does this by calling the `write()` method of the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the character is written.

public void write(char[] buf)

Parameters

`buf`

An array of characters to write to the stream.

Overrides

`Writer.write(char[])`

Description

This method writes the given array of characters to the underlying output stream. The method does this by calling `write(buf, 0, buf.length)` for the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the characters are written.

public void write(char[] buf, int off, int len)

Parameters

`buf`

An array of characters to write to the stream.

`off`

An offset into the array.

`len`

The number of characters to write.

Overrides

`Writer.write(char[], int, int)`

Description

This method writes `len` characters from the given array, starting `off` elements from the beginning of the array, to the underlying output stream. The method does this by calling `write(buf, off, len)` for the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the characters are written.

public void write(String s)

Parameters

`s`

A `String` to write to the stream.

Overrides

`Writer.write(String)`

Description

This method writes the given `String` to the underlying output stream. The method does this by calling `write(s, 0, s.length)` for the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the `String` is written.

public void write(String s, int off, int len)

Parameters

`s`

A `String` to write to the stream.

`off`

An offset into the string.

`len`

The number of characters to write.

Overrides

`Writer.write(String, int, int)`

Description

This method writes `len` characters from the given `String`, starting `off` elements from the beginning of the string, to the underlying output stream. The method does this by calling `write(s, off, len)` for the underlying output stream and catching any exceptions that are thrown. If necessary, the method blocks until the characters of the `String` are written.

Protected Instance Methods

setError

protected void setError()

Description

This method sets the error state of the `PrintWriter` object to `true`. Any subsequent calls to `getError()` will return `true`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

PushbackInputStream

Name

PushbackInputStream

Synopsis

Class Name:

`java.io.PushbackInputStream`

Superclass:

`java.io.FilterInputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `PushbackInputStream` class represents a byte stream that allows data to be pushed back into the stream. In other words, after data has been read from a PushbackInputStream, it can be pushed back into the stream so that it can be reread. This functionality is useful for implementing things like parsers that need to read data and then return it to the input stream.

The PushbackInputStream has been enhanced as of JDK 1.1 to support a pushback buffer that is larger than one byte. Prior to JDK 1.1, the class supported only a one-byte buffer using the protected variable pushBack. As of 1.1, that variable has been replaced by the buf and pos variables.

Class Summary

```
public class java.io.PushbackInputStream extends java.io.FilterInputStream {
  // Variables
  protected byte[] buf;                            // New in 1.1
  protected int pos;                               // New in 1.1
  // Constructors
  public PushbackInputStream(InputStream in);
  public PushbackInputStream(InputStream in,
                             int size);            // New in 1.1
  // Instance Methods
  public int available();
  public boolean markSupported();
  public int read();
  public int read(byte[] b, int off, int len);
  public void unread(int b);
  public void unread(byte[] b);                    // New in 1.1
  public void unread(byte[] b, int off, int len); // New in 1.1
}
```

Variables

buf

protected byte[] buf

Availability

New as of JDK 1.1

Description

The buffer that holds data that has been pushed back.

pos

protected int pos

Availability

New as of JDK 1.1

Description

The position of pushed-back data in the buffer. When there is no pushed-back data, `pos` is `buf.length`. As data is pushed back, `pos` decreases. As pushed-back data is read, `pos` increases. When the pushback buffer is full, `pos` is 0.

Constructors

PushbackInputStream

public PushbackInputStream(InputStream in)

Parameters

`in`

The input stream to wrap.

Description

This constructor creates a `PushbackInputStream` that reads from the given `InputStream`, using a pushback buffer with the default size of one byte.

public PushBackInputStream(InputStream in, int size)

Availability

New as of JDK 1.1

Parameters

`in`

The input stream to wrap.

`size`

The size of the pushback buffer.

Description

This constructor creates a `PushbackInputStream` that reads from the given `InputStream`, using a pushback buffer of the given size.

Instance Methods

available

public int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.available()`

Description

This method returns the number of bytes that can be read without having to wait for more data to become available. This is `b` + `u`, where `b` is the number of bytes in the pushback buffer and `u` is the number of available bytes in the underlying stream.

markSupported

public boolean markSupported()

Returns

The `boolean` value `false`.

Overrides

`FilterInputStream.markSupported()`

Description

This method returns `false` to indicate that this class does not support `mark()` and `reset()`.

read

public int read() throws IOException

Returns

The next byte of data, or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read()`

Description

This method reads a byte of data. If there is any data in the pushback buffer, the method returns the next byte in the pushback buffer. Otherwise, it calls the `read()` method of the underlying stream. The method blocks until the byte is read, the end of the stream is encountered, or an exception is thrown.

public int read(byte b[], int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read, or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read(byte[], int, int)`

Description

This method copies bytes from the stream into the given array `b`, starting at index `off` and continuing for `len` bytes. If the array can be populated solely from the pushback buffer, the method returns immediately. Otherwise, the `read(byte[], int, int)` method of the underlying stream is called to make up the difference. The method blocks until some data is available.

unread

public void unread(int b) throws IOException

Parameters

`b`

The value to push back.

Throws

`IOException`

If the pushback buffer is full.

Description

This method puts the given byte into the pushback buffer.

public void unread(byte[] b) throws IOException

Availability

New as of JDK 1.1

Parameters

`b`

An array of bytes to push back.

Throws

`IOException`

If the pushback buffer is full.

Description

This method puts all of the bytes in the given array into the pushback buffer.

public void unread(byte[] b, int off, int len) throws IOException

Availability

New as of JDK 1.1

Parameters

`b`

An array of bytes to push back.

`off`

An offset into the array.

`len`

The number of bytes to push back.

Throws

`IOException`

If the pushback buffer is full.

Description

This method puts `len` bytes from the given array, starting at offset `off`, into the pushback buffer.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`FilterInputStream`
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`mark(int)`	`FilterInputStream`	`notify()`	`Object`
`notifyAll()`	`Object`	`read(byte[])`	`FilterInputStream`
`reset()`	`FilterInputStream`	`skip(long)`	`FilterInputStream`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

PrintWriter BOOK INDEX PushbackReader

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

PushbackReader

Name

PushbackReader

Synopsis

Class Name:

```
java.io.PushbackReader
```

Superclass:

```
java.io.FilterReader
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `PushbackReader` class represents a character stream that allows data to be pushed back into the stream. In other words, after data has been read from a `PushbackReader`, it can be pushed back into the stream so that it can be reread. This functionality is useful for implementing things like parsers that need to read data and then return it to the input stream. `PushbackReader` is the character-oriented equivalent of `PushbackInputStream`.

Class Summary

```
public class java.io.PushbackReader extends java.io.FilterReader {
  // Constructors
  public PushbackReader(Reader in);
  public PushbackReader(Reader in, int size);
  // Instance Methods
  public void close();
  public boolean markSupported();
  public int read();
  public int read(char[] cbuf, int off, int len);
  public boolean ready();
  public void unread(int c);
  public void unread(char[] cbuf);
  public void unread(char[] cbuf, int off, int len);
}
```

Constructors

PushbackReader

public PushbackReader(Reader in)

Parameters

`in`

The reader to wrap.

Description

This constructor creates a `PushbackReader` that reads from the given `Reader`, using a pushback buffer with the default size of one byte.

public PushbackReader(Reader in, int size)

Parameters

`in`

The reader to wrap.

`size`

The size of the pushback buffer.

Description

This constructor creates a `PushbackReader` that reads from the given `Reader`, using a pushback buffer of the given size.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterReader.close()`

Description

This method closes the reader and releases the system resources that are associated with it.

markSupported

public boolean markSupported()

Returns

The `boolean` value `false`.

Overrides

`FilterReader.markSupported()`

Description

This method returns `false` to indicate that this class does not support `mark()` and `reset()`.

read

public int read() throws IOException

Returns

The next character of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterReader.read()`

Description

This method reads a character of data. If there is any data in the pushback buffer, the method returns the next character in the pushback buffer. Otherwise, it calls the `read()` method of the underlying stream. The method blocks until the character is read, the end of the stream is encountered, or an exception is thrown.

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

An offset into the array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterReader.read(char[], int, int)`

Description

This method copies characters from the stream into the given array `cbuf`, starting at index `off` and continuing for `len` characters. If the array can be populated solely from the pushback buffer, the method returns immediately. Otherwise, the `read(char[], int, int)` method of the underlying stream is called to make up the difference. The method blocks until some data is available.

ready

public boolean ready() throws IOException

Returns

A `boolean` value that indicates whether the stream is ready to be read.

Throws

`IOException`

If the stream is closed.

Overrides

`FilterReader.ready()`

Description

If there is data in the pushback buffer, or if the underlying stream is ready, this method returns `true`. The underlying stream is ready if the next `read()` is guaranteed not to block.

unread

public void unread(int c) throws IOException

Parameters

`c`

The value to push back.

Throws

`IOException`

If the pushback buffer is full.

Description

This method puts the given character into the pushback buffer.

public void unread(char[] cbuf) throws IOException

Parameters

`cbuf`

An array of characters to push back.

Throws

`IOException`

If the pushback buffer is full.

Description

This method puts all of the characters in the given array into the pushback buffer.

public void unread(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to push back.

`off`

An offset into the array.

`len`

The number of characters to push back.

Throws

`IOException`

If the pushback buffer is full.

Description

This method puts `len` characters from the given array, starting at offset `off`, into the pushback buffer.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`mark(int)`	`FilterReader`
`notify()`	`Object`	`notifyAll()`	`Object`
`read(char[])`	`FilterReader`	`reset()`	`FilterReader`
`skip(long)`	`FilterReader`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

PushbackInputStream BOOK INDEX RandomAccessFile

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

RandomAccessFile

Name

RandomAccessFile

Synopsis

Class Name:

`java.io.RandomAccessFile`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.DataInput`, `java.io.DataOutput`

Availability:

JDK 1.0 or later

Description

The RandomAccessFile class reads data from and writes data to a file. The file is specified using a File object or a String that represents a pathname. Both constructors take a mode parameter that specifies whether the file is being opened solely for reading, or for reading and writing. Each of the constructors can throw a SecurityException if the application does not have permission to access the specified file using the given mode.

Unlike FileInputStream and FileOutputStream, RandomAccessFile supports random access to the data in the file; the seek() method allows you to alter the current position of the file pointer to any location in the file. RandomAccessFile implements both the DataInput and DataOutput interfaces, so it supports reading and writing of all the primitive data types.

Class Summary

```
public class java.io.RandomAccessFile extends java.lang.Object
             implements java.io.DataInput, java.io.DataOutput {
  // Constructors
  public RandomAccessFile(File file, String mode);
  public RandomAccessFile(String name, String mode);
  // Instance Methods
  public native void close();
  public final FileDescriptor getFD();
  public native long getFilePointer();
  public native long length();
  public native int read();
  public int read(byte[] b);
  public int read(byte[] b, int off, int len);
  public final boolean readBoolean();
  public final byte readByte();
  public final char readChar();
  public final double readDouble();
  public final float readFloat();
  public final void readFully(byte[] b);
  public final void readFully(byte[] b, int off, int len);
  public final int readInt();
  public final String readLine();
  public final long readLong();
  public final short readShort();
  public final String readUTF();
  public final int readUnsignedByte();
  public final int readUnsignedShort();
  public native void seek(long pos);
  public int skipBytes(int n);
  public native void write(int b);
  public void write(byte[] b);
  public void write(byte[] b, int off, int len);
  public final void writeBoolean(boolean v);
  public final void writeByte(int v);
  public final void writeBytes(String s);
  public final void writeChar(int v);
  public final void writeChars(String s);
  public final void writeDouble(double v);
  public final void writeFloat(float v);
  public final void writeInt(int v);
  public final void writeLong(long v);
  public final void writeShort(int v);
  public final void writeUTF(String str);
}
```

Constructors

RandomAccessFile

public RandomAccessFile(File file, String mode) throws IOException

Parameters

`file`

The file to be accessed.

`mode`

The mode of access to the file: either `"r"` for read access or `"rw"` for read/write access.

Throws

`IOException`

If any kind of I/O error occurs.

`IllegalArgumentException`

If `mode` is not `"r"` or `"rw"`.

`SecurityException`

If the application does not have permission to read the named file, or if `mode` is `"rw"` and the application does not have permission to write to the named file.

Description

This constructor creates a `RandomAccessFile` to access the specified `File` in the specified mode.

public RandomAccessFile(String name, String mode) throws IOException

Parameters

`name`

A `String` that contains the pathname of the file to be accessed. The path must conform to the requirements of the native operating system.

`mode`

The mode of access to the file: either `"r"` for read access or `"rw"` for read/write access.

Throws

`IOException`

If any kind of I/O error occurs.

`IllegalArgumentException`

If `mode` is not `"r"` or `"rw"`.

`SecurityException`

If the application does not have permission to read the named file, or if `mode` is `"rw"` and the application does not have permission to write to the named file.

Description

This constructor creates a `RandomAccessFile` to access the file with the specified `name` in the specified mode.

Instance Methods

close

public native void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the file and releases the system resources that are associated with it.

getFD

public final FileDescriptor getFD() throws IOException

Returns

The file descriptor for the file that supplies data for this object.

Throws

`IOException`

If there is no `FileDescriptor` associated with this object.

Description

This method returns the file descriptor associated with this `RandomAccessFile`.

getFilePointer

public native long getFilePointer() throws IOException

Returns

> The current position in the file.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

> This method returns the current position in the file. The position is the offset, in bytes, from the beginning of the file where the next read or write operation occurs.

length

public native long length() throws IOException

Returns

> The length of the file.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

> This method returns the length of the file in bytes.

read

public native int read() throws IOException

Returns

The next byte or `-1` if the end of file is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads the next byte from the file. The method blocks until the byte is read, the end of the file is encountered, or an exception is thrown.

public int read(byte b[]) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

Returns

The number of bytes read or `-1` if the end of file is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads bytes from the file into the given array. The method reads up to `b.length` bytes of data from the stream. The method blocks until there is some data available.

public int read(byte b[], int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled.

`off`

An offset into the array.

`len`

The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of file is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads up to `len` bytes from the file into the given array, starting at index `off`. The method blocks until there is some input available.

readBoolean

public final boolean readBoolean() throws IOException

Returns

The `boolean` value read from the file.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readBoolean()`

Description

This method reads a byte as a `boolean` value from the file. A byte that contains a zero is read as `false`. A byte that contains any other value is read as `true`. The method blocks until the byte is read, the end of the file is encountered, or an exception is thrown.

readByte

public final byte readByte() throws IOException

Returns

The `byte` value read from the file.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readByte()`

Description

This method reads a signed 8-bit value, a `byte`, from the file. The method blocks until the byte is read, the end of the file is encountered, or an exception is thrown.

readChar

public final char readChar() throws IOException

Returns

The `char` value read from the file.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readChar()`

Description

This method reads a 16-bit Unicode character from the file. The method reads two bytes from the file and then creates a `char` value using the first byte read as the most significant byte. The method blocks until the two bytes are read, the end of the file is encountered, or an exception is thrown.

readDouble

public final double readDouble() throws IOException

Returns

The `double` value read from the file.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readDouble()`

Description

This method reads a 64-bit `double` quantity from the file. The method reads a `long` value from the file as if using the `readLong()` method. The `long` value is then converted to a `double` using the `longBitsToDouble()` method in `Double`. The method blocks until the necessary eight bytes are read, the end of the file is encountered, or an exception is thrown.

readFloat

public final float readFloat() throws IOException

Returns

The `float` value read from the file.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readFloat()`

Description

This method reads a 32-bit `float` quantity from the file. The method reads an `int` value from the file as if using the `readInt()` method. The `int` value is then converted to a `float` using the `intBitsToFloat()` method in `Float`. The method blocks until the necessary four bytes are read, the end of the file is encountered, or an exception is thrown.

readFully

public final void readFully(byte b[]) throws IOException

Parameters

`b`

The array to fill.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readFully(byte[])`

Description

This method reads bytes into the given array `b` until the array is full. The method reads repeatedly from the file to fill the array. The method blocks until all of the bytes are read, the end of the file is encountered, or an exception is thrown.

public final void readFully(byte b[], int off, int len) throws IOException

Parameters

`b`

The array to fill.

`off`

An offset into the array.

`len`

The number of bytes to read.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readFully(byte[], int, int)`

Description

This method reads `len` bytes into the given array, starting at offset `off`. The method reads repeatedly from the file to fill the array. The method blocks until all of the bytes are read, the end of the file is encountered, or an exception is thrown.

readInt

public final int readInt() throws IOException

Returns

The `int` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readInt()`

Description

This method reads a signed 32-bit `int` quantity from the file. The method reads four bytes from the file and then creates an `int` quantity, using the first byte read as the most significant byte. The method blocks until the four bytes are read, the end of the file is encountered, or an exception is thrown.

readLine

public final String readLine() throws IOException

Returns

A `String` that contains the line read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other I/O error occurs.

Implements

`DataInput.readLine()`

Description

This method reads the next line of text from the file. The method reads bytes of data from the file until it encounters a line terminator. A line terminator is a carriage return (`'\r'`), a newline character (`'\n'`), a carriage return immediately followed by a newline character, or the end of the file. The method blocks until a line terminator is read, the end of the file is encountered, or an exception is thrown.

The method does not convert bytes to characters correctly.

readLong

public final long readLong() throws IOException

Returns

The `long` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readLong()`

Description

This method reads a signed 64-bit `long` quantity from the file. The method reads eight bytes from the file and then creates a `long` quantity, using the first byte read as the most significant byte. The method blocks until the eight bytes are read, the end of the file is encountered, or an exception is thrown.

readShort

public final short readShort() throws IOException

Returns

The `short` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readShort()`

Description

This method reads a signed 16-bit `short` quantity from the file. The method reads two bytes from the file and then creates a `short` quantity, using the first byte read as the most significant byte. The method blocks until the two bytes are read, the end of the file is encountered, or an exception is thrown.

readUnsignedByte

public final int readUnsignedByte() throws IOException

Returns

The unsigned `byte` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Returns

Implements

`DataInput.readUnsignedByte()`

Description

This method reads an unsigned 8-bit quantity from the file. The method reads a byte from the file and returns that byte. The method blocks until the byte is read, the end of the file is encountered, or an exception is thrown.

readUnsignedShort

public final int readUnsignedShort() throws IOException

Returns

The unsigned `short` value read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

Implements

`DataInput.readUnsignedShort()`

Description

This method reads an unsigned 16-bit quantity from the file. The method reads two bytes from the file and creates an unsigned `short` quantity using the first byte read as the most significant byte. The method blocks until the two bytes are read, the end of the file is encountered, or an exception is thrown.

readUTF

public final String readUTF() throws IOException

Returns

The `String` read from the stream.

Throws

`EOFException`

If the end of the file is encountered.

`IOException`

If any other kind of I/O error occurs.

`UTFDataFormatException`

If the bytes do not represent a valid UTF-8 encoding.

Implements

`DataInput.readUTF()`

Description

This method reads a UTF-8 encoded string from the file. The method reads the first two bytes from the file as unsigned `short` values, to get the number of bytes in the encoded string. Then the following bytes are read and interpreted UTF-8 encoded bytes; these bytes are converted into characters for the resulting `String`. This method blocks until all of the bytes in the encoded string have been read, the end of the file is encountered, or an exception is thrown. See Appendix B, *The UTF-8 Encoding* for information about the UTF-8 encoding.

seek

public native void seek(long pos) throws IOException

Parameters

`pos`

The new position in the file.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method sets the current file position to the specified position. The position is the offset, in bytes, from the beginning of the file where the next read or write operation occurs.

skipBytes

public int skipBytes(int n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of skipped bytes.

Throws

`EOFException`

If EOF is encountered.

`IOException`

If any I/O error occurs.

Implements

`DataInput.skipBytes()`

Description

This method skips over `n` bytes.

write

public native void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.write(int)`

Description

This method writes the low-order eight bits of `b` to the file as a `byte`.

public void write(byte b[]) throws IOException

Parameters

`b`

An array of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.write(byte[])`

Description

This method writes the bytes in the given array to the file.

public void write(byte b[], int off, int len) throws IOException

Parameters

`b`

An array of bytes to write.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.write(byte[], int, int)`

Description

This method writes `len` bytes from the given array, starting `off` elements from the beginning of the array, to the file.

writeBoolean

public final void writeBoolean(boolean v) throws IOException

Parameters

`v`

The `boolean` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeBoolean()`

Description

If `v` is `true`, this method writes a byte that contains the value `1` to the file. If `v` is `false`, the method writes a byte that contains the value 0.

writeByte

public final void writeByte(int v) throws IOException

Parameters

`v`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeByte()`

Description

This method writes an 8-bit `byte` to the file, using the low-order eight bits of the given integer `v`.

writeBytes

public final void writeBytes(String s) throws IOException

Parameters

`s`

The `String` to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeBytes()`

Description

This method writes the characters in the given `String` to the file as a sequence of 8-bit bytes. The high-order bytes of the characters in the string are ignored.

writeChar

public final void writeChar(int v) throws IOException

Parameters

`v`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeChar()`

Description

This method writes a 16-bit `char` to the file, using the low-order 16 bits of the given integer `v`.

writeChars

public final void writeChars(String s) throws IOException

Parameters

`s`

The `String` to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeChars()`

Description

This method writes the characters in the given `String` object to the file as a sequence of 16-bit characters.

writeDouble

public final void writeDouble(double v) throws IOException

Parameters

`v`

The `double` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeDouble()`

Description

This method writes a 64-bit `double` to the file. The `double` value is converted to a `long` using `doubleToLongBits()` of `Double`; the `long` value is then written to the file as eight bytes with the high-order byte first.

writeFloat

public final void writeFloat(float v) throws IOException

Parameters

`v`

The `float` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeFloat()`

Description

This method writes a 32-bit `float` to the file. The `float` value is converted to a `int` using `floatToIntBits()` of `Float`; the `int` value is then written to the file as four bytes with the high-order byte first.

writeInt

public final void writeInt(int v) throws IOException

Parameters

`v`

The `int` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeInt()`

Description

This method writes a 32-bit `int` to the file. The value is written as four bytes with the high-order byte first.

writeLong

public final void writeLong(long v) throws IOException

Parameters

`v`

The `long` value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeLong()`

Description

This method writes a 64-bit `long` to the file. The value is written as eight bytes with the high-order byte first.

writeShort

public final void writeShort(int v) throws IOException

Parameters

`v`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

`DataOutput.writeShort()`

Description

This method writes a 16-bit `short` to the file, using the low-order 16 bits of the given integer `v`.

writeUTF

public final void writeUTF(String str) throws IOException

Parameters

`str`

The `String` to write.

Throws

`IOException`

If any kind of I/O error occurs.

Implements

DataOutput.writeUTF()

Description

This method writes the given String to the file using the UTF-8 encoding. See Appendix B, *The UTF-8 Encoding* for information about the UTF-8 encoding.

Inherited Methods

Reader

Name

Reader

Synopsis

Class Name:

`java.io.Reader`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.io.BufferedReader`, `java.io.CharArrayReader`,

`java.io.FilterReader`, `java.io.InputStreamReader`,

`java.io.PipedReader`, `java.io.StringReader`

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The Reader class is an abstract class that is the superclass of all classes that represent input character streams. Reader defines the basic input methods that all character streams provide. A similar hierarchy of classes, based around InputStream, deals with byte streams instead of character streams.

Reader is designed so that read() and read(char[]) both call read(char[], int, int). Thus, a subclass can simply override read(char[], int, int), and all of the read methods will work. Note that this is different from the design of InputStream, where the read() method is the catch-all method. The design of Reader is cleaner and more efficient.

Reader also defines a mechanism for marking a position in the stream and returning to it later, via the mark() and reset() methods. Another method, markSupported(), tells whether or not this mark-and-reset functionality is available in a particular subclass.

Class Summary

```
public abstract class java.io.Reader extends java.lang.Object {
  // Variables
  protected Object lock;
  // Constructors
  protected Reader();
  protected Reader(Object lock);
  // Instance Methods
  public abstract void close();
  public void mark(int readAheadLimit);
  public boolean markSupported();
  public int read();
  public int read(char[] cbuf);
  public abstract int read(char[] cbuf, int off, int len);
  public boolean ready();
  public void reset();
  public long skip(long n) throws IOException;
}
```

Variables

lock

protected Object lock

Description

The object used to synchronize operations on this `Reader` object. For efficiency's sake, a particular implementation of a character stream can choose to synchronize its operations on something other than instances of itself. Thus, any subclass should synchronize on the `lock` object, instead of using a `synchronized` method or the `this` object.

Constructors

Reader

protected Reader()

Description

This constructor creates a `Reader` that synchronizes on the `Reader` itself, or in other words, on the `this` object.

protected Reader(Object lock)

Parameters

`lock`

The object to use for synchronization.

Description

This constructor creates a `Reader` that synchronizes on the given object.

Instance Methods

close

public abstract void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the reader and releases any system resources associated with it.

A subclass of `Reader` must implement this method.

mark

public void mark(int readheadLimit) throws IOException

Parameters

`readAheadLimit`

The maximum number of characters that can be read before the saved position becomes invalid.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method tells this `Reader` object to remember its current position, so that the position can be restored by a call to the `reset()` method. The `Reader` can read `readAheadLimit` characters beyond the marked position before the mark becomes invalid.

The implementation of the `mark()` method in `Reader` simply throws an exception to indicate that the mark-and-reset functionality is not implemented. A subclass must override the method to provide the functionality.

markSupported

public boolean markSupported()

Returns

`true` if this reader supports `mark()` and `reset()`; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not this object supports mark-and-reset functionality.

The `markSupported()` method in `Reader` always returns `false`. A subclass that implements the mark-and-reset functionality should override the method to return `true`.

read

public int read() throws IOException

Returns

The next character of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads the next character of input. The character is returned as an integer in the range `0x0000` to `0xFFFF`. The method blocks until the character is read, the end of stream is encountered, or an exception is thrown.

The implementation of this method in `Reader` reads the character by calling `read(cb, 0, 1)`, where `cb` is a character array, and returning `cb[0]`. Although it is not strictly necessary, a subclass that wants to provide efficient single-character reads should override this method.

public int read(char[] cbuf) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads characters of input to fill the given array by calling `read(cbuf, 0, cbuf.length)`. The method blocks until some data is available.

A subclass does not usually need to override this method, as it can override `read(char[], int, int)` and have `read(char[])` work automatically.

`public abstract int read(char[] cbuf, int off, int len) throws IOException`

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

An offset into the array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads up to `len` characters of input into the given array starting at index `off`. The method blocks until some data is available.

A subclass of `Reader` must implement this method.

ready

public boolean ready() throws IOException

Returns

> A `boolean` value that indicates whether the reader is ready to be read.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

> This method returns `true` if the next `read()` is guaranteed to not block.
>
> The implementation of the `ready()` method in `Reader` always returns `false`. A subclass should override this method as appropriate.

reset

public void reset() throws IOException

Throws

> `IOException`
>
> > If there was no previous call to the `mark()` method or the saved position has been invalidated.

Description

> This method restores the position of the stream to the position that was saved by a previous call to `mark()`.
>
> The implementation of the `reset()` method in `Reader` throws an exception to indicate that mark-and-reset functionality is not supported by default. A subclass must override the method to provide the functionality.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of characters to skip.

Returns

The actual number of characters skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method skips `n` characters of input. In other words, it moves the position of the stream forward by `n` characters.

The implementation of the `skip()` method in `Reader` simply calls `read(cb, 0, n)` where `cb` is a character array that is at least `n` bytes long. A subclass may want to override this method to implement a more efficient skipping algorithm.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

SequenceInputStream

Name

SequenceInputStream

Synopsis

Class Name:

```
java.io.SequenceInputStream
```

Superclass:

```
java.io.InputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The SequenceInputStream class allows a series of InputStream objects to be seamlessly concatenated into one stream. In other words, a SequenceInputStream appears and functions as a single InputStream. Internally, however, the SequenceInputStream reads data from each InputStream in the specified order. When the end of a stream is encountered, data is automatically read from the next stream.

Class Summary

```
public class java.io.SequenceInputStream extends java.io.InputStream {
  // Constructors
  public SequenceInputStream(Enumeration e);
  public SequenceInputStream(InputStream s1, InputStream s2);
  // Instance Methods
  public int available();                         // New in 1.1
  public void close();
  public int read();
  public int read(byte[] buf, int pos, int len);
}
```

Constructors

SequenceInputStream

public SequenceInputStream(Enumeration e)

Parameters

e

An Enumeration of input streams.

Description

This constructor creates a SequenceInputStream that reads from each of the InputStream objects in the given Enumeration. Each object in the Enumeration must be an InputStream.

public SequenceInputStream(InputStream s1, InputStream s2)

Parameters

`s1`

An input stream.

`s2`

Another input stream.

Description

This constructor creates a `SequenceInputStream` that reads first from `s1` and then from `s2`.

Instance Methods

available

public int available() throws IOException

Availability

New as of JDK 1.1

Returns

The number of bytes that can be read without blocking, or 0 if the end of the final stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.available()`

Description

This method returns the number of bytes that can be read without having to wait for more data to become available. The method returns the result of calling `available()` on the current stream. If the end of the final stream is encountered, the method returns 0.

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.close()`

Description

This method closes the stream and releases the system resources that are associated with it. The method closes all the `InputStream` objects attached to this object.

read

public int read() throws IOException

Returns

The next byte of data or `-1` if the end of the final stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read()`

Description

This method reads the next byte of data from the current stream. When the end of the current stream is encountered, that stream is closed, and the first byte of the next `InputStream` is read. If there are no more `InputStream` objects in the `SequenceInputStream`, `-1` is returned to signify the end of the `SequenceInputStream`. The method blocks until the byte is read, the end of the final stream is encountered, or an exception is thrown.

public int read(byte[] buf, int off, int len) throws IOException

Parameters

`buf`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the final stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`InputStream.read(byte[], int, int)`

Description

This method reads up to `len` bytes of input from the current stream into the given array starting at index `off`. When the end of the current stream is encountered, that stream is closed, and bytes are read from the next `InputStream`. If there are no more `InputStream` objects in the `SequenceInputStream`, `-1` is returned to signify the end of the `SequenceInputStream`. The method blocks until there is some data available.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`mark(int)`	`InputStream`
`markSupported()`	`InputStream`	`notify()`	`Object`
`notifyAll()`	`Object`	`reset()`	`InputStream`
`skip(long)`	`InputStream`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

StreamTokenizer

Name

StreamTokenizer

Synopsis

Class Name:

`java.io.StreamTokenizer`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `StreamTokenizer` class performs a lexical analysis on an `InputStream` object and breaks the stream into tokens. Although `StreamTokenizer` is not a general-purpose parser, it recognizes tokens that are similar to those used in the Java language. A `StreamTokenizer` recognizes identifiers, numbers, quoted strings, and various comment styles.

A `StreamTokenizer` object can be wrapped around an `InputStream`. In this case, when the `StreamTokenizer` reads bytes from the stream, the bytes are converted to Unicode characters by simply zero-extending the byte values to 16 bits. As of Java 1.1, a `StreamTokenizer` can be wrapped around a `Reader` to eliminate this problem.

The `nextToken()` method returns the next token from the stream. The rest of the methods in `StreamTokenizer` control how the object interprets the characters that it reads and tokenizes them.

The parsing functionality of `StreamTokenizer` is controlled by a table and a number of flags. Each character that is read from the `InputStream` is in the range `'\u0000'` to `'\uFFFF'`. The character value looks up attributes of the character in the table. A character can have zero or more of the following attributes: whitespace, alphabetic, numeric, string quote, and comment character.

By default, a `StreamTokenizer` recognizes the following:

- Whitespace characters between `'\u0000'` and `'\u0020'`
- Alphabetic characters from `'a'` through `'z'`, `'A'` through `'Z'`, and `'\u00A0'` and `'\u00FF'`.
- Numeric characters `'1'`, `'2'`, `'3'`, `'4'`, `'5'`, `'6'`, `'7'`, `'8'`, `'9'`, `'0'`, `'.'`, and `'-'`
- String quote characters "`'`" and "`'`"
- Comment character "`/`"

Class Summary

```
public class java.io.StreamTokenizer extends java.lang.Object {
  // Variables
  public double nval;
  public String sval;
  public int ttype;
  public final static int TT_EOF;
  public final static int TT_EOL;
  public final static int TT_NUMBER;
  public final static int TT_WORD;
  // Constructors
  public StreamTokenizer(InputStream in);           // Deprecated in 1.1
  public StreamTokenizer(Reader in);                // New in 1.1
  // Instance Methods
  public void commentChar(int ch);
  public void eolIsSignificant(boolean flag);
  public int lineno();
  public void lowerCaseMode(boolean flag);
  public int nextToken();
  public void ordinaryChar(int ch);
  public void ordinaryChars(int low, int hi);
  public void parseNumbers();
  public void pushBack();
  public void quoteChar(int ch);
  public void resetSyntax();
  public void slashSlashComments(boolean flag);
  public void slashStarComments(boolean flag);
  public String toString();
  public void whitespaceChars(int low, int hi);
  public void wordChars(int low, int hi);
}
```

Variables

nval

public double nval

Description

> This variable contains the value of a `TT_NUMBER` token.

sval

public String sval

Description

> This variable contains the value of a `TT_WORD` token.

ttype

public int ttype

Description

> This variable indicates the token type. The value is either one of the `TT_` constants defined below or the character that has just been parsed from the input stream.

TT_EOF

public final static int TT_EOF = -1

Description

> This token type indicates that the end of the stream has been reached.

TT_EOL

public final static int TT_EOL = '\n'

Description

> This token type indicates that the end of a line has been reached. The value is not returned by `nextToken()` unless `eolIsSignificant(true)` has been called.

TT_NUMBER

public final static int TT_NUMBER = -2

Description

> This token type indicates that a number has been parsed. The number is placed in `nval`.

TT_WORD

public final static int TT_WORD = -3

Description

> This token type indicates that a word has been parsed. The word is placed in `sval`.

Constructors

StreamTokenizer

public StreamTokenizer(InputStream in)

Availability

Deprecated as of JDK 1.1

Parameters

`in`

The input stream to tokenize.

Description

This constructor creates a `StreamTokenizer` that reads from the given `InputStream`. As of JDK 1.1, this method is deprecated and `StreamTokenizer(Reader)` should be used instead.

public StreamTokenizer(Reader in)

Availability

New as of JDK 1.1

Parameters

`in`

The reader to tokenize.

Description

This constructor creates a `StreamTokenizer` that reads from the given `Reader`.

Instance Methods

commentChar

public void commentChar(int ch)

Parameters

`ch`

The character to use to indicate comments.

Description

This method tells this `StreamTokenizer` to treat the given character as the beginning of a comment that ends at the end of the line. The `StreamTokenizer` ignores all of the characters from the comment character to the end of the line. By default, a `StreamTokenizer` treats the `'/'` character as a comment character. This method may be called multiple times if there are multiple characters that begin comment lines.

To specify that a character is not a comment character, use `ordinaryChar()`.

eolIsSignificant

public void eolIsSignificant(boolean flag)

Parameters

`flag`

A `boolean` value that specifies whether or not this `StreamTokenizer` returns `TT_EOL` tokens.

Description

A `StreamTokenizer` recognizes `"\n"`, `"\r"`, and `"\r\n"` as the end of a line. By default, end-of-line characters are treated as whitespace and thus, the `StreamTokenizer` does not return `TT_EOL` tokens from `nextToken()`. Call `eolIsSignificant(true)` to tell the `StreamTokenizer` to return `TT_EOL` tokens.

lineo

public int lineno()

Returns

The current line number.

Description

This method returns the current line number. Line numbers begin at 1.

lowerCaseMode

public void lowerCaseMode(boolean flag)

Parameters

`flag`

A `boolean` value that specifies whether or not this `StreamTokenizer` returns `TT_WORD` tokens in lowercase.

Description

By default, a `StreamTokenizer` does not change the case of the words that it parses. However if you call `lowerCaseMode(true)`, whenever `nextToken()` returns a `TT_WORD` token, the word in `sval` is converted to lowercase.

nextToken

public int nextToken() throws IOException

Returns

One of the token types (`TT_EOF`, `TT_EOL`, `TT_NUMBER`, or `TT_WORD`) or a character code.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method reads the next token from the stream. The value returned is the same as the value of the variable `ttype`. The `nextToken()` method parses the following tokens:

`TT_EOF`

> The end of the input stream has been reached.

`TT_EOL`

> The end of a line has been reached. The `eolIsSignificant()` method controls whether end-of-line characters are treated as whitespace or returned as `TT_EOL` tokens.

`TT_NUMBER`

> A number has been parsed. The value can be found in the variable `nval`. The `parseNumbers()` method tells the `StreamTokenizer` to recognize numbers distinct from words.

`TT_WORD`

> A word has been parsed. The word can be found in the variable `sval`.

Quoted string

> A quoted string has been parsed. The variable `ttype` is set to the quote character, and `sval` contains the string itself. You can tell the `StreamTokenizer` what characters to use as quote characters using `quoteChar()`.

Character

> A single character has been parsed. The variable `ttype` is set to the character value.

ordinaryChar

public void ordinaryChar(int ch)

Parameters

`ch`

> The character to treat normally.

Description

This method causes this `StreamTokenizer` to treat the given character as an *ordinary* character. This means that the character has no special significance as a comment, string quote, alphabetic, numeric, or whitespace character. For example, to tell the `StreamTokenizer` that the slash does not start a single-line comment, use `ordinaryChar('/')`.

ordinaryChars

public void ordinaryChars(int low, int hi)

Parameters

`low`

The beginning of a range of character values.

`hi`

The end of a range of character values.

Description

This method tells this `StreamTokenizer` to treat all of the characters in the given range as ordinary characters. See the description of `ordinaryChar()` above for more information.

parseNumbers

public void parseNumbers()

Description

This method tells this `StreamTokenizer` to recognize numbers. The `StreamTokenizer` constructor calls this method, so the default behavior of a `StreamTokenizer` is to recognize numbers. This method modifies the syntax table of the `StreamTokenizer` so that the following characters have the numeric attribute: `'1'`, `'2'`, `'3'`, `'4'`, `'5'`, `'6'`, `'7'`, `'8'`, `'9'`, `'0'`, `'.'`, and `'-'`

When the parser encounters a token that has the format of a double-precision floating-point number, the token is treated as a number rather than a word. The `ttype` variable is set to `TT_NUMBER`, and `nval` is set to the value of the number.

To use a `StreamTokenizer` that does not parse numbers, make the above characters ordinary using `ordinaryChar()` or `ordinaryChars()`:

pushBack

public void pushBack()

Description

This method has the effect of pushing the current token back onto the stream. In other words, after a call to this method, the next call to the `nextToken()` method returns the same result as the previous call to the `nextToken()`method without reading any input.

quoteChar

public void quoteChar(int ch)

Parameters

`ch`

The character to use as a delimiter for quoted strings.

Description

This method tells this `StreamTokenizer` to treat the given character as the beginning or end of a quoted string. By default, the single-quote character and the double-quote character are string-quote characters. When the parser encounters a string-quote character, the `ttype` variable is set to the quote character, and `sval` is set to the actual string. The string consists of all the characters after (but not including) the string-quote character up to (but not including) the next occurrence of the same string-quote character, a line terminator, or the end of the stream.

To specify that a character is not a string-quote character, use `ordinaryChar()`.

resetSyntax

public void resetSyntax()

Description

This method resets this `StreamTokenizer`, which causes it to treat all characters as ordinary characters. See the description of `ordinaryChar()` above for more information.

slashSlashComments

public void slashSlashComments(boolean flag)

Parameters

`flag`

A `boolean` value that specifies whether or not this `StreamTokenizer` recognizes double-slash comments (`//`).

Description

By default, a `StreamTokenizer` does not recognize double-slash comments. However, if you call `slashSlashComments(true)`, the `nextToken()` method recognizes and ignores double-slash comments.

slashStarComments

public void slashStarComments(boolean flag)

Parameters

`flag`

A `boolean` value that specifies whether or not this `StreamTokenizer` recognizes slash-star (`/* ... */`) comments.

Description

By default, a `StreamTokenizer` does not recognize slash-star comments. However, if you call `slashStarComments(true)`, the `nextToken()` method recognizes and ignores slash-star comments.

toString

public String toString()

Returns

A `String` representation of the current token.

Overrides

`Object.toString()`

Description

This method returns a string representation of the current token recognized by the `nextToken()` method. This string representation consists of the value of `ttype`, the value of `sval` if the token is a word or the value of `nval` if the token is a number, and the current line number.

whitespaceChars

public void whitespaceChars(int low, int hi)

Parameters

`low`

The beginning of a range of character values.

`hi`

The end of a range of character values.

Description

This method causes this `StreamTokenizer` to treat characters in the specified range as whitespace. The only function of whitespace characters is to separate tokens in the stream.

wordChars

public void wordChars(int low, int hi)

Parameters

`low`

The beginning of a range of character values.

`hi`

The end of a range of character values.

Description

This method causes this `StreamTokenizer` to treat characters in the specified range as characters that are part of a word token, or, in other words, consider the characters to be alphabetic. A word token consists of a sequence of characters that begins with an alphabetic character and is followed by zero or more numeric or alphabetic characters.

Inherited Methods

StringBufferInputStream

Name

StringBufferInputStream

Synopsis

Class Name:

```
java.io.StringBufferInputStream
```

Superclass:

```
java.io.InputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

Deprecated as of JDK 1.1

Description

The `StringBufferInputStream` class represents a byte stream whose data source is a `String`. This class is similar to the `ByteArrayInputStream` class, which uses a `byte` array as its data source.

`StringBufferInputStream` is deprecated as of JDK 1.1 because it does not correctly convert characters to bytes. The `StringReader` class should now be used to create a character stream from a `String`.

Class Summary

```
public class java.io.StringBufferInputStream extends java.io.InputStream {
  // Variables
  protected String buffer;
  protected int count;
  protected int pos;
  // Constructor
  public StringBufferInputStream(String s);
  // Instance Methods
  public synchronized int available();
  public synchronized int read();
  public synchronized int read(byte[] b, int off, int len);
  public synchronized void reset();
  public synchronized long skip(long n);
}
```

Variables

buffer

protected String buffer

Description

> The buffer that stores the data for the input stream.

count

protected int count

Description

> The size of the buffer, or in other words, the length of the string.

pos

protected int pos

Description

The current stream position.

Constructors

StringBufferInputStream

public StringBufferInputStream(String s)

Parameters

`s`

The `String` to use.

Description

This constructor creates a `StringBufferInputStream` that uses the given `String` as its data source. Note that the data is not copied, so changes made to the `String` affect the data that the `StringBufferInputStream` returns.

Instance Methods

available

public synchronized int available()

Returns

The number of bytes remaining in the string.

Overrides

`InputStream.available()`

Description

This method returns the number of bytes that are left in the string. This is the length of the string, `count`, minus the current stream position, `pos`.

read

public synchronized int read()

Returns

The next byte of data or `-1` if the end of the string is encountered.

Overrides

`InputStream.read()`

Description

This method returns the next byte from the string. The method takes the next character from the string and returns the low eight bits of that character as a byte, which is not the correct way to convert characters into bytes. The method cannot block.

public synchronized int read(byte b[], int off, int len)

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the string is encountered immediately.

Overrides

`InputStream.read(byte[], int, int)`

Description

This method copies bytes from the internal buffer into the given array `b`, starting at index `off` and continuing for `len` bytes. The method takes each character from the string and returns the low eight bits of that character as a byte, which is not the correct way to convert characters into bytes.

reset

public synchronized void reset()

Overrides

`InputStream.reset()`

Description

This method sets the position of the `StringBufferInputStream` back to the beginning of the internal buffer.

skip

public synchronized long skip(long n)

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Overrides

`InputStream.skip()`

Description

This method skips `n` bytes of the string. If you try to skip past the end of the string, the stream is positioned at the end of the string.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`InputStream`
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`mark(int)`	`InputStream`	`markSupported()`	`InputStream`
`notify()`	`Object`	`notifyAll()`	`Object`
`read(byte[])`	`InputStream`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

StringReader

Name

StringReader

Synopsis

Class Name:

`java.io.StringReader`

Superclass:

`java.io.Reader`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `StringReader` class represents a character stream whose data source is a `String`. This class is similar to the `CharArrayReader` class, which uses a `char` array as its data source.

`StringReader` is meant to replace the `StringBufferInputStream` class as of JDK 1.1. Unlike `StringBufferInputStream`, `StringReader` handles Unicode characters and supports `mark()` and `reset()`.

Class Summary

```
public class java.io.StringReader extends java.io.Reader {
  // Constructors
  public StringReader(String s);
  // Instance Methods
  public void close();
  public void mark(int readAheadLimit);
  public boolean markSupported();
  public int read();
  public int read(char[] cbuf, int off, int len);
  public boolean ready();
  public void reset();
  public long skip(long ns);
}
```

Constructors

StringReader

public StringReader(String s)

Parameters

`s`

The `String` to use.

Description

This constructor creates a `StringReader` that uses the given `String` as its data source. The data is not copied, so changes made to the `String` affect the data that the `StringReader` returns.

Instance Methods

close

public void close()

Overrides

`Reader.close()`

Description

This method closes the reader by removing the link between this `StringReader` and the `String` it was created with.

mark

public void mark(int readAheadLimit) throws IOException

Parameters

`readAheadLimit`

The maximum number of characters that can be read before the saved position becomes invalid.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.mark()`

Description

This method causes the `StringReader` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position, and thus re-read a portion of the string. Because the data for this stream comes from a `String`, there is no limit on reading ahead, so `readAheadLimit` is ignored.

markSupported

public boolean markSupported()

Returns

The `boolean` value `true`.

Overrides

`Reader.markSupported()`

Description

This method returns `true` to indicate that this class supports `mark()` and `reset()`.

read

public int read() throws IOException

Returns

The next character or `-1` if the end of the string is encountered.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.read()`

Description

This method returns the next character from the string. The method cannot block.

public int read(char[] cbuf, int off, int len) throws IOException

Parameters

`cbuf`

An array of characters to be filled from the stream.

`off`

An offset into the character array.

`len`

The number of characters to read.

Returns

The actual number of characters read or `-1` if the end of the string is encountered immediately.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.read(char[], int, int)`

Description

This method copies up to `len` characters from the internal buffer into the given array `cbuf`, starting at index `off`.

ready

public boolean ready() throws IOException

Returns

A `boolean` value that indicates whether the stream is ready to be read.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.ready()`

Description

If there is any data left to be read from the string, this method returns `true`.

reset

public void reset() throws IOException

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.reset()`

Description

This method resets the position of the `StringReader` to the position that was saved by calling the `mark()` method. If `mark()` has not been called, the `StringReader` is reset to read from the beginning of the string.

skip

public long skip(long ns) throws IOException

Parameters

`ns`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If the stream is closed or any other kind of I/O error occurs.

Overrides

`Reader.skip()`

Description

This method skips `ns` characters of input. If you try to skip past the end of the string, the stream is positioned at the end of the string.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals (Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`read(char[])`	`Reader`
`toString()`	`Object`	`wait()`	`Object`

`wait(long)`	`Object`	`wait(long, int)`	`Object`

StringBufferInputStream BOOK INDEX StringWriter

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

StringWriter

Name

StringWriter

Synopsis

Class Name:

`java.io.StringWriter`

Superclass:

`java.io.Writer`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `StringWriter` class represents a stream whose data is written to a string. This class is similar to the `CharArrayWriter` class, which writes its data to a `char` array. The `StringWriter` class uses a `StringBuffer` to store its data; a `String` can be retrieved with the `toString()` method.

Class Summary

```
public class java.io.StringWriter extends java.io.Writer {
  // Constructors
  public StringWriter();
  protected StringWriter(int initialSize);
  // Instance Methods
  public void close();
  public void flush();
  public StringBuffer getBuffer();
  public String toString();
  public void write(int c);
  public void write(char[] cbuf, int off, int len);
  public void write(String str);
  public void write(String str, int off, int len);
}
```

Constructors

StringWriter

public StringWriter()

Description

> This constructor creates a `StringWriter` with an internal buffer that has a default size of 16 characters. The buffer grows automatically as data is written to the stream.

protected StringWriter (int initialSize)

Parameters

> `initialSize`

The initial buffer size.

Description

This constructor creates a `StringWriter` with an internal buffer that has a size of `initialSize` characters. The buffer grows automatically as data is written to the stream.

Instance Methods

close

public void close()

Overrides

`Writer.close()`

Description

This method does nothing. For most subclassesof `Writer`, this method releases any system resources that are associated with the `Writer` object. However, the `StringWriter`'s internal buffer may be needed for subsequent calls to `toString()`. For this reason, `close()` does nothing, and the internal buffer is not released until the `StringWriter` is garbage collected.

flush

public void flush()

Overrides

`Writer.flush()`

Description

This method does nothing. The `StringWriter` writes data directly into its internal buffer; thus it is never necessary to flush the stream.

getBuffer

public StringBuffer getBuffer()

Returns

A reference to the internal data buffer.

Description

This method returns a reference to the `StringBuffer` object that is used in this `StringWriter`.

toString

public String toString()

Returns

A `String` constructed from the internal data buffer.

Overrides

`Object.toString()`

Description

This method returns a reference to a `String` object created from the characters stored in this object's internal buffer.

write

public void write(int c)

Parameters

`c`

The value to write.

Overrides

`Writer.write(int)`

Description

This method writes the given value into the internal buffer. If the buffer is full, it is expanded.

public void write(char[] cbuf, int off, int len)

Parameters

`cbuf`

An array of characters to write to the stream.

`off`

An offset into the character array.

`len`

The number of characters to write.

Overrides

`Writer.write(char[], int, int)`

Description

This method copies `len` characters to this object's internal buffer from `cbuf`, starting `off` elements from the beginning of the array. If the internal buffer is full, it is expanded.

public void write(String str)

Parameters

`str`

A `String` to write to the stream.

Overrides

`Writer.write(String)`

Description

This method copies the characters of `str` into this object's internal buffer. If the internal buffer is full, it is expanded.

public void write(String str, int off, int len)

Parameters

`str`

A `String` to write to the stream.

`off`

An offset into the string.

`len`

The number of characters to write.

Overrides

`Writer.write(String, int, int)`

Description

This method copies `len` characters to this object's internal buffer from `str`, starting `off` characters from the beginning of the given string. If the internal buffer is full, it is expanded.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`

`notifyAll()`	`Object`	`wait()`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Writer

Name

Writer

Synopsis

Class Name:

`java.io.Writer`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.io.BufferedWriter`, `java.io.CharArrayWriter`,

`java.io.FilterWriter`, `java.io.OutputStreamWriter`,

`java.io.PipedWriter`, `java.io.PrintWriter`,

`java.io.StringWriter`

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `Writer` class is an `abstract` class that is the superclass of all classes that represent output character streams. `Writer` defines the basic output methods that all character streams provide. A similar hierarchy of classes, based around `OutputStream`, deals with byte streams instead of character streams.

`Writer` is designed so that `write(int b)` and `write(char[])` both call `write(char[], int, int)`. Thus, a subclass can simply override `write(char[], int, int)` and all of the `write` methods will work. Note that this is different from the design of `OutputStream`, where the `write(int b)` method is the catch-all method. The design of `Writer` is cleaner and more efficient.

Some `Writer` subclasses may implement buffering to increase efficiency. `Writer` provides a method--`flush()`--that tells the `Writer` to write any buffered output to the underlying device, which may be a disk drive or a network.

Class Summary

```
public abstract class java.io.Writer extends java.lang.Object {
  // Variables
  protected Object lock;
  // Constructors
  protected Writer();
  protected Writer(Object lock);
  // Instance Methods
  public abstract void close();
  public abstract void flush();
  public void write(int c);
  public void write(char[] cbuf);
  public abstract void write(char[] cbuf, int off, int len);
  public void write(String str);
  public void write(String str, int off, int len);
}
```

Variables

lock

protected Object lock

Description

The object used to synchronize operations on this `Writer` object. For efficiency's sake, a particular implementation of a character stream can choose to synchronize its operations on something other than instances of itself. Thus, any subclass should synchronize on the `lock` object, instead of using a `synchronized` method or the `this` object.

Constructors

Writer

protected Writer()

Description

This constructor creates a `Writer` that synchronizes on the `Writer` itself, or in other words, on the `this` object.

protected Writer(Object lock)

Parameters

`lock`

The object to use for synchronization.

Description

This constructor creates a `Writer` that synchronizes on the given object.

Instance Methods

close

public abstract void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method flushes the writer and then closes it, releasing any system resources associated with it.

A subclass of `Writer` must implement this method.

flush

public void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method forces any characters that may be buffered by this `Writer` to be written to the underlying device.

A subclass of `Writer` must implement this method.

write

public void write(int c) throws IOException

Parameters

`c`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes a character containing the lowest sixteen bits of the given integer value.

The implementation of this method in `Writer` writes the character by calling `write(cb, 1)` where `cb` is a character array that contains the given value in `cb[0]`. Although it is not strictly necessary, a subclass that wants to provide efficient single-character writes should override this method.

public void write(char[] cbuf) throws IOException

Parameters

`cbuf`

An array of characters to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes the given array of characters to the stream by calling `write(cbuf, 0, cbuf.length)`.

A subclass does not usually need to override this method, as it can override `write(char[], int, int)` and have `write(char[])` work automatically.

`public abstract void write(char[] cbuf, int off, int len) throws IOException`

Parameters

`cbuf`

An array of characters to write to the stream.

`off`

An offset into the array.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes `len` characters contained in the given array starting at index `off`.

A subclass of `Writer` must implement this method.

public void write(String str) throws IOException

Parameters

`str`

A string to write to the stream.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes the given string to the stream by calling `write(str,str.length)`.

A subclass does not usually need to override this method, as it can override `write(char[], int, int)` and have it work automatically.

public void write(String str, int off, int len) throws IOException

Parameters

`str`

A string to write to the stream.

`off`

An offset into the string.

`len`

The number of characters to write.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method writes `len` characters contained in the given string starting at index `off`. The method does this by creating an array of characters for the specified portion of the string and then calling `write(cb, 0, cb.length)` on the character array `cb`.

A subclass does not usually need to override this method, as it can override `write(char[], int, int)` and have it work automatically.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JDK 1.0 or later

Description

An `ArithmeticException` is thrown to indicate an exceptional arithmetic condition, such as integer division by zero.

Class Summary

```
public class java.lang.ArithmeticException
           extends java.lang.RuntimeException {
  // Constructors
  public ArithmeticException();
  public ArithmeticException(String s);
}
```

Constructors

ArithmeticException

public ArithmeticException()

Description

This constructor creates an `ArithmeticException` with no associated detail message.

public ArithmeticException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates `ArithmeticException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

ArrayIndexOutOfBoundsException

Name

ArrayIndexOutOfBoundsException

Synopsis

Class Name:

`java.lang.ArrayIndexOutOfBoundsException`

Superclass:

`java.lang.IndexOutOfBoundsException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `ArrayIndexOutOfBoundsException` is thrown when an out-of-range index is detected by an array object. An out-of-range index occurs when the index is less than zero or greater than or equal to the size of the array.

Class Summary

```
public class java.lang.ArrayIndexOutOfBoundsException
             extends java.lang.IndexOutOfBoundsException {
  // Constructors
  public ArrayIndexOutOfBoundsException();
  public ArrayIndexOutOfBoundsException(int index);
  public ArrayIndexOutOfBoundsException(String s);
}
```

Constructors

ArrayIndexOutOfBoundsException

public ArrayIndexOutOfBoundsException()

Description

> This constructor creates an `ArrayIndexOutOfBoundsException` with no associated detail message.

public ArrayIndexOutOfBoundsException(int index)

Parameters

> `index`
>
> > The index value that was out-of-bounds

Description

> This constructor creates an `ArrayIndexOutOfBoundsException` with an associated message that mentions the specified index.

public ArrayIndexOutOfBoundsException(String s)

Parameters

> `s`

The detail message.

Description

This constructor creates an `ArrayIndexOutOfBoundsException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From

ArrayStoreException

Synopsis

Class Name:

`java.lang.ArrayStoreException`

Superclass:

`java.lang.RuntimeException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `ArrayStoreException` is thrown when there is an attempt to store a value in an array element that is incompatible with the type of the array.

Class Summary

```
public class java.lang.ArrayStoreException
             extends java.lang.RuntimeException {
  // Constructors
  public ArrayStoreException();
  public ArrayStoreException(String s);
}
```

Constructors

ArrayStoreException

public ArrayStoreException()

Description

This constructor creates an `ArrayStoreException` with no associated detail message.

public ArrayStoreException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `ArrayStoreException` with the specified detail message.

Boolean

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Boolean

Name

Boolean

Synopsis

Class Name:

```
java.lang.Boolean
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

```
java.io.Serializable
```

Availability:

JDK 1.0 or later

Description

The `Boolean` class provides an object wrapper for a `boolean` value. This is useful when you need to treat a `boolean` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `boolean` value for one of these arguments, but you can provide a reference to a `Boolean` object that encapsulates the `boolean` value. Furthermore, as of JDK 1.1, the `Boolean` class is necessary to support the Reflection API and class literals.

Class Summary

```
public final class java.lang.Boolean {
    // Constants
    public final static Boolean FALSE;
    public final static Boolean TRUE;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Boolean(boolean value);
    public Boolean(String s);
    // Class Methods
    public static boolean getBoolean(String name);
    public static Boolean valueOf(String s);
    // Instance Methods
    public boolean booleanValue();
    public boolean equals(Object obj);
    public int hashCode();
    public String toString();
}
```

Constants

TRUE

public static final Boolean TRUE

Description

> A constant `Boolean` object that has the value `true`.

FALSE

public static final Boolean FALSE

Description

A constant `Boolean` object that has the value `false`.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `boolean`. It is always true that `Boolean.TYPE == boolean.class`.

Constructors

Boolean

`public Boolean(boolean value)`

Parameters

`value`

The `boolean` value to be made into a `Boolean` object.

Description

Constructs a `Boolean` object with the given value.

`public Boolean(String s)`

Parameters

`s`

The string to be made into a `Boolean` object.

Description

Constructs a `Boolean` object with the value specified by the given string. If the string equals `'true'` (ignoring case), the value of the object is `true`; otherwise it is `false`.

Class Methods

getBoolean

`public static boolean getBoolean(String name)`

Parameters

`name`

The name of a system property.

Returns

The `boolean` value of the system property.

Description

This methods retrieves the `boolean` value of a named system property.

valueOf

`public static Boolean valueOf(String s)`

Parameters

`s`

The string to be made into a `Boolean` object.

Returns

A `Boolean` object with the value specified by the given string.

Description

This method returns a `Boolean` object with the value `true` if the string equals `"true"` (ignoring case); otherwise the value of the object is `false`.

Instance Methods

booleanValue

```
public boolean booleanValue()
```

Returns

The `boolean` value contained by the object.

equals

```
public boolean equals(Object obj)
```

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Boolean`, and it contains the same value as the object this method is associated with.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `boolean` value of the object.

Overrides

`Object.hashCode()`

toString

`public String toString()`

Returns

`"true"` if the value of the object is `true`; `"false"` otherwise.

Overrides

`Object.toString()`

Description

This method returns a string representation of the `Boolean` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`

`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Byte

Name

Byte

Synopsis

Class Name:

`java.lang.Byte`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `Byte` class provides an object wrapper for a `byte` value. This is useful when you need to treat a `byte` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `byte` value for one of these arguments, but you can provide a reference to a `Byte` object that encapsulates the `byte` value. Furthermore, the `Byte` class is necessary as of JDK 1.1 to support the Reflection API and class literals.

The `Byte` class also provides a number of utility methods for converting `byte` values to other primitive types and for converting `byte` values to strings and vice versa.

Class Summary

```
public final class java.lang.Byte extends java.lang.Number {
  // Constants
  public static final byte MAX_VALUE;
  public static final byte MIN_VALUE;
  public static final Class TYPE;
  // Constructors
  public Byte(byte value);
  public Byte(String s);
  // Class Methods
  public static Byte decode(String nm);
  public static byte parseByte(String s);
  public static byte parseByte(String s, int radix);
  public static String toString(byte b);
  public static Byte valueOf(String s, int radix);
  public static Byte valueOf(String s);
  // Instance Methods
  public byte byteValue();
  public double doubleValue;
  public boolean equals(Object obj);
  public float floatValue
  public int hashCode();
  public int intValue();
  public long longValue();
  public short shortValue();
  public String toString();
}
```

Constants

MAX_VALUE

public static final byte MAX_VALUE= 127

The largest value that can be represented by a `byte`.

MIN_VALUE

public static final byte MIN_VALUE= -128

The smallest value that can be represented by a `byte`.

TYPE

public static final Class TYPE

The `Class` object that represents the primitive type `byte`. It is always true that `Byte.TYPE` == `byte.class`.

Constructors

Byte

public Byte(byte value)

Parameters

> `value`
>
> > The `byte` value to be encapsulated by this object.

Description

> Creates a `Byte` object with the specified byte value.

public Byte(String s) throws NumberFormatException

Parameters

> `s`
>
> > The string to be made into a `Byte` object.

Throws

> `NumberFormatException`
>
> > If the sequence of characters in the given `String` does not form a valid `byte` literal.

Description

> Constructs a `Byte` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

decode

public static Byte decode(String nm) throws NumberFormatException

Parameters

`nm`

A `String` representation of the value to be encapsulated by a `Byte` object. If the string begins with # or `0x`, it is a radix 16 representation of the value. If the string begins with `0`, it is a radix 8 representation of the value. Otherwise, it is assumed to be a radix 10 representation of the value.

Returns

A `Byte` object that encapsulates the given value.

Throws

`NumberFormatException`

If the `String` contains any non-digit characters other than a leading minus sign or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

This method returns a `Byte` object that encapsulates the given value.

parseByte

public static byte parseByte(String s) throws NumberFormatException

Parameters

`s`

The `String` to be converted to a `byte` value.

Returns

The numeric value of the byte represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte` or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

This method returns the numeric value of the `byte` represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static byte parseByte(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a `byte` value.

`radix`

The radix used in interpreting the characters in the `String` as digits. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If `radix` is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the byte represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte`, `radix` is not in the appropriate range, or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

This method returns the numeric value of the `byte` represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toString

public String toString(byte b)

Parameters

b

The byte value to be converted to a string.

Returns

The string representation of the given value.

Description

This method returns a String object that contains the decimal representation of the given value.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

valueOf

public static Byte valueOf(String s) throws NumberFormatException

Parameters

s

The string to be made into a Byte object.

Returns

The Byte object constructed from the string.

Throws

NumberFormatException

If the String does not contain a valid representation of a byte or the value represented by the String is less than Byte.MIN_VALUE or greater than Byte.MAX_VALUE.

Description

Constructs a `Byte` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Byte valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Byte` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Byte` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `byte`, radix is not in the appropriate range, or the value represented by the `String` is less than `Byte.MIN_VALUE` or greater than `Byte.MAX_VALUE`.

Description

Constructs a `Byte` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

Instance Methods

byteValue

public byte byteValue()

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`.

doubleValue

public double doubleValue()

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Byte` and it contains the same value as the object this method is associated with.

floatValue

public float floatValue()

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`.

hashCode

public int hashCode()

Returns

A hashcode based on the `byte` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object.

intValue

public int intValue()

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`.

longValue

public long longValue()

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

public short shortValue()

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`.

toString

public String toString()

Returns

The string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-` if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

JDK 1.0 or later

Description

The `Character` class provides an object wrapper for a `char` value. This is useful when you need to treat a char value as an object. For example, there are a number of utility methods that take a reference to an Object as one of their arguments. You cannot specify a char value for one of these arguments, but you can provide a reference to a Character object that encapsulates the char value. Furthermore, as of JDK 1.1, the Character class is necessary to support the Reflection API and class literals.

In Java, Character objects represent values defined by the Unicode standard. Unicode is defined by an organization called the Unicode Consortium. The defining document for Unicode is *The Unicode Standard, Version 2.0* (ISBN 0-201-48345-9). More recent information about Unicode is available at *http://unicode.org*. Appendix A, *The Unicode 2.0 Character Set*, contains a table that lists the characters defined by the Unicode 2.0 standard.

The Character class provides some utility methods, such as methods for determining the type (e.g., uppercase or lowercase, digit or letter) of a character and for converting from uppercase to lowercase. The logic for these utility methods is based on a Unicode attribute table that is part of the Unicode standard. That table is available at *ftp://unicode.org/pub/2.0-Update/UnicodeData-2.0.14.txt*.

Some of the methods in the Character class are concerned with characters that are digits; these characters are used by a number of other classes to convert strings that contain numbers into actual numeric values. The digit-related methods all use a radix value to interpret characters. The *radix* is the numeric base used to represent numbers as characters or strings. Octal is a radix 8 representation, while hexadecimal is a radix 16 representation. The methods that require a radix parameter use it to determine which characters should be treated as valid digits. In radix 2, only the characters `0' and `1' are valid digits. In radix 16, the characters `0' through `9', `a' through `z', and `A' through `Z' are considerd valid digits.

Class Summary

```
public final class java.lang.Character extends java.lang.Object
                                       implements java.io.Serializable {

Constants

COMBINING_SPACING_MARK

`public final static byte COMBINING_SPACING_MARK`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

CONNECTOR_PUNCTUATION

`public final static byte CONNECTOR_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

CONTROL

`public final static byte CONTROL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

CURRENCY_SYMBOL

`public final static byte CURRENCY_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

DASH_PUNCTUATION

`public final static byte DASH_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

DECIMAL_DIGIT_NUMBER

`public final static byte DECIMAL_DIGIT_NUMBER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

ENCLOSING_MARK

`public final static byte ENCLOSING_MARK`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

END_PUNCTUATION

`public final static byte END_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

FORMAT

`public final static byte FORMAT`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

LETTER_NUMBER

`public final static byte LETTER_NUMBER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

LINE_SEPARATOR

`public final static byte LINE_SEPARATOR`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

LOWERCASE_LETTER

`public final static byte LOWERCASE_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

MATH_SYMBOL

`public final static byte MATH_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

MAX_RADIX

`public static final int MAX_RADIX = 36`

Description

The maximum value that can be specified for a radix.

MAX_VALUE

`public final static char MAX_VALUE = '\ufff'f`

Description

The largest value that can be represented by a `char`.

MIN_RADIX

`public static final int MIN_RADIX = 2`

Description

The minimum value that can be specified for a radix.

MIN_VALUE

`public final static char MIN_VALUE = '\u0000'`

Description

The smallest value that can be represented by a `char`.

MODIFIER_LETTER

`public final static byte MODIFIER_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

MODIFIER_SYMBOL

`public final static byte MODIFIER_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

NON_SPACING_MARK

`public final static byte NON_SPACING_MARK`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_LETTER

`public final static byte OTHER_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_NUMBER

`public final static byte OTHER_NUMBER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_PUNCTUATION

`public final static byte OTHER_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

OTHER_SYMBOL

`public final static byte OTHER_SYMBOL`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

PARAGRAPH_SEPARATOR

`public final static byte PARAGRAPH_SEPARATOR`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

PRIVATE_USE

`public final static byte PRIVATE_USE`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

SPACE_SEPARATOR

`public final static byte SPACE_SEPARATOR`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

START_PUNCTUATION

`public final static byte START_PUNCTUATION`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

SURROGATE

`public final static byte SURROGATE`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

TITLECASE_LETTER

`public final static byte TITLECASE_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `char`. It is always true that `Character.TYPE == char.class`.

UNASSIGNED

`public final static byte UNASSIGNED`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

UPPERCASE_LETTER

`public final static byte UPPERCASE_LETTER`

Availability

New as of JDK 1.1

Description

This constant can be returned by the `getType()` method as the general category of a Unicode character.

Constructors

Character

`public Character(char value)`

Parameters

`value`

The `char` value to be encapsulated by this object.

Description

Creates a `Character` object with the given `char` value.

Class Methods

digit

`public static int digit(char ch, int radix)`

Parameters

`ch`

A `char` value that is a legal digit in the given radix.

`radix`

The radix used in interpreting the specified character as a digit. If `radix` is in the range 2 through 10, only characters for which the `isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the digit. This method returns `-1` if the value of `ch` is not considered a valid digit, if `radix` is less than `MIN_RADIX`, or if `radix` is greater than `MAX_RADIX`.

Description

Returns the numeric value represented by a digit character. For example, `digit('7',10)` returns 7. If the value of `ch` is not a valid digit, the method returns `-1`. For example, `digit('7',2)` returns `-1` because `'7'` is not a valid digit in radix 2. A number of methods in other classes use this method to convert strings that contain numbers to actual numeric values. The `forDigit()` method is an approximate inverse of this method.

If `radix` is greater than 10, characters in the range `A' to `A'+`radix`-11 are treated as valid digits. Such a character has the numeric value `ch`-`A'+10. By the same token, if `radix` is greater than 10, characters in the range `a' to `a'+`radix`-11 are treated as valid digits. Such a character has the numeric value `ch`-`a'+10.

forDigit

`public static char forDigit(int digit, int radix)`

Parameters

`digit`

The numeric value represented as a digit character.

`radix`

The radix used to represent the specified value.

Returns

The character that represents the digit corresponding to the specified numeric value. The method returns `\ 0' if `digit` is less than 0, if `digit` is equal to or greater than `radix`, if `radix` is less than `MIN_RADIX`, or if `radix` is greater than `MAX_RADIX`.

Description

This method returns the character that represents the digit corresponding to the specified numeric value. If `digit` is in the range 0 through 9, the method returns `0'+`digit`. If `digit` is in the range 10 through `MAX_RADIX`-1, the method returns `a'+`digit`-10. The method returns `\ 0' if `digit` is less than 0, if `digit` is equal to or greater than `radix`, if `radix` is less than `MIN_RADIX`, or if `radix` is greater than `MAX_RADIX`.

getNumericValue

`public static int getNumericValue(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value.

Returns

The Unicode numeric value of the character as a nonnegative integer. This method returns `-1` if the character has no numeric value; it returns `-2` if the character has a numeric value that is not a nonnegative integer, such as `1/2`.

Description

This method returns the Unicode numeric value of the specified character as a nonnegative integer.

getType

`public static int getType(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value.

Returns

An `int` value that represents the Unicode general category type of the character.

Description

This method returns the Unicode general category type of the specified character. The value corresponds to one of the general category constants defined by `Character`.

isDefined

`public static boolean isDefined(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character has an assigned meaning in the Unicode character set; otherwise `false`.

Description

This method returns `true` if the specified character value has an assigned meaning in the Unicode character set.

isDigit

`public static boolean isDigit(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as a digit in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a digit, based on the definition of the character in Unicode.

isIdentifierIgnorable

`public static boolean isIdentifierIgnorable(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is ignorable in a Java or Unicode identifier; otherwise `false`.

Description

This method determines whether or not the specified character is ignorable in a Java or Unicode identifier. The following characters are ignorable in a Java or Unicode identifier:

`\u0000 - \u0008 \u000E - \u001B \u007F - \u009F`	ISO control characters that aren't whitespace
`\u200C - \u200F`	Join controls
`\u200A - \u200E`	Bidirectional controls
`\u206A - \u206F`	Format controls
`\uFEFF`	Zero-width no-break space

isISOControl

`public static boolean isISOControl(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is an ISO control character; otherwise `false`.

Description

This method determines whether or not the specified character is an ISO control character. A character is an ISO control character if it falls in the range `\u0000` through `\u001F` or `\u007F` through `\u009F`.

isJavaIdentifierPart

`public static boolean isJavaIdentifierPart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear after the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Java identifier after the first character. A character is considered part of a Java identifier if and only if it is a letter, a digit, a currency symbol (e.g., $), a connecting punctuation character (e.g., _), a numeric letter (e.g., a Roman numeral), a combining mark, a nonspacing mark, or an ignorable control character.

isJavaIdentifierStart

`public static boolean isJavaIdentifierStart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear as the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Java identifier as the first character. A character is considered a start of a Java identifier if and only if it is a letter, a currency symbol (e.g., $), or a connecting punctuation character (e.g., _).

isJavaLetter

`public static boolean isJavaLetter(char ch)`

Availability

Deprecated as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear as the first character in a Java identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear as the first character in a Java identifier. A character is considered a Java letter if and only if it is a letter, the character $, or the character _ . This method returns `false` for digits because digits are not allowed as the first character of an identifier.

This method is deprecated as of JDK 1.1. You should use `isJavaIdentifierStart()` instead.

isJavaLetterOrDigit

`public static boolean isJavaLetterOrDigit(char ch)`

Availability

Deprecated as of JDK 1.1

Parameters

ch

A char value to be tested.

Returns

true if the specified character can appear after the first character in a Java identifier; otherwise false.

Description

This method returns true if the specified character can appear in a Java identifier after the first character. A character is considered a Java letter or digit if and only if it is a letter, a digit, the character $, or the character _.

This method is deprecated as of JDK 1.1. You should use isJavaIdentifierPart() instead.

isLetter

public static boolean isLetter(char ch)

Parameters

ch

A char value to be tested.

Returns

true if the specified character is defined as a letter in the Unicode character set; otherwise false.

Description

This method determines whether or not the specified character is a letter, based on the definition of the character in Unicode. This method does not consider character values in ranges that have not been assigned meanings by Unicode to be letters.

isLetterOrDigit

public static boolean isLetterOrDigit(char ch)

Parameters

ch

A `char` value to be tested.

Returns

`true` if the specified character is defined as a letter in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a letter or a digit, based on the definition of the character in Unicode. There are some ranges that have not been assigned meanings by Unicode. If a character value is in one of these ranges, this method does not consider the character to be a letter.

isLowerCase

`public static boolean isLowerCase (char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as lowercase in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is lowercase. Unicode defines a number of characters that do not have case mappings; if the specified character is one of these characters, the method returns `false`.

isSpace

`public static boolean isSpace(char ch)`

Availability

Deprecated as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as whitespace in the ISO-Latin-1 character set; otherwise `false`.

Description

This method determines whether or not the specified character is whitespace. This method recognizes the whitespace characters shown in the following table.

`\u0009`	Horizontal tab
`\u000A`	Newline
`\u000C`	Formfeed
`\u000D`	Carriage return
`\u0020 ` ``	Space

This method is deprecated as of JDK 1.1. You should use `isWhitespace()` instead.

isSpaceChar

`public static boolean isSpaceChar(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is a Unicode 2.0 space characters; otherwise `false`.

Description

This method determines if the specified character is a space character according to the Unicode 2.0 specification. A character is considered to be a Unicode space character if and only if it has the general category "Zs", "Zl", or "Zp" in the Unicode specification.

isTitleCase

`public static boolean isTitleCase(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as titlecase in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is a titlecase character. Unicode defines a number of characters that do not have case mappings; if the specified character is one of these characters, the method returns `false`.

Many characters are defined by the Unicode standard as having upper- and lowercase forms. There are some characters defined by the Unicode standard that also have a titlecase form. The glyphs for these characters look like a combination of two Latin letters. The titlecase form of these characters has a glyph that looks like a combination of an uppercase Latin character and a lowercase Latin character; this case should be used when the character appears as the first character of a word in a title. For example, one of the Unicode characters that has a titlecase form looks like the letter `D' followed by the letter `Z'. Here is what the three forms of this letter look like:

Uppercase	`DZ'
Titlecase	`Dz'
Lowercase	`dz'

isUnicodeIdentifierPart

`public static boolean isUnicodeIdentifierPart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear after the first character in a Unicode identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Unicode identifier after the first character. A character is considered part of a Unicode identifier if and only if it is a letter, a digit, a connecting punctuation character (e.g., _), a numeric letter (e.g., a Roman numeral), a combining mark, a nonspacing mark, or an ignorable control character.

isUnicodeIdentifierStart

`public static boolean isUnicodeIdentifierStart(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character can appear as the first character in a Unicode identifier; otherwise `false`.

Description

This method returns `true` if the specified character can appear in a Unicode identifier as the first character. A character is considered a start of a Unicode identifier if and only if it is a letter.

isUpperCase

`public static boolean isUpperCase(char ch)`

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as uppercase in the Unicode character set; otherwise `false`.

Description

This method determines whether or not the specified character is uppercase. Unicode defines a number of characters that do not have case mappings; if the specified character is one of these characters, the method returns `false`.

isWhitespace

`public static boolean isWhitespace(char ch)`

Availability

New as of JDK 1.1

Parameters

`ch`

A `char` value to be tested.

Returns

`true` if the specified character is defined as whitespace according to Java; otherwise `false`.

Description

This method determines whether or not the specified character is whitespace. This method recognizes the following as whitespace:

Unicode category "Zs" except `\u00A0` and `\uFEFF`	Unicode space separators except no-break spaces
Unicode category "Zl"	Unicode line separators
Unicode category "Zp"	Unicode paragraph separators
`\u0009`	Horizontal tab
`\u000A`	Linefeed

`\u000B`	Vertical tab
`\u000C`	Formfeed
`\u000D`	Carriage return
`\u001C`	File separator
`\u001D`	Group separator
`\u001E`	Record separator
`\u001F`	Unit separator

toLowerCase

`public static char toLowerCase(char ch)`

Parameters

`ch`

A `char` value to be converted to lowercase.

Returns

The lowercase equivalent of the specified character, or the character itself if it cannot be converted to lowercase.

Description

This method returns the lowercase equivalent of the specified character value. If the specified character is not uppercase or if it has no lowercase equivalent, the character is returned unmodified. The Unicode attribute table determines if a character has a mapping to a lowercase equivalent.

Some Unicode characters in the range `\u2000` through `\u2FFF` have lowercase mappings. For example, `\u2160` (Roman numeral one) has a lowercase mapping to `\u2170` (small Roman numeral one). The `toLowerCase()` method maps such characters to their lowercase equivalents even though the method `isUpperCase()` does not return `true` for such characters.

toTitleCase

`public static char toTitleCase(char ch)`

Parameters

`ch`

A `char` value to be converted to titlecase.

Returns

The titlecase equivalent of the specified character, or the character itself if it cannot be converted to titlecase.

Description

This method returns the titlecase equivalent of the specified character value. If the specified character has no titlecase equivalent, the character is returned unmodified. The Unicode attribute table is used to determine the character's titlecase equivalent.

Many characters are defined by the Unicode standard as having upper- and lowercase forms. There are some characters defined by the Unicode standard that also have a titlecase form. The glyphs for these characters look like a combination of two Latin letters. The titlecase form of these characters has a glyph that looks like a combination of an uppercase Latin character and a lowercase Latin character; this case should be used when the character appears as the first character of a word in a title. For example, one of the Unicode characters that has a titlecase form looks like the letter `D' followed by the letter `Z'. Here is what the three forms of this letter look like:

Uppercase	`DZ'
Titlecase	`Dz'
Lowercase	`dz'

toUpperCase

`public static char toUpperCase(char ch)`

Parameters

`ch`

A `char` value to be converted to lowercase.

Returns

The uppercase equivalent of the specified character, or the character itself if it cannot be converted to uppercase.

Description

This method returns the uppercase equivalent of the specified character value. If the specified character is not lowercase or if it has no uppercase equivalent, the character is returned unmodified. The Unicode attribute table determines if a character has a mapping to an uppercase equivalent.

Some Unicode characters in the range `\u2000` through `\u2FFF` have uppercase mappings. For example, `\u2170` (small Roman numeral one) has a lowercase mapping to `\u2160` (Roman numeral one). The `toUpperCase()` method maps such characters to their uppercase equivalents even though the method `isLowerCase()` does not return `true` for such characters.

Instance Methods

charValue

`public char charValue()`

Returns

The `char` value contained by the object.

equals

`public boolean equals(Object obj)`

Parameters

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Character`, and it contains the same value as the object this method is associated with.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `char` value of the object.

Overrides

`Object.hashCode()`

toString

`public String toString()`

Returns

A `String` of length one that contains the character value of the object.

Overrides

`Object.toString()`

Description

This method returns a string representation of the `Character` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Class

Name

Class

Synopsis

Class Name:

`java.lang.Class`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Seriablizable`

Availability:

JDK 1.0 or later

Description

As of Java 1.1, instances of the `Class` class are used as run-time descriptions of all Java data types, both reference types and primitive types. The `Class` class has also been greatly expanded in 1.1 to provide support for the Reflection API. Prior to 1.1, `Class` just provided run-time descriptions of reference types.

A `Class` object provides considerable information about the data type. You can use the `isPrimitive()` method to find out if a Class object describes a primitive type, while isArray() indicates if the object describes an array type. If a Class object describes a class or interface type, there are numerous methods that return information about the fields, methods, and constructors of the type. This information is returned as java.lang.reflect.Field, java.lang.reflect.Method, and java.lang.reflect.Constructor objects.

There are a number of ways that you can get a Class object for a particular data type:

- If you have an object, you can get the Class object that describes the class of that object by calling the object's getClass()method. Every class inherits this method from the Object class.

- As of Java 1.1, you can get the Class object that describes any Java type using the new class literal syntax. A class literal is simply the name of a type (a class name or a primitive type name) followed by a period and the class keyword. For example:

  ```
  Class s = String.class;
  Class i = int.class;
  Class v = java.util.Vector.class;
  ```

- In Java 1.0, you can get the Class object from the name of a data type using the forName() class method of Class. For example:

  ```
  Class v = Class.forName("java.util.Vector");
  ```

  This technique still works in Java 1.1, but it is more cumbersome (and less efficient) than using a class literal.

You can create an instance of a class using the newInstance() method of a Class object, if the class has a constructor that takes no arguments.

The Class class has no public constructors; it cannot be explicitly instantiated. Class objects are normally created by the ClassLoader class or a ClassLoader object.

Class Summary

```
public final class java.lang.Class extends java.lang.Object
                                   implements java.io.Serializable {
    // Class Methods
    public static native Class forName(String className);
    // Instance Methods
    public Class[] getClasses();                             // New in 1.1
    public native ClassLoader getClassLoader();
    public native Class getComponentType();                  // New in 1.1
    public Constructor
           getConstructor(Class[] parameterTypes);           // New in 1.1
    public Constructor[] getConstructors();                  // New in 1.1

    public String toString();
}
```

Class Methods

forName

`public static Class forName(String className) throws ClassNotFoundException`

Parameters

`className`

Name of a class qualified by the name of its package. If the class is defined inside of another class, all dots (`.`) that separate the top-level class name from the class to load must be changed to dollar signs ($) for the name to be recognized.

Returns

A `Class` object that describes the named class.

Throws

`ClassNotFoundException`

If the class cannot be loaded because it cannot be found.

Description

This method dynamically loads a class if it has not already been loaded. The method returns a `Class` object that describes the named class.

The most common use of `forName()` is for loading classes on the fly when an application wants to use classes it wasn't built with. For example, a web browser uses this technique. When a browser needs to load an applet, the browser calls `Class.forName()` for the applet. The method loads the class if it has not already been loaded and returns the `Class` object that encapsulates the class. The browser then creates an instance of the applet by calling the `Class` object's `newInstance()` method.

When a class is loaded using a `ClassLoader` object, any classes loaded at the instigation of that class are also loaded using the same `ClassLoader` object. This method implements that security policy by trying to find a `ClassLoader` object to load the named class. The method searches the stack for the most recently invoked method associated with a class that was loaded using a `ClassLoader` object. If such a class is found, the `ClassLoader` object associated with that class is used.

Instance Methods

getClasses

`public Class[] getClasses()`

Availability

New as of JDK 1.1

Returns

An array of `Class` objects that contains the `public` classes and interfaces that are members of this class.

Description

If this `Class` object represents a reference type, this method returns an array of `Class` objects that lists all of the `public` classes and interfaces that are members of this class or interface. The list includes `public` classes and interfaces that are inherited from superclasses and that are defined by this class or interface. If there are no `public` member classes or interfaces, or if this `Class` represents a primitive type, the method returns an array of length `0`.

As of Java 1.1.1, this method always returns an array of length `0`, no matter how many `public` member classes this class or interface actually declares.

getClassLoader

`public native ClassLoader getClassLoader()`

Returns

The `ClassLoader` object used to load this class or `null` if this class was not loaded with a `ClassLoader`.

Description

This method returns the `ClassLoader` object that was used to load this class. If this class was not loaded with a `ClassLoader`, `null` is returned.

This method is useful for making sure that a class gets loaded with the same class loader as was used for loading this `Class` object.

getComponentType

`public native Class getComponentType()`

Availability

New as of JDK 1.1

Returns

A `Class` object that describes the component type of this class if it is an array type.

Description

If this `Class` object represents an array type, this method returns a `Class` object that describes the component type of the array. If this `Class` does not represent an array type, the method returns `null`.

getConstructor

`public Constructor getConstructor(Class[] parameterTypes) throws NoSuchMethodException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the constructor.

Returns

A `Constructor` object that reflects the specified `public` constructor of this class.

Throws

`NoSuchMethodException`

If the specified constructor does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns a `Constructor` object that reflects the specified `public` constructor of this class. The constructor is located by searching all of the constructors of the class for a `public` constructor that has exactly the same formal parameters as specified. If this `Class` does not represent a class, the method returns `null`.

getConstructors

`public Constructor[] getConstructors() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Constructor` objects that reflect the `public` constructors of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns an array of `Constructor` objects that reflect the `public` constructors of this class. If there are no `public` constructors, or if this `Class` does not represent a class, the method returns an array of length `0`.

getDeclaredClasses

`public Class[] getDeclaredClasses() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Class` objects that contains all of the declared classes and interfaces that are members of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a reference type, this method returns an array of `Class` objects that lists all of the classes and interfaces that are members of this class or interface. The list includes `public`, `protected`, default access, and `private` classes and interfaces that are defined by this class or interface, but it excludes classes and interfaces inherited from superclasses. If there are no such member classes or interfaces, or if this `Class` represents a primitive type, the method returns an array of length `0`.

As of Java 1.1.1, this method always returns an array of length `0`, no matter how many member classes this class or interface declares.

getDeclaredConstructor

```
 public Constructor getDeclaredConstructor(Class[] parameterTypes) throws
NoSuchMethodException, SecurityException
```

Availability

New as of JDK 1.1

Parameters

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the constructor.

Returns

A `Constructor` object that reflects the specified declared constructor of this class.

Throws

`NoSuchMethodException`

If the specified constructor does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns a `Constructor` object that reflects the specified declared constructor of this class. The constructor is located by searching all of the constructors of the class for a `public`, `protected`, default access, or `private` constructor that has exactly the same formal parameters as specified. If this `Class` does not represent a class, the method returns `null`.

getDeclaredConstructors

```
public Constructor[] getDeclaredConstructors() throws SecurityException
```

Availability

New as of JDK 1.1

Returns

An array of `Constructor` objects that reflect the declared constructors of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class, this method returns an array of `Constructor` objects that reflect the `public`, `protected`, default access, and `private` constructors of this class. If there are no declared constructors, or if this `Class` does not represent a class, the method returns an array of length `0`.

getDeclaredField

```
public Field getDeclaredField(String name) throws NoSuchFieldException,
SecurityException
```

Availability

New as of JDK 1.1

Parameters

name

The simple name of the field.

Returns

A Field object that reflects the specified declared field of this class.

Throws

NoSuchFieldException

If the specified field does not exist.

SecurityException

If the checkMemberAccess() method of the SecurityManager throws a SecurityException.

Description

If this Class object represents a class or interface, this method returns a Field object that reflects the specified declared field of this class. The field is located by searching all of the fields of the class (but not inherited fields) for a public, protected, default access, or private field that has the specified simple name. If this Class does not represent a class or interface, the method returns null.

getDeclaredFields

public Field[] getDeclaredFields() throws SecurityException

Availability

New as of JDK 1.1

Returns

An array of Field objects that reflect the declared fields of this class.

Throws

SecurityException

If the checkMemberAccess() method of the SecurityManager throws a SecurityException.

Description

If this Class object represents a class or interface, this method returns an array of Field objects that reflect the public, protected, default access, and private fields declared by this class, but excludes inherited fields. If there are no declared fields, or if this `Class` does not represent a class or interface, the method returns an array of length `0`.

This method does not reflect the implicit `length` field for array types. The methods of the class `Array` should be used to manipulate array types.

getDeclaredMethod

`public Method getDeclaredMethod(String name, Class[] parameterTypes) throws NoSuchMethodException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the method.

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the method.

Returns

A `Method` object that reflects the specified declared method of this class.

Throws

`NoSuchMethodException`

If the specified method does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Method` object that reflects the specified declared method of this class. The method is located by searching all of the methods of the class (but not inherited methods) for a `public`, `protected`, default access, or `private` method that has the specified simple name and exactly the same formal parameters as specified. If this `Class` does not represent a class or interface, the method returns `null`.

getDeclaredMethods

public Method[] getDeclaredMethods() throws SecurityException

Availability

New as of JDK 1.1

Returns

An array of `Method` objects that reflect the declared methods of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Method` objects that reflect the `public`, `protected`, default access, and `private` methods declared by this class, but excludes inherited methods. If there are no declared methods, or if this `Class` does not represent a class or interface, the method returns an array of length `0`.

getDeclaringClass

`public Class getDeclaringClass()`

Availability

New as of JDK 1.1

Returns

A `Class` object that represents the declaring class if this class is a member of another class.

Description

If this `Class` object represents a class or interface that is a member of another class or interface, this method returns a `Class` object that describes the declaring class or interface. If this class or interface is not a member of another class or interface, or if it represents a primitive type, the method returns `null`.

getField

`public Field getField(String name) throws NoSuchFieldException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the field.

Returns

A `Field` object that reflects the specified `public` field of this class.

Throws

`NoSuchFieldException`

If the specified field does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Field` object that reflects the specified `public` field of this class. The field is located by searching all of the fields of the class, including any inherited fields, for a `public` field that has the specified simple name. If this `Class` does not represent a class or interface, the method returns `null`.

getFields

`public Field[] getFields() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Field` objects that reflect the `public` fields of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Field` objects that reflect the `public` fields declared by this class and any inherited `public` fields. If there are no `public` fields, or if this `Class` does not represent a class or interface, the method returns an array of length `0`.

This method does not reflect the implicit `length` field for array types. The methods of the class `Array` should be used to manipulate array types.

getInterfaces

`public native Class[] getInterfaces()`

Returns

An array of the interfaces implemented by this class or extended by this interface.

Description

If the `Class` object represents a class, this method returns an array that refers to all of the interfaces that the class implements. The order of the interfaces referred to in the array is the same as the order in the class declaration's `implements` clause. If the class does not implement any interfaces, the length of the returned array is 0.

If the object represents an interface, this method returns an array that refers to all of the interfaces that this interface extends. The interfaces occur in the order they appear in the interface declaration's `extends` clause. If the interface does not extend any interfaces, the length of the returned array is 0.

If the object represents a primitive or array type, the method returns an array of length 0.

getMethod

`public Method getMethod(String name, Class[] parameterTypes) throws NoSuchMethodException, SecurityException`

Availability

New as of JDK 1.1

Parameters

`name`

The simple name of the method.

`parameterTypes`

An array of `Class` objects that describes the parameter types, in declared order, of the method.

Returns

A `Method` object that reflects the specified `public` method of this class.

Throws

`NoSuchMethodException`

If the specified method does not exist.

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns a `Method` object that reflects the specified `public` method of this class. The method is located by searching all of the methods of the class, including any inherited methods, for a `public` method that has the specified simple name and exactly the same formal parameters as specified. If this `Class` does not represent a class or interface, the method returns `null`.

getMethods

`public Method[] getMethods() throws SecurityException`

Availability

New as of JDK 1.1

Returns

An array of `Method` objects that reflect the `public` methods of this class.

Throws

`SecurityException`

If the `checkMemberAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

If this `Class` object represents a class or interface, this method returns an array of `Method` objects that reflect the `public` methods declared by this class and any inherited `public` methods. If there are no `public` methods or if this `Class` doesn't represent a class or interface, the method returns an array of length `0`.

getModifiers

`public native int getModifiers()`

Availability

New as of JDK 1.1

Returns

An integer that represents the modifier keywords used to declare this class.

Description

If this `Class` object represents a class or interface, this method returns an integer value that represents the modifiers used to declare the class or interface. The `Modifier` class should be used to decode the returned value.

getName

`public native String getName()`

Returns

The fully qualified name of this class or interface.

Description

This method returns the fully qualified name of the type represented by this `Class` object.

If the object represents the class of an array, the method returns a `String` that contains as many left square brackets as there are dimensions in the array, followed by a code that indicates the type of element contained in the base array. Consider the following:

```
(new int [3][4][5]).getClass().getName()
```

This code returns "`[[[I`". The codes used to indicate the element type are as follows:

Code	**Type**
`[`	array
`B`	`byte`
`C`	`char`
`d`	`double`
`F`	`float`
`I`	`int`
`J`	`long`

`L` *fully_qualified_class_name*	class or interface
`S`	`short`
`Z`	`boolean`

getResource

`public URL getResource(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

A `URL` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name for this `Class` object and returns a `URL` object that is connected to the resource. The rules for searching for a resource associated with a class are implemented by the `ClassLoader` for the class; this method simply calls the `getResource()` method of the `ClassLoader`. If this class does not have a `ClassLoader` (i.e., it is a system class), the method calls the `ClassLoader.getSystemResource()` method.

getResourceAsStream

`public InputStream getResourceAsStream(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

An `InputStream` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name for this `Class` object and returns an `InputStream` object that is connected to the resource. The rules for searching for a resource associated with a class are implemented by the `ClassLoader` for the class; this method simply calls the `getResourceAsStream()` method of the `ClassLoader`. If this class does not have a `ClassLoader` (i.e., it is a system class), the method calls the `ClassLoader.getSystemResourceAsStream()` method.

getSigners

`public native Object[] getSigners()`

Availability

New as of JDK 1.1

Returns

An array of `Object`s that represents the signers of this class.

Description

This method returns an array of objects that represents the digital signatures for this class.

getSuperclass

`public native Class getSuperclass()`

Returns

The superclass of this class or `null` if there is no superclass.

Description

If the `Class` object represents a class other than `Object`, this method returns the `Class` object that represents its superclass. If the object represents an interface, the `Object` class, or a primitive type, the method returns `null`.

isArray

`public native boolean isArray()`

Availability

New as of JDK 1.1

Returns

`true` if this object describes an array type; otherwise `false`.

isAssignableFrom

`public native boolean isAssignableFrom(Class cls)`

Availability

New as of JDK 1.1

Parameters

`cls`

A `Class` object to be tested.

Returns

`true` if the type represented by `cls` is assignable to the type of this class: otherwise `false`.

Throws

`NullPointerException`

If `cls` is `null`.

Description

This method determines whether or not the type represented by `cls` is assignable to the type of this class. If this class represents a class, this class must be the same as `cls` or a superclass of `cls`. If this class represents an interface, this class must be the same as `cls` or a superinterface of `cls`. If this class represents a primitive type, this class must be the same as `cls`.

isInstance

`public native boolean isInstance(Object obj)`

Availability

New as of JDK 1.1

Parameters

`obj`

An `Object` to be tested.

Returns

`true` if `obj` can be cast to the reference type specified by this class; otherwise `false`.

Throws

`NullPointerException`

If `obj` is `null`.

Description

This method determines whether or not the object represented by `obj` can be cast to the type of this class object without causing a `ClassCastException`. This method is the dynamic equivalent of the `instanceof` operator.

isInterface

`public native boolean isInterface()`

Returns

`true` if this object describes an interface; otherwise `false`.

isPrimitive

`public native boolean isPrimitive()`

Availability

New as of JDK 1.1

Returns

`true` if this object describes a primitive type; otherwise `false`.

newInstance

`public native Object newInstance () throws InstantiationException, IllegalAccessException`

Returns

A reference to a new instance of this class.

Throws

`InstantiationException`

If the `Class` object represents an interface or an `abstract` class.

`IllegalAccessException`

If the class or an initializer is not accessible.

Description

This method creates a new instance of this class by performing these steps:

1. It creates a new object of the class represented by the `Class` object.
2. It calls the constructor for the class that takes no arguments.
3. It returns a reference to the initialized object.

The `newInstance()` method is useful for creating an instance of a class that has been dynamically loaded using the `forName()` method.

The reference returned by this method is usually cast to the type of object that is instantiated.

The `newInstance()` method can throw objects that are not instances of the classes it is declared to throw. If the constructor invoked by `newInstance()` throws an exception, the exception is thrown by `newInstance()` regardless of the class of the object.

toString

`public String toString()`

Returns

A `String` that contains the name of the class with either `'class'` or `'interface'` prepended as appropriate.

Overrides

`Object.toString()`

Description

This method returns a string representation of the `Class` object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals()`	`Object`

ClassCastException

Name

ClassCastException

Synopsis

Class Name:

`java.lang.ClassCastException`

Superclass:

`java.lang.RuntimeException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `ClassCastException` is thrown when there is an attempt to cast a reference to an object to an inappropriate type.

Class Summary

```
public class java.lang.ClassCastException
             extends java.lang.RuntimeException {
  // Constructors
  public ClassCastException();
  public ClassCastException(String s);
}
```

Constructors

ClassCastException

public ClassCastException()

Description

This constructor creates a `ClassCastException` with no associated detail message.

public ClassCastException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `ClassCastException` with the specified detail message.

Inherited Methods

ClassCircularityError BOOK INDEX ClassLoader

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ClassLoader

Name

ClassLoader

Synopsis

Class Name:

`java.lang.ClassLoader`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `ClassLoader` class provides a mechanism for Java to load classes over a network or from any source other than the local filesystem. The default class-loading mechanism loads classes from files found relative to directories specified by the `CLASSPATH` environment variable. This default mechanism does not use an instance of the `ClassLoader` class.

An application can implement another mechanism for loading classes by declaring a subclass of the `abstract ClassLoader` class. A subclass of `ClassLoader` must override the `loadClass()` to define a class-loading policy.

This method implements any sort of security that is necessary for the class-loading mechanism. The other methods of ClassLoader are final, so they cannot be overridden.

A ClassLoader object is typically used by calling its loadClass() method to explicitly load a top-level class, such as a subclass of Applet. The ClassLoader that loads the class becomes associated with the class; it can be obtained by calling the getClassLoader() method of the Class object that represents the class.

Once a class is loaded, it must be resolved before it can be used. Resolving a class means ensuring that all of the other classes it references are loaded. In addition, all of the classes that they reference must be loaded, and so on, until all of the needed classes have been loaded. Classes are resolved using the resolveClass() method of the ClassLoader object that loaded the initial class. This means that when a ClassLoader object is explicitly used to load a class, the same ClassLoader is used to load all of the classes that it references, directly or indirectly.

Classes loaded using a ClassLoader object may attempt to load additional classes without explicitly using a ClassLoader object. They can do this by calling the Class class' forName() method. However, in such a situation, a ClassLoader object is implicitly used. See the description of Class.forName() for more information.

Java identifies a class by a combination of its fully qualified name and the class loader that was used to load the class. If you write a subclass of ClassLoader, it should not attempt to directly load local classes. Instead, it should call findSystemClass(). A local class that is loaded directly by a ClassLoader is considered to be a different class than the same class loaded by findSystemClass(). This can lead to having two copies of the same class loaded, which can cause a number of inconsistencies. For example, the class' equals() method may decide that the same object is not equal to itself.

Class Summary

```
public abstract class java.lang.ClassLoader extends java.lang.Object {
    // Constructors
    protected ClassLoader();
    // Class Methods
    public static final URL
           getSystemResource(String name);                 // New in 1.1
    public static final InputStream
           getSystemResourceAsStream(String name);         // New in 1.1
    // Public Instance Methods
    public URL getResource(String name);                   // New in 1.1
    public InputStream getResourceAsStream(String name);    // New in 1.1
    public Class loadClass(String name);                   // New in 1.1

    // Protected Instance Methods
    protected final Class defineClass(byte data[],
              int offset, int length);              // Deprecated in 1.1
    protected final Class defineClass(String name,
              byte[] data, int offset, int length);        // New in 1.1
    protected final Class findLoadedClass(String name);     // New in 1.1
    protected final Class findSystemClass(String name);
    protected abstract Class loadClass(String name, boolean resolve);
    protected final void resolveClass(Class c);
    protected final void setSigners(Class cl,
              Object[] signers);                           // New in 1.1
}
```

Constructors

ClassLoader

`protected ClassLoader()`

Throws

`SecurityException`

If there is a `SecurityManager` object installed and its `checkCreateClassLoader()` method throws a `SecurityException` when called by this constructor.

Description

Initializes a `ClassLoader` object. Because `ClassLoader` is an `abstract` class, only subclasses of the class can access this constructor.

Class Methods

getSystemResource

`public static final URL getSystemResource(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A system resource name.

Returns

A `URL` object that is connected to the specified system resource or `null` if the resource cannot be found.

Description

This method finds a system resource with the given name and returns a `URL` object that is connected to the resource. The resource name can be any system resource.

getSystemResourceAsStream

`public static final InputStream getSystemResourceAsStream(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A system resource name.

Returns

An `InputStream` object that is connected to the specified system resource or `null` if the resource cannot be found.

Description

This method finds a system resource with the given name and returns an `InputStream` object that is connected to the resource. The resource name can be any system resource.

Public Instance Methods

getResource

`public URL getResource(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

A `URL` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name and returns a `URL` object that is connected to the resource.

A resource is a file that contains data (e.g., sound, images, text) and it can be part of a package. The name of a resource is a sequence of identifiers separated by "`/`". For example, a resource might have the name *help/american/logon.html* . System resources are found on the host machine using the conventions of the host implementation. For example, the "`/`" in the resource name may be treated as a path separator, with the entire resource name treated as a relative path to be found under a directory in `CLASSPATH`.

The implementation of `getResource()` in `ClassLoader` simply returns `null`. A subclass can override this method to provide more useful functionality.

getResourceAsStream

`public InputStream getResourceAsStream(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

A resource name.

Returns

An `InputStream` object that is connected to the specified resource or `null` if the resource cannot be found.

Description

This method finds a resource with the given name and returns an `InputStream` object that is connected to the resource.

A resource is a file that contains data (e.g., sound, images, text) and it can be part of a package. The name of a resource is a sequence of identifiers separated by `` `/' ``. For example, a resource might have the name *help/american/logon.html*. System resources are found on the host machine using the conventions of the host implementation. For example, the `` `/' `` in the resource name may be treated as a path separator, with the entire resource name treated as a relative path to be found under a directory in `CLASSPATH`.

The implementation of `getResourceAsStream()` in `ClassLoader` simply returns `null`. A subclass can override this method to provide more useful functionality.

loadClass

public Class loadClass(String name) throws ClassNotFoundException

Availability

New as of JDK 1.1

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

Returns

The `Class` object for the specified class.

Throws

`ClassNotFoundException`

If it cannot find a definition for the named class.

Description

This method loads the named class by calling `loadClass(name, true)`.

Protected Instance Methods

defineClass

`protected final Class defineClass(byte data[], int offset, int length)`

Availability

Deprecated as of JDK 1.1

Parameters

`data`

An array that contains the byte codes that define a class.

`offset`

The offset in the array of byte codes.

`length`

The number of byte codes in the array.

Returns

The newly created `Class` object.

Throws

`ClassFormatError`

If the `data` array does not constitute a valid class definition.

Description

This method creates a `Class` object from the byte codes that define the class. Before the class can be used, it must be resolved. The method is intended to be called from an implementation of the `loadClass()` method.

Note that this method is deprecated as of Java 1.1. You should use the version of `defineClass()` that takes a `name` parameter and is therefore more secure.

`protected final Class defineClass(String name, byte data[], int offset, int length)`

Availability

New as of JDK 1.1

Parameters

`name`

The expected name of the class to be defined or `null` if it is not known. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

`data`

An array that contains the byte codes that define a class.

`offset`

The offset in the array of byte codes.

`length`

The number of byte codes in the array.

Returns

The newly created `Class` object.

Throws

`ClassFormatError`

If the `data` array does not constitute a valid class definition.

Description

This method creates a `Class` object from the byte codes that define the class. Before the class can be used, it must be resolved. The method is intended to be called from an implementation of the `loadClass()` method.

findLoadedClass

`protected final Class findLoadedClass(String name)`

Availability

New as of JDK 1.1

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

Returns

The `Class` object for the specified loaded class or `null` if the class cannot be found.

Description

This method finds the specified class that has already been loaded.

findSystemClass

`protected final Class findSystemClass(String name) throws ClassNotFoundException`

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

Returns

The `Class` object for the specified system class.

Throws

`ClassNotFoundException`

If the default class-loading mechanism cannot find a definition for the class.

`NoClassDefFoundError`

If the default class-loading mechanism cannot find the class.

Description

This method finds and loads a system class if it has not already been loaded. A *system class* is a class that is loaded by the default class-loading mechanism from the local filesystem. An implementation of the `loadClass()` method typically calls this method to attempt to load a class from the locations specified by the `CLASSPATH` environment variable.

loadClass

`protected abstract Class loadClass(String name, boolean resolve) throws ClassNotFoundException`

Parameters

`name`

The name of the class to be returned. The class name should be qualified by its package name. The lack of an explicit package name specifies that the class is part of the default package.

`resolve`

Specifies whether or not the class should be resolved by calling the `resolveClass()` method.

Returns

The `Class` object for the specified class.

Throws

`ClassNotFoundException`

If it cannot find a definition for the named class.

Description

An implementation of this `abstract` method loads the named class and returns its `Class` object. It is permitted and encouraged for an implementation to cache the classes it loads, rather than load one each time the method is called. An implementation of this method should do at least the following:

1. Load the byte codes that comprise the class definition into a `byte[]`.
2. Call the `defineClass()` method to create a `Class` object to represent the class definition.
3. If the `resolve` parameter is `true`, call the `resolveClass()` method to resolve the class.

If an implementation of this method caches the classes that it loads, it is recommended that it use an instance of the `java.util.Hashtable` to implement the cache.

resolveClass

`protected final void resolveClass(Class c)`

Parameters

`c`

The `Class` object for the class to be resolved.

Description

This method resolves the given `Class` object. Resolving a class means ensuring that all of the other classes that the `Class` object references are loaded. In addition, all of the classes that they reference must be loaded, and so on, until all of the needed classes have been loaded.

The `resolveClass()` method should be called by an implementation of the `loadClass()` method when the value of the `loadClass()` method's `resolve` parameter is `true`.

setSigners

`protected final void setSigners(Class cl, Object[] signers)`

Availability

New as of JDK 1.1

Parameters

`cl`

The `Class` object for the class to be signed.

`signers`

An array of `Object`s that represents the signers of this class.

Description

This method specifies the objects that represent the digital signatures for this class.

ClassNotFoundException

Name

ClassNotFoundException

Synopsis

Class Name:

`java.lang.ClassNotFoundException`

Superclass:

`java.lang.Exception`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `ClassNotFoundException` is thrown to indicate that a class to be loaded cannot be found.

Class Summary

```
public class java.lang.ClassNotFoundException extends java.lang.Exception {
  // Constructors
  public ClassNotFoundException();
  public ClassNotFoundException(String s);
}
```

Constructors

ClassNotFoundException

public ClassNotFoundException()

Description

This constructor creates a `ClassNotFoundException` with no associated detail message.

public ClassNotFoundException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `ClassNotFoundException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`fillInStackTrace()`	`Throwable`	`finalize()`	`Object`
`getClass()`	`Object`	`getLocalizedMessage()`	`Throwable`

ClassLoader BOOK INDEX Cloneable

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Cloneable

Name

Cloneable

Synopsis

Interface Name:

> `java.lang.Cloneable`

Super-interface:

> None

Immediate Sub-interfaces:

> `java.text.CharacterIterator`

Implemented by:

> `java.awt.GridBagConstraints`, `java.awt.Insets`,
>
> `java.awt.image.ImageFilter`,
>
> `java.text.BreakIterator`,

java.text.Collator, java.text.DateFormat,

java.text.DateFormatSymbols,

java.text.DecimalFormatSymbols,

java.text.Format, java.text.NumberFormat,

java.util.BitSet, java.util.Calendar,

java.util.Date, java.util.Hashtable,

java.util.Locale, java.util.TimeZone,

java.util.Vector

Availability:

JDK 1.0 or later

Description

The Cloneable interface provides no functionality; it declares no methods or variables. This interface is simply provided as a way of indicating that an object can be cloned (that is, copied). A class that is declared as implementing this interface is assumed to have overridden the Object class' implementation of clone() with an implementation that can successfully clone instances of the class. The implementation of clone() that is provided by the Object class simply throws a CloneNotSupportedException.

Interface Declaration

```
public interface java.lang.Cloneable {
}
```

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `CloneNotSupportedException` is thrown when the `clone()` method has been called for an object that does not implement the `Cloneable` interface and thus cannot be cloned.

Class Summary

```
public class java.lang.CloneNotSupportedException
             extends java.lang.Exception {
  // Constructors
  public CloneNotSupportedException();
  public CloneNotSupportedException(String s);
}
```

Constructors

CloneNotSupportedException

public CloneNotSupportedException()

Description

This constructor creates a `CloneNotSupportedException` with no associated detail message.

public CloneNotSupportedException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `CloneNotSupportedException` with the specified detail message.

Cloneable | BOOK INDEX | Compiler

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Compiler

Name

Compiler

Synopsis

Class Name:

`java.lang.Compiler`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Compiler` class encapsulates a facility for compiling Java classes to native code. As provided by Sun, the methods of this class do not actually do anything. However, if the system property `java.compiler` has been defined and if the method `System.loadLibrary()` is able to load the library named by the property, the methods of this class use the implementations provided in the library.

The `Compiler` class has no `public` constructors, so it cannot be instantiated.

Class Summary

```
public final class java.lang.Compiler extends java.lang.Object {
    // Class Methods
    public static native Object command(Object any);
    public static native boolean compileClass(Class clazz);
    public static native boolean compileClasses(String string);
    public static native void disable();
    public static native void enable();
}
```

Class Methods

command

`public static native Object command(Object any)`

Parameters

`any`

The permissible value and its meaning is determined by the compiler library.

Returns

A value determined by the compiler library, or `null` if no compiler library is loaded.

Description

This method directs the compiler to perform an operation specified by the given argument. The available operations, if any, are determined by the compiler library.

compileClass

`public static native boolean compileClass(Class clazz)`

Parameters

`clazz`

The class to be compiled to native code.

Returns

`true` if the compilation succeeds, or `false` if the compilation fails or no compiler library is loaded.

Description

This method requests the compiler to compile the specified class to native code.

compileClasses

`public static native boolean compileClasses(String string)`

Parameters

`string`

A string that specifies the names of the classes to be compiled.

Returns

`true` if the compilation succeeds or `false` if the compilation fails or no compiler library is loaded.

Description

This method requests the compiler to compile all of the classes named in the string.

disable

```
public static native void disable()
```

Description

This method disables the compiler if one is loaded.

enable

```
public static native void enable()
```

Description

This method enables the compiler if one is loaded.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`

CloneNotSupportedException BOOK INDEX Double

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Double

Name

Double

Synopsis

Class Name:

`java.lang.Double`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Double` class provides an object wrapper for a `double` value. This is useful when you need to treat a `double` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `double` value for one of these arguments, but you can provide a reference to a `Double` object that encapsulates the `double` value. Furthermore, as of JDK 1.1, the `Double` class is necessary to support the Reflection API and class literals.

In Java, `double` values are represented using the IEEE 754 format. The `Double` class provides constants for the three special values that are mandated by this format: `POSITIVE_INFINITY`, `NEGATIVE_INFINITY`, and `NaN` (not-a-number).

The `Double` class also provides some utility methods, such as methods for determining whether a `double` value is an infinity value or NaN, for converting `double` values to other primitive types, and for converting a `double` to a `String` and vice versa.

Class Summary

```
public final class java.lang.Double extends java.lang.Number {
    // Constants
    public final static double MAX_VALUE;
    public final static double MIN_VALUE;
    public final static double NaN;
    public final static double NEGATIVE_INFINITY;
    public final static double POSITIVE_INFINITY;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Double(double value);
    public Double(String s);
    // Class Methods
    public static native long doubleToLongBits(double value);
    public static boolean isInfinite(double v);
    public static boolean isNaN(double v);
    public static native double longBitsToDouble(long bits);
    public static String toString(double d);
    public static Double valueOf(String s);
    // Instance Methods
    public byte byteValue();                           // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public boolean isInfinite();
    public boolean isNaN();
    public long longValue();
    public short shortValue();                         // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final double MAX_VALUE = 1.79769313486231570e+308`

Description

The largest value that can be represented by a `double`.

MIN_VALUE

`public static final double MIN_VALUE = 4.94065645841246544e-324`

Description

The smallest value that can be represented by a `double`.

NaN

`public static final double NaN = 0.0 / 0.0`

Description

This variable represents the value not-a-number (NaN), which is a special value produced by `double` operations such as division of zero by zero. When NaN is one of the operands, most arithmetic operations return NaN as the result.

Most comparison operators (<, <=, ==, >=, >) return `false` when one of their arguments is NaN. The exception is `!=`, which returns `true` when one of its arguments is NaN.

NEGATIVE_INFINITY

`public static final double NEGATIVE_INFINITY = -1.0 / 0.0`

Description

> This variable represents the value negative infinity, which is produced when a `double` operation underflows or a negative `double` value is divided by zero. Negative infinity is by definition less than any other `double` value.

POSITIVE_INFINITY

`public static final double POSITIVE_INFINITY = 1.0 / 0.0`

Description

> This variable represents the value positive infinity, which is produced when a `double` operation overflows or a positive `double` value is divided by zero. Positive infinity is by definition greater than any other `double` value.

TYPE

`public static final Class TYPE`

Availability

> New as of JDK 1.1

Description

> The `Class` object that represents the type `double`. It is always true that `Double.TYPE` == `double.class`.

Constructors

Double

`public Double(double value)`

Parameters

`value`

The `double` value to be encapsulated by this object.

Description

Creates a `Double` object with the specified `double` value.

public Double(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Double` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `double` literal.

Description

Constructs a `Double` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `double` literal.

Class Methods

doubleToLongBits

`public static native long doubleToLongBits(double value)`

Parameters

`value`

The `double` value to be converted.

Returns

The `long` value that contains the same sequence of bits as the representation of the given `double` value.

Description

This method returns the `long` value that contains the same sequence of bits as the representation of the given `double` value. The meaning of the bits in the result is defined by the IEEE 754 floating-point format: bit 63 is the sign bit, bits 62-52 are the exponent, and bits 51-0 are the mantissa.

An argument of `POSITIVE_INFINITY` produces the result `0x7ff0000000000000L`, an argument of `NEGATIVE_INFINITY` produces the result `0xfff0000000000000L`, and an argument of `NaN` produces the result `0x7ff8000000000000L`.

The value returned by this method can be converted back to the original `double` value by the `longBitsToDouble()` method.

isInfinite

```
static public boolean isInfinite(double v)
```

Parameters

`v`

The `double` value to be tested.

Returns

`true` if the specified value is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

This method determines whether or not the specified value is an infinity value.

isNaN

`public static boolean isNaN(double v)`

Parameters

`v`

The `double` value to be tested.

Returns

`true` if the specified value is equal to `NaN`; otherwise `false`.

Description

This method determines whether or not the specified value is NaN.

longBitsToDouble

`public static native double longBitsToDouble(long bits)`

Parameters

`bits`

The `long` value to be converted.

Returns

The `double` value whose representation is the same as the bits in the given `long` value.

Description

This method returns the `double` value whose representation is the same as the bits in the given `double` value. The meaning of the bits in the `long` value is defined by the IEEE 754 floating-point format: bit 63 is the sign bit, bits 62-52 are the exponent, and bits 51-0 are the mantissa. The argument `0x7f80000000000000L` produces the result `POSITIVE_INFINITY` and the argument `0xff80000000000000L` produces the result `NEGATIVE_INFINITY`. Arguments in the ranges `0x7ff0000000000001L` through `0x7fffffffffffffffL` and

`0xfff0000000000001L` through `0xffffffffffffffffL` all produce the result `NaN`.

Except for NaN values not normally used by Java, this method is the inverse of the `doubleToLongBits()` method.

toString

`public static String toString(double d)`

Parameters

`d`

The `double` value to be converted.

Returns

A string representation of the given value.

Description

This method returns a `String` object that contains a representation of the given `double` value.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of `d` is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

valueOf

```
public static Double valueOf(String s) throws NumberFormatException
```

Parameters

`s`

The string to be made into a `Double` object.

Returns

The `Double` object constructed from the string.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `double` literal.

Description

Constructs a `Double` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `double` literal. This method ignores leading and trailing white space in the string.

Instance Methods

byteValue

```
public byte byteValue()
```

Availability

New as of JDK 1.1

Returns

> The value of this object as a `byte`.

Overrides

> `Number.byteValue()`

Description

> This method returns the truncated value of this object as a `byte`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `byte`, the method returns `Byte.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `byte`, the method returns `Byte.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

doubleValue

`public double doubleValue()`

Returns

> The value of this object as a `double`.

Overrides

> `Number.doubleValue()`

Description

> This method returns the value of this object as a `double`.

equals

`public boolean equals(Object obj)`

Parameters

> `obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Double` and it contains the same value as the object this method is associated with. More specifically, the method returns `true` if the `doubleToLongBits()` method returns the same result for the values of both objects.

This method produces a different result than the `==` operator when both values are `NaN`. In this case, the `==` operator produces `false`, while this method returns `true`. By the same token, the method also produces a different result when the two values are `+0.0` and `-0.0`. In this case, the `==` operator produces `true`, while this method returns `false`.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns this object value as a `float`. Rounding may occur.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `double` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object. More specifically, if `d` is the value of the object, and `bitValue` is defined as:

```
long bitValue = Double.doubleToLongBits(d)
```

then the hashcode returned by this method is computed as follows:

```
(int)(bitValue ^ (bitValue>>>32))
```

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the truncated value of this object as an `int`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `int`, the method returns `Integer.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `int`, the method returns `Integer.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

isInfinite

`public boolean isInfinite()`

Returns

> `true` if the value of this object is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

> This method determines whether or not the value of this object is an infinity value.

isNaN

`public boolean isNaN()`

Returns

> `true` if the value of this object is equal to `NaN`; otherwise `false`.

Description

> This method determines whether or not the value of this object is NaN.

longValue

`public long longValue()`

Returns

> The value of this object as a `long`.

Overrides

> `Number.longValue()`

Description

> This method returns the truncated value of this object as a `long`. More specifically, if the value of

the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value too large to be represented by a `long`, the method returns `Long.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value too small to be represented by a `long`, the method returns `Long.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

shortValue

`public short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the truncated value of this object as a `short`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `short`, the method returns `Short.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `short`, the method returns `Short.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

toString

`public String toString()`

Returns

A string representation of the value of this object.

Overrides

```
Object.toString()
```

Description

This method returns a `String` object that contains a representation of the value of this object.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of this object is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

Error

Name

Error

Synopsis

Class Name:

`java.lang.Error`

Superclass:

`java.lang.Throwable`

Immediate Subclasses:

`java.awt.AWTError`, `java.lang.LinkageError`,

`java.lang.ThreadDeath`,

`java.lang.VirtualMachineError`

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Error` class is the superclass of all of the standard error classes that can be thrown in Java. The subclasses of `Error` are normally thrown by the class loader, the virtual machine, or other support code. Application-specific code should not normally throw any of the standard error classes.

An `Error` or one of its subclasses is typically thrown when an unpredictable run-time error, such as running out of memory, occurs. Because of the unpredictable nature of the events that cause errors to be thrown, a method does not have to declare the `Error` class or any of its subclasses in the `throws` clause of its method declaration.

A Java program should not try to handle the standard error classes. Most of these error classes represent nonrecoverable errors and as such, they cause the Java run-time system to print an error message and terminate program execution.

Class Summary

```
public class java.lang.Error extends java.lang.Throwable {
  // Constructors
  public Error();
  public Error(String s);
}
```

Constructors

Error

public Error()

Description

> This constructor creates an `Error` with no associated detail message.

public Error(String s)

Parameters

> `s`
>
> > The detail message.

Description

This constructor creates an `Error` with the specified detail message.

Inherited Methods

`java.text.FormatException`,

`java.util.TooManyListenersException`,

`java.util.zip.DataFormatException`

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Exception` class is the superclass of all of the standard exception classes that can be thrown in Java. The subclasses of `Exception` represent exceptional conditions a normal Java program may want to handle. Any explicitly thrown object in a Java program should be an instance of a subclass of `Exception`.

Many of the standard exceptions are also subclasses of `RuntimeException`. Run-time exceptions represent run-time conditions that can occur generally in any Java method, so a method is not required to declare that it throws any of the run-time exceptions. However, if a method can throw any of the other standard exceptions, it must declare them in its `throws` clause.

A Java program should try to handle all of the standard exception classes, since they represent routine abnormal conditions that should be anticipated and caught to prevent program termination.

Class Summary

```
public class java.lang.Exception extends java.lang.Throwable {
  // Constructors
  public Exception();
  public Exception(String s);
}
```

Constructors

Exception

public Exception()

Description

This constructor creates an `Exception` with no associated detail message.

public Exception(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `Exception` with the specified message.

Inherited Methods

ExceptionInInitializerError

Name

ExceptionInInitializerError

Synopsis

Class Name:

`java.lang.ExceptionInInitializerError`

Superclass:

`java.lang.LinkageError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `ExceptionInInitializerError` is thrown when an unexpected exception has been thrown in a static initializer.

Class Summary

```
public class java.lang.ExceptionInInitializer
             extends java.lang.LinkageError {
  // Constructors
  public ExceptionInInitializerError();
  public ExceptionInInitializerError(Throwable thrown);
  public ExceptionInInitializerError(String s);
  // Instance Methods
  public Throwable getException();
}
```

Constructors

ExceptionInInitializerError

public ExceptionInInitializerError()

Description

This constructor creates an `ExceptionInInitializerError` with no associated detail message.

public ExceptionInInitializerError(Throwable thrown)

Parameters

`thrown`

The exception that was thrown in the static initializer.

Description

This constructor creates an `ExceptionInInitializerError` that refers to the specified exception.

public ExceptionInInitializerError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `ExceptionInInitializerError` with the specified detail message.

Instance Methods

getException

public Throwable getException()

Returns

The exception object that was thrown in the static initializer.

Description

This methods returns the exception that caused this error to be thrown.

Inherited Methods

Method	Inherited From	Method	Inherited From

Float

Name

Float

Synopsis

Class Name:

    java.lang.Float

Superclass:

    java.lang.Number

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The Float class provides an object wrapper for a float value. This is useful when you need to treat a float value as an object. For example, there are a number of utility methods that take a reference to an Object as one of their arguments. You cannot specify a float value for one of these arguments, but you can provide a reference to a Float object that encapsulates the float value. Furthermore, as of JDK 1.1, the Float class is necessary to support the Reflection API and class literals.

In Java, float values are represented using the IEEE 754 format. The Float class provides constants for the three special values that are mandated by this format: POSITIVE_INFINITY, NEGATIVE_INFINITY, and NaN (not-a-number).

The Float class also provides some utility methods, such as methods for determining whether a floatx value is an infinity value or NaN, for converting float values to other primitive types, and for converting a float to a String and vice versa.

Class Summary

```
public final class java.lang.Float extends java.lang.Number {
    // Constants
    public static final float MIN_VALUE;
    public static final float MAX_VALUE;
    public static final float NaN;
    public static final float NEGATIVE_INFINITY;
    public static final float POSITIVE_INFINITY;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Float(double value);
    public Float(float value);
    public Float(String s);
    // Class Methods
    public static native int floatToIntBits(float value);
    public static native float intBitsToFloat(int bits);
    public static boolean isInfinite(float v);
    public static boolean isNaN(float v);
    public static String toString(float f);
    public static Float valueOf(String s);
    // Instance Methods
    public byte byteValue();                           // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public boolean isInfinite();
    public boolean isNaN();
    public long longValue();
    public short shortValue();                         // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final float MAX_VALUE = 3.40282346638528860e+38f`

Description

> The largest value that can be represented by a `float`.

MIN_VALUE

`public static final float MIN_VALUE = 1.40129846432481707e-45f`

Description

> The smallest value that can be represented by a `float`.

NaN

`public static final float NaN = 0.0f / 0.0f`

Description

> This variable represents the value NaN, a special value produced by `float` operations such as division of zero by zero. When NaN is one of the operands, most arithmetic operations return NaN as the result. Most comparison operators (<, <=, ==, >=, >) return `false` when one of their arguments is NaN. The exception is `!=`, which returns `true` when one of its arguments is NaN.

NEGATIVE_INFINITY

`public static final float NEGATIVE_INFINITY = -1.0f / 0.0f`

Description

> This variable represents the value negative infinity, which is produced when a `float` operation underflows or a negative `float` value is divided by zero. Negative infinity is by definition less than any other `float` value.

POSITIVE_INFINITY

`public static final float POSITIVE_INFINITY = 1.0f / 0.0f`

Description

> This variable represents the value positive infinity, which is produced when a `float` operation overflows or a positive `float` value is divided by zero. Positive infinity is by definition greater than any other `float` value.

TYPE

`public static final Class TYPE`

Availability

> New as of JDK 1.1

Description

> The `Class` object that represents the type `float`. It is always true that `Float.TYPE` == `float.class`.

Constructors

Float

`public Float(double value)`

Parameters

`value`

The `double` value to be encapsulated by this object.

Description

Creates a `Float` object with the specified `double` value. The value is rounded to `float` precision.

public Float(float value)

Parameters

`value`

The `float` value to be encapsulated by this object.

Description

Creates a `Float` object with the specified `float` value.

public Float(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Float` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `float` literal.

Description

Constructs a `Float` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `float` literal.

Class Methods

floatToIntBits

public static native int floatToIntBits(float value)

Parameters

> value
>
> > The float value to be converted.

Returns

> The int value that contains the same sequence of bits as the representation of the given float value.

Description

> This method returns the int value that contains the same sequence of bits as the representation of the given float value. The meaning of the bits in the result is defined by the IEEE 754 floating-point format: bit 31 is the sign bit, bits 30-23 are the exponent, and bits 22-0 are the mantissa. An argument of POSITIVE_INFINITY produces the result 0x7f800000, an argument of NEGATIVE_INFINITY produces the result 0xff800000, and an argument of NaN produces the result 0x7fc00000.
>
> The value returned by this method can be converted back to the original float value by the intBitsToFloat() method.

intBitsToFloat

public static native float intBitsToFloat(int bits)

Parameters

> bits
>
> > The int value to be converted.

Returns

The `float` value whose representation is the same as the bits in the given `int` value.

Description

This method returns the `float` value whose representation is the same as the bits in the given `int` value. The meaning of the bits in the `int` value is defined by the IEEE 754 floating-point format: bit 31 is the sign bit, bits 30-23 are the exponent, and bits 22-0 are the mantissa. The argument `0x7f800000` produces the result `POSITIVE_INFINITY`, and the argument `0xff800000` produces the result `NEGATIVE_INFINITY`. Arguments in the ranges `0x7f800001` through `0x7f8fffff` and `0xff800001` through `0xff8fffffL` all produce the result `NaN`.

Except for NaN values not normally used by Java, this method is the inverse of the `floatToIntBits()` method.

isInfinite

`public static boolean isInfinite(float v)`

Parameters

`v`

The `float` value to be tested.

Returns

`true` if the specified value is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

This method determines whether or not the specified value is an infinity value.

isNaN

`public static boolean isNaN(float v)`

Parameters

`v`

The `float` value to be tested.

Returns

`true` if the specified value is equal to `NaN`; otherwise `false`.

Description

This method determines whether or not the specified value is NaN.

toString

`public static String toString(float f)`

Parameters

`f`

The `float` value to be converted.

Returns

A string representation of the given value.

Description

This method returns a `String` object that contains a representation of the given `float` value.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of `f` is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

valueOf

```
public static Float valueOf(String s) throws NumberFormatException
```

Parameters

`s`

The string to be made into a `Float` object.

Returns

The `Float` object constructed from the string.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `float` literal.

Description

Constructs a `Float` object with the value specified by the given string. The string must contain a sequence of characters that forms a legal `float` literal. This method ignores leading and trailing whitespace in the string.

Instance Methods

byteValue

`public byte byteValue()`

Availability

> New as of JDK 1.1

Returns

> The value of this object as a `byte`.

Overrides

> `Number.byteValue()`

Description

> This method returns the truncated value of this object as a `byte`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `byte`, the method returns `Byte.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `byte`, the method returns `Byte.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

doubleValue

`public double doubleValue()`

Returns

> The value of this object as a `double`.

Overrides

> `Number.doubleValue()`

Description

> This method returns the value of this object as a `double`.

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Float` and it contains the same value as the object this method is associated with. More specifically, the method returns `true` if the `floatToIntBits()` method returns the same result for the values of both objects.

This method produces a different result than the `==` operator when both values are `NaN`. In this case, the `==` operator produces `false`, while this method returns `true`. By the same token, the method also produces a different result when the two values are `+0.0` and `-0.0`. In this case, the `==` operator produces `true`, while this method returns `false`.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `float` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object. More specifically, if `f` is the value of the object, this method returns `Float.floatToIntBits(f)`.

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the truncated value of this object as an `int`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `int`, the method returns `Integer.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `int`, the method returns `Integer.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

isInfinite

`public boolean isInfinite(float v)`

Returns

`true` if the value of this object is equal to `POSITIVE_INFINITY` or `NEGATIVE_INFINITY`; otherwise `false`.

Description

This method determines whether or not the value of this object is an infinity value.

isNaN

`public boolean isNaN()`

Returns

`true` if the value of this object is equal to `NaN`; otherwise `false`.

Description

This method determines whether or not the value of this object is NaN.

longValue

`public long longValue()`

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

> This method returns the truncated value of this object as a `long`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by a `long`, the method returns `Long.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by a `long`, the method returns `Long.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

shortValue

`public short shortValue()`

Availability

> New as of JDK 1.1

Returns

> The value of this object as a `short`.

Overrides

> `Number.shortValue()`

Description

> This method returns the truncated value of this object as a `short`. More specifically, if the value of the object is `NaN`, the method returns 0. If the value is `POSITIVE_INFINITY`, or any other value that is too large to be represented by an `short`, the method returns `Short.MAX_VALUE`. If the value is `NEGATIVE_INFINITY`, or any other value that is too small to be represented by an `short`, the method returns `Short.MIN_VALUE`. Otherwise, the value is rounded toward zero and returned.

toString

`public String toString()`

Returns

> A string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains a representation of the value of this object.

The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.

For other values, the exact string representation depends on the value being converted. If the absolute value of this object is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.

Note that the definition of this method has changed as of JDK 1.1. Prior to that release, the method provided a string representation that was equivalent to the `%g` format of the `printf` function in C.

ExceptionInInitializerError | BOOK INDEX | IllegalAccessError

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

IllegalAccessError

Name

IllegalAccessError

Synopsis

Class Name:

`java.lang.IllegalAccessError`

Superclass:

`java.lang.IncompatibleClassChangeError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `IllegalAccessError` is thrown when a class attempts to access a field or call a method it does not have access to. Usually this error is caught by the compiler; this error can occur at run-time if the definition of a class changes after the class that references it was last compiled.

Class Summary

```
public class java.lang.IllegalAccessError
             extends java.lang.IncompatibleClassChangeError {
  // Constructors
  public IllegalAccessError();
  public IllegalAccessError(String s);
}
```

Constructors

IllegalAccessError

public IllegalAccessError()

Description

This constructor creates an `IllegalAccessError` with no associated detail message.

public IllegalAccessError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `IllegalAccessError` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`fillInStackTrace()`	`Throwable`	`finalize()`	`Object`

`getClass()`	`Object`	`getLocalizedMessage()`	`Throwable`
`getMessage()`	`Throwable`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`printStackTrace()`	`Throwable`	`printStackTrace(PrintStream)`	`Throwable`
`printStackTrace(PrintWriter)`	`Throwable`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Description

An `IllegalAccessException` is thrown when a program tries to dynamically load a class (i.e., uses the forName() method of the Class class, or the findSystemClass() or the loadClass() method of the ClassLoader class) and the currently executing method does not have access to the specified class because it is in another package and not public. This exception is also thrown when a program tries to create an instance of a class (i.e., uses the newInstance() method of the Class class) that does not have a zero-argument constructor accessible to the caller.

Class Summary

```
public class java.lang.IllegalAccessException extends java.lang.Exception {
  // Constructors
  public IllegalAccessException();
  public IllegalAccessException(String s);
}
```

Constructors

IllegalAccessException

public IllegalAccessException()

Description

This constructor creates an IllegalAccessException with no associated detail message.

public IllegalAccessException(String s)

Parameters

s

The detail message.

Description

This constructor creates an IllegalAccessException with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	equals(Object)	Object

IncompatibleClassChangeError

Name

IncompatibleClassChangeError

Synopsis

Class Name:

`java.lang.IncompatibleClassChangeError`

Superclass:

`java.lang.LinkageError`

Immediate Subclasses:

`java.lang.AbstractMethodError`,

`java.lang.IllegalAccessError`,

`java.lang.InstantiationError`,

`java.lang.NoSuchFieldError`,

`java.lang.NoSuchMethodError`

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `IncompatibleClassChangeError` or one of its subclasses is thrown when a class refers to another class in an incompatible way. This situation occurs when the current definition of the referenced class is incompatible with the definition of the class that was found when the referring class was compiled. For example, say class `A` refers to a method in class `B`. Then, after class `A` is compiled, the method is removed from class `B`. When class `A` is loaded, the run-time system discovers that the method in class `B` no longer exists and throws an error.

Class Summary

```
public class java.lang.IncompatibleClassChangeError
             extends java.lang.LinkageError {
  // Constructors
  public IncompatibleClassChangeError();
  public IncompatibleClassChangeError(String s);
}
```

Constructors

IncompatibleClassChangeError

public IncompatibleClassChangeError()

Description

This constructor creates an `IncompatibleClassChangeError` with no associated detail message.

public IncompatibleClassChangeError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `IncompatibleClassChangeError` with the specified detail message.

IncompatibleClassChangeError BOOK INDEX Integer

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Integer

Name

Integer

Synopsis

Class Name:

> `java.lang.Integer`

Superclass:

> `java.lang.Number`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> JDK 1.0 or later

Description

The `Integer` class provides an object wrapper for an `int` value. This is useful when you need to treat an `int` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify an `int` value for one of these arguments, but you can provide a reference to an `Integer` object that encapsulates the `int` value. Also, as of JDK 1.1, the `Integer` class is necessary to support the

Reflection API and class literals.

The `Integer` class also provides a number of utility methods for converting `int` values to other primitive types and for converting `int` values to strings and vice versa.

Class Summary

```
public final class java.lang.Integer extends java.lang.Number {
    // Constants
    public static final int MAX_VALUE;
    public static final int MIN_VALUE;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Integer(int value);
    public Integer(String s);
    // Class Methods
    public static Integer decode(String nm)            // New in 1.1
    public static Integer getInteger(String nm);
    public static Integer getInteger(String nm, int val);
    public static Integer getInteger(String nm, Integer val);
    public static int parseInt(String s);
    public static int parseInt(String s, int radix;
    public static String toBinaryString(long i);
    public static String toHexString(long i);
    public static String toOctalString(long i);
    public static String toString(int i);
    public static String toString(int i, int radix);
    public static Integer valueOf(String s);
    public static Integer valueOf(String s, int radix);
    // Instance Methods
    public byte byteValue();                           // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public long longValue();
    public short shortValue();                         // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final int MAX_VALUE = 0x7fffffff // 2147483647`

Description

The largest value that can be represented by an `int`.

MIN_VALUE

`public static final int MIN_VALUE = 0x80000000 // -2147483648`

Description

The smallest value that can be represented by an `int`.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `int`. It is always true that `Integer.TYPE` == `int.class`.

Constructors

Integer

`public Integer(int value)`

Parameters

`value`

The `int` value to be encapsulated by this object.

Description

Creates an `Integer` object with the specified `int` value.

`public Integer(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into an `Integer` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `int` literal.

Description

Constructs an `Integer` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

decode

`public static Integer decode(String nm)`

Availability

New as of JDK 1.1

Parameters

`nm`

A `String` representation of the value to be encapsulated by an `Integer` object. If the string begins with # or `0x`, it is a radix 16 representation of the value. If the string begins with `0`, it is a radix 8 representation of the value. Otherwise, it is assumed to be a radix 10 representation of the value.

Returns

An `Integer` object that encapsulates the given value.

Throws

`NumberFormatException`

If the `String` contains any nondigit characters other than a leading minus sign or the value represented by the `String` is less than `Integer.MIN_VALUE` or greater than `Integer.MAX_VALUE`.

Description

This method returns an `Integer` object that encapsulates the given value.

getInteger

`public static Integer getInteger(String nm)`

Parameters

`nm`

The name of a system property.

Returns

The value of the system property as an `Integer` object, or an `Integer` object with the value 0 if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as an `Integer` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Integer getInteger(String nm, int val)`

Parameters

`nm`

The name of a system property.

`val`

A default `int` value for the property.

Returns

The value of the system property as an `Integer` object, or an `Integer` object with the value `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as an `Integer` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Integer getInteger(String nm, Integer val)`

Parameters

`nm`

The name of a system property.

`val`

A default `Integer` value for the property.

Returns

The value of the system property as an `Integer` object, or the `Integer` object `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as an `Integer` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's as a decimal integer.

parseInt

`public static int parseInt(String s) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to an `int` value.

Returns

The numeric value of the integer represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer.

Description

This method returns the numeric value of the integer represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static int parseInt(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to an `int` value.

`radix`

The radix used in interpreting the characters in the `String` as digits. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If `radix` is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the integer represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer, or `radix` is not in the appropriate range.

Description

This method returns the numeric value of the integer represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toBinaryString

`public static String toBinaryString(int value)`

Parameters

`value`

The `int` value to be converted to a string.

Returns

A string that contains the binary representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned binary number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^32 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more `0' and `1' characters. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method begins with `1'.

toHexString

`public static String toHexString(int value)`

Parameters

`value`

The `int` value to be converted to a string.

Returns

A string that contains the hexadecimal representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned hexadecimal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^32 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', `9', `a', `b', `c', `d', `e', and `f'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with `0'.

To produce a string that contains upper- instead of lowercase letters, use the `String.toUpperCase()` method.

toOctalString

`public static String toOctalString(int value)`

Parameters

`value`

The `int` value to be converted to a string.

Returns

A string that contains the octal representation of the given value.

Description

This method returns a `String` object that contains a representation of the given value as an unsigned octal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^32 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', and `7'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with `0'.

toString

`public static String toString(int i)`

Parameters

`i`

The `int` value to be converted to a string.

Returns

The string representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

public static String toString(int i, int radix)

Parameters

i

The int value to be converted to a string.

radix

The radix used in converting the value to a string. This value must be in the range Character.MIN_RADIX to Character.MAX_RADIX.

Returns

The string representation of the given value in the specified radix.

Description

This method returns a String object that contains the representation of the given value in the specified radix.

This method returns a string that begins with `-' if the given value is negative. The rest of the string is a sequence of one or more characters that represent the magnitude of the given value. The characters that can appear in the sequence are determined by the value of radix. If *N* is the value of radix, the first *N* characters on the following line can appear in the sequence:

```
0123456789abcdefghijklmnopqrstuvwxyz
```

The method does not verify that radix is in the proper range. If radix is less than Character.MIN_RADIX or greater than Character.MAX_RADIX, the value 10 is used instead of the given value.

This method returns "0" if its argument is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

valueOf

public static Integer valueOf(String s) throws NumberFormatException

Parameters

s

The string to be made into an `Integer` object.

Returns

The `Integer` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer.

Description

Constructs an `Integer` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Integer valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into an `Integer` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Integer` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of an integer or `radix` is not in the appropriate range.

Description

Constructs an `Integer` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

Instance Methods

byteValue

`public byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`. The high order bits of the value are discarded.

doubleValue

`public double doubleValue()`

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Integer` and it contains the same value as the object this method is associated with.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`. Rounding may occur.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `int` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object.

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`.

longValue

`public long longValue()`

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

`public short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`. The high order bits of the value are discarded.

toString

`public String toString()`

Returns

The string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-' if the value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if the value of the object is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

InstantiationError

Name

InstantiationError

Synopsis

Class Name:

`java.lang.InstantiationError`

Superclass:

`java.lang.IncompatibleClassChangeError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `InstantiationError` is thrown in response to an attempt to instantiate an `abstract` class or interface.

Usually this error is caught by the compiler; this error can occur at run-time if the definition of a class is changed after the class that references it was last compiled.

Class Summary

```
public class java.lang.InstantiationError
             extends java.lang.IncompatibleClassChangeError {
  // Constructors
  public InstantiationError();
  public InstantiationError(String s);
}
```

Constructors

InstantiationError

public InstantiationError()

Description

This constructor creates an `InstantiationError` with no associated detail message.

public InstantiationError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `InstantiationError` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`fillInStackTrace()`	`Throwable`	`finalize()`	`Object`

`getClass()`	`Object`	`getLocalizedMessage()`	`Throwable`
`getMessage()`	`Throwable`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`printStackTrace()`	`Throwable`	`printStackTrace(PrintStream)`	`Throwable`
`printStackTrace(PrintWriter)`	`Throwable`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

InstantiationException

Synopsis

Class Name:

`java.lang.InstantiationException`

Superclass:

`java.lang.Exception`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `InstantiationException` is thrown in response to an attempt to instantiate an abstract class or an interface using the `newInstance()` method of the `Class` class.

Class Summary

```
public class java.lang.InstantiationException extends java.lang.Exception {
  // Constructors
  public InstantiationException();
  public InstantiationException(String s);
}
```

Constructors

InstantiationException

public InstantiationException()

Description

This constructor creates an `InstantiationException` with no associated detail message.

public InstantiationException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `InstantiationException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

InternalError

Name

InternalError

Synopsis

Class Name:

`java.lang.InternalError`

Superclass:

`java.lang.VirtualMachineError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `InternalError` is thrown to signal an internal error within the virtual machine.

Class Summary

```
public class java.lang.InternalError extends java.lang.VirtualMachineError {
  // Constructors
  public InternalError();
  public InternalError(String s);
}
```

Constructors

InternalError

public InternalError()

Description

This constructor creates an `InternalError` with no associated detail message.

public InternalError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `InternalError` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Long

Name

Long

Synopsis

Class Name:

`java.lang.Long`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Long` class provides an object wrapper for a `long` value. This is useful when you need to treat a `long` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `long` value for one of these arguments, but you can provide a reference to a `Long` object that encapsulates the `long` value. Furthermore, as of JDK 1.1, the `Long` class is necessary to support the Reflection API and class literals.

The `Long` class also provides a number of utility methods for converting `long` values to other primitive types and for converting `long` values to strings and vice versa.

Class Summary

```
public final class java.lang.Long extends java.lang.Number {
    // Constants
    public static final long MIN_VALUE;
    public static final long MAX_VALUE;
    public final static Class TYPE;                   // New in 1.1
    // Constructors
    public Long(long value);
    public Long(String s);
    // Class Methods
    public static Long getLong(String nm);
    public static Long getLong(String nm, long val);
    public static Long getLong(String nm, Long val);
    public static long parseLong(String s);
    public static long parseLong(String s, int radix);
    public static String toBinaryString(long i);
    public static String toHexString(long i);
    public static String toOctalString(long i);
    public static String toString(long i);
    public static String toString(long i, int radix);
    public static Long valueOf(String s);
    public static Long valueOf(String s, int radix);
    // Instance Methods
    public byte byteValue();                          // New in 1.1
    public double doubleValue();
    public boolean equals(Object obj);
    public float floatValue();
    public int hashCode();
    public int intValue();
    public long longValue();
    public short shortValue();                        // New in 1.1
    public String toString();
}
```

Constants

MAX_VALUE

`public static final long MAX_VALUE = 0x7fffffffffffffffL`

Description

The largest value that can be represented by a `long`.

MIN_VALUE

`public static final long MIN_VALUE = 0x8000000000000000L`

Description

The smallest value that can be represented by a `long`.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `long`. It is always true that `Long.TYPE` == `long.class`.

Constructors

Long

`public Long(long value)`

Parameters

`value`

The `long` value to be encapsulated by this object.

Description

Creates a `Long` object with the specified `long` value.

`public Long(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Long` object.

Throws

`NumberFormatException`

If the sequence of characters in the given `String` does not form a valid `long` literal.

Description

Constructs a `Long` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

getLong

`public static Integer getLong(String nm)`

Parameters

`nm`

The name of a system property.

Returns

The value of the system property as a `Long` object or a `Long` object with the value 0 if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as a `Long` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or `#` and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Long getLong(String nm, long val)`

Parameters

`nm`

The name of a system property.

`val`

A default value for the property.

Returns

The value of the system property as a `Long` object or a `Long` object with the value `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as a `Long` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or # and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

`public static Long getLong(String nm, Long val)`

Parameters

`nm`

The name of a system property.

`val`

A default value for the property.

Returns

The value of the system property as a `Long` object, or the `Long` object `val` if the named property does not exist or cannot be parsed.

Description

This method retrieves the value of the named system property and returns it as a `Long` object. The method obtains the value of the system property as a `String` using `System.getProperty()`.

If the value of the property begins with `0x` or # and is not followed by a minus sign, the rest of the value is parsed as a hexadecimal integer. If the value begins with `0`, it's parsed as an octal integer; otherwise it's parsed as a decimal integer.

parseLong

`public static long parseLong(String s) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a `long` value.

Returns

The numeric value of the `long` represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long` value.

Description

This method returns the numeric value of the `long` represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static long parseLong(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a `long` value.

`radix`

The radix used in interpreting the characters in the `String` as digits. It must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If `radix` is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' may be considered valid digits.

Returns

The numeric value of the `long` represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long` or `radix` is not in the appropriate range.

Description

This method returns the numeric value of the `long` represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toBinaryString

`public static String toBinaryString(long value)`

Parameters

`value`

The `long` value to be converted to a string.

Returns

A string that contains the binary representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned binary number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^64 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more `0' and `1' characters. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method begins with `1'.

toHexString

`public static String toHexString(long value)`

Parameters

`value`

The `long` value to be converted to a string.

Returns

A string that contains the hexadecimal representation of the given value.

Description

This method returns a `String` object that contains the representation of the given value as an unsigned hexadecimal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^64 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', `9', `a', `b', `c', `d', `e', and `f'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with `0'.

To produce a string that contains upper- instead of lowercase letters, use the `String.toUpperCase()` method.

toOctalString

`public static String toOctalString(long value)`

Parameters

`value`

The `long` value to be converted to a string.

Returns

A string that contains the octal representation of the given value.

Description

This method returns a `String` object that contains a representation of the given value as an unsigned octal number. To convert the given value to an unsigned quantity, the method simply uses the value as if it were not negative. In other words, if the given value is negative, the method adds 2^64 to it. Otherwise the value is used as it is.

The string returned by this method contains a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', and `7'. The method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with `0'.

toString

`public static String toString(long i)`

Parameters

`i`

The `long` value to be converted to a string.

Returns

The string representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `` `-' `` if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "`-0`".

`public static String toString(long i, int radix)`

Parameters

`i`

The `long` value to be converted to a string.

`radix`

The radix used in converting the value to a string. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The string representation of the given value in the specified radix.

Description

This method returns a `String` object that contains the representation of the given value in the specified radix.

This method returns a string that begins with`` `-' `` if the given value is negative. The rest of the string is a sequence of one or more characters that represent the magnitude of the given value. The characters that can appear in the sequence are determined by the value of `radix`. If *N* is the value of `radix`, the first *N* characters on the following line can appear in the sequence:

`0123456789abcdefghijklmnopqrstuvwxyz`

The method does not verify that `radix` is in the proper range. If `radix` is less than `Character.MIN_RADIX` or greater than `Character.MAX_RADIX`, the value 10 is used instead of the given value.

This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "`-`0".

valueOf

`public static Long valueOf(String s) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Long` object.

Returns

The `Long` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long`.

Description

Constructs a `Long` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `-` character. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Long valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Long` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Long` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `long`.

Description

Constructs a `Long` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

The method does not verify that `radix` is in the proper range. If `radix` is less than `Character.MIN_RADIX` or greater than `Character.MAX_RADIX`, the value 10 is used instead of the given value.

Instance Methods

byteValue

`public byte byteValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`. The high order bits of the value are discarded.

doubleValue

`public double doubleValue()`

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`. Rounding may occur.

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Long` and it contains the same value as the object this method is associated with.

floatValue

`public float floatValue()`

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`. Rounding may occur.

hashCode

`public int hashCode()`

Returns

A hashcode based on the `long` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode computed from the value of this object. More specifically, the result is the exclusive OR of the two halves of the `long` value represented by the object. If `value` is the value of the object, the method returns a result equivalent to the following expression:

```
(int)(value^(value>>>32))
```

intValue

`public int intValue()`

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`. The high-order bits of the value are discarded.

longValue

`public long longValue()`

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

`public short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`. The high-order bits of the value are discarded.

toString

`public String toString()`

Returns

The string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `-' if the value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if the value of the object is 0. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

Math

Name

Math

Synopsis

Class Name:

> `java.lang.Math`

Superclass:

> `java.lang.Object`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> JDK 1.0 or later

Description

The `Math` class contains constants for the mathematical values pi and *e*. The class also defines methods that compute various mathematical functions, such as trigonometric and exponential functions. All of these constants and methods are `static`. In other words, it is not necessary to create an instance of the `Math` class in order to use its constants and methods. In fact, the `Math` class does not define any `public` constructors, so it cannot be instantiated.

To ensure that the methods in this class return consistent results under different implementations of Java, all of the methods use the algorithms from the well-known Freely-Distributable Math Library package, *fdlibm*. This package is part of the network library *netlib*. The library can be obtained through the URL *http://netlib.att.com*. The algorithms used in this class are from the version of *fdlibm* dated January 4, 1995. *fdlibm* provides more than one definition for some functions. In those cases, the "IEEE 754 core function" version is used.

Class Summary

```
public final class java.lang.Math extends java.lang.Object {
    // Constants
    public static final double E;
    public static final double PI;
    // Class Methods
    public static int abs(int a);
    public static long abs(long a);
    public static float abs(float a);
    public static double abs(double a);
    public static native double acos(double a);
    public static native double asin(double a);
    public static native double atan(double a);
    public static native double atan2(double a, double b);
    public static native double ceil(double a);
    public static native double cos(double a);
    public static native double exp(double a);
    public static native double floor(double a);
    public static native double IEEEremainder(double f1, double f2);
    public static native double log(double a);
    public static int max(int a, int b);
    public static long max(long a, long b);
    public static float max(float a, float b);
    public static double max(double a, double b);
    public static int min(int a, int b);
    public static long min(long a, long b);
    public static float min(float a, float b);
    public static double min(double a, double b);
    public static native double pow(double a, double b);
    public static synchronized double random();
    public static native double rint(double a);
    public static int round(float a);
    public static long round(double a);
    public static native double sin(double a);
    public static native double sqrt(double a);
    public static native double tan(double a);
}
```

Constants

E

`public static final double E = 2.7182818284590452354`

Description

> The value of this constant is *e*, the base for natural logarithms.

PI

`public static final double PI = 3.14159265358979323846`

Description

> The value for this constant is pi.

Class Methods

abs

`public static double abs(double a)`

Parameters

`a`

A `double` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument to this method is negative or positive zero, the method should return positive zero. If the argument is positive or negative infinity, the method returns positive infinity. If the argument is NaN, the method returns NaN.

`public static float abs(float a)`

Parameters

`a`

A `float` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument to this method is negative or positive zero, the method should return positive zero. If the argument is positive or negative infinity, the method returns positive infinity. If the argument is NaN, the method returns NaN.

`public static int abs(int a)`

Parameters

`a`

An `int` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument is `Integer.MIN_VALUE`, the method actually returns `Integer.MIN_VALUE` because the true absolute value of `Integer.MIN_VALUE` is one greater than the largest positive value that can be represented by an `int`.

`public static long abs(long a)`

Parameters

`a`

A `long` value.

Returns

The absolute value of its argument.

Description

This method returns the absolute value of its argument.

If the argument is `Long.MIN_VALUE`, the method actually returns `Long.MIN_VALUE` because the true absolute value of `Long.MIN_VALUE` is one greater than the largest positive value represented by a `long`.

acos

`public static native double acos(double a)`

Parameters

`a`

A `double` value greater than or equal to `-1.0` and less than or equal to `1.0`.

Returns

The arc cosine measured in radians; the result is greater than or equal to `0.0` and less than or equal to pi.

Description

This method returns the arc cosine of the given value.

If the value is NaN or its absolute value is greater than `1.0`, the method returns NaN.

asin

`public static native double asin(double a)`

Parameters

`a`

A `double` value greater than or equal to `-1.0` and less than or equal to `1.0`.

Returns

The arc sine measured in radians; the result is greater than or equal to -pi/2 and less than or equal to pi/2.

Description

This method returns the arc sine of the given value.

If the value is NaN or its absolute value is greater than `1.0`, the method returns NaN. If the value is positive zero, the method returns positive zero. If the value is negative zero, the method returns negative zero.

atan

`public static native double atan(double a)`

Parameters

`a`

A `double` value greater than or equal to `-1.0` and less than or equal to `1.0`.

Returns

The arc tangent measured in radians; the result is greater than or equal to -pi/2 and less than or equal to pi/2.

Description

This method returns the principle value of the arc tangent of the given value.

If the value is NaN, the method returns NaN. If the value is positive zero, the method returns positive zero. If the value is negative zero, the method returns negative zero.

atan2

`public static native double atan2(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The theta component of the polar coordinate (*r*,theta) that corresponds to the cartesian coordinate (`a`,`b`); the result is measured in radians and is greater than or equal to -pi and less than or equal to pi.

Description

This method returns the theta component of the polar coordinate (*r*,theta) that corresponds to the cartesian coordinate (`a`,`b`). It computes theta as the principle value of the arc tangent of `b`/`a`, using the signs of both arguments to determine the quadrant (and sign) of the return value.

If either argument is NaN, the method returns NaN.

If the first argument is positive zero and the second argument is positive, then the method returns positive zero. If the first argument is positive zero and the second argument is negative, then the method returns the `double` value closest to pi.

If the first argument is negative zero and the second argument is positive, the method returns negative zero. If the first argument is negative zero and the second argument is negative, the method returns the `double` value closest to -pi.

If the first argument is positive and finite and the second argument is positive infinity, the method returns positive zero. If the first argument is positive and finite and the second argument is negative infinity, the method returns the `double` value closest to pi.

If the first argument is negative and finite and the second argument is positive infinity, the method returns negative zero. If the first argument is negative and finite and the second argument is negative infinity, the method returns the `double` value closest to -pi.

If the first argument is positive and the second argument is positive zero or negative zero, the method returns the `double` value closest to pi/2. If the first argument is negative and the second argument is positive or negative zero, the method returns the `double` value closest to -pi/2.

If the first argument is positive infinity and the second argument is finite, the method returns the `double` value closest to pi/2. If the first argument is negative infinity and the second argument is finite, the method returns the `double` value closest to -pi/2.

If both arguments are positive infinity, the method returns the `double` value closest to pi/4. If the first argument is positive infinity and the second argument is negative infinity, the method returns the `double` value closest to 3pi/4. If the first argument is negative infinity and the second argument is positive infinity, the method returns the `double` value closest to -pi/4. If both arguments are negative infinity, the method returns the `double` value closest to -3pi/4.

ceil

```
public static native double ceil(double a)
```

Parameters

`a`

A `double` value.

Returns

The smallest integer greater than or equal to the given value.

Description

This method performs the ceiling operation. It returns the smallest integer that is greater than or equal to its argument.

If the argument is NaN, an infinity value, or a zero value, the method returns that same value. If the argument is less than zero but greater than `-1.0`, the method returns negative zero.

cos

`public static native double cos(double a)`

Parameters

`a`

A `double` value that's an angle measured in radians.

Returns

The cosine of the given angle.

Description

This method returns the cosine of the given angle measured in radians.

If the angle is NaN or an infinity value, the method returns NaN.

exp

`public static native double exp(double a)`

Parameters

`a`

A `double` value.

Returns

`e^a`

Description

This method returns the exponential function of `a`. In other words, *e* is raised to the value specified by the parameter `a`, where *e* is the base of the natural logarithms.

If the value is NaN, the method returns NaN. If the value is positive infinity, the method returns positive infinity. If the value is negative infinity, the method returns positive zero.

floor

`public static native double floor(double a)`

Parameters

`a`

A `double` value.

Returns

The greatest integer less than or equal to the given value.

Description

This method performs the floor operation. It returns the largest integer that is less than or equal to its argument.

If the argument is NaN, an infinity value, or a zero value, the method returns that same value.

IEEEremainder

`public static native double IEEEremainder(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The remainder of `a` divided by `b` as defined by the IEEE 754 standard.

Description

This method returns the remainder of `a` divided by `b` as defined by the IEEE 754 standard. This operation involves first determining the mathematical quotient of `a`/`b` rounded to the nearest integer. If the quotient is equally close to two integers, it is rounded to the even integer. The method then returns `a-(b x` *`Q`*`)`, where *`Q`* is the rounded quotient.

If either argument is NaN, the method returns NaN. If the first argument is positive or negative infinity and the second argument is positive or negative zero, the method also returns NaN. If the first argument is a finite value and the second argument is positive or negative infinity, the method returns its first argument.

log

`public static native double log(double a)`

Parameters

`a`

A `double` value that is greater than `0.0`.

Returns

The natural logarithm of `a`.

Description

This method returns the natural logarithm (base *e*) of its argument.

In particular, if the argument is positive infinity, the method returns positive infinity. If the argument is positive or negative zero, the method returns negative infinity. If the argument is less than zero, the method returns NaN. If the argument is NaN, the method returns NaN.

max

`public static double max(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to positive infinity.

If one argument is positive zero and the other is negative zero, the method returns positive zero. If either argument is NaN, the method returns NaN.

`public static float max(float a, float b)`

Parameters

`a`

A `float` value.

`b`

A `float` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to positive infinity.

If one argument is positive zero and the other is negative zero, the method returns positive zero. If either argument is NaN, the method returns NaN.

`public static int max(int a, int b)`

Parameters

`a`

An `int` value.

`b`

An `int` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to `Integer.MAX_VALUE`.

`public static long max(long a, long b)`

Parameters

`a`

A `long` value.

`b`

A `long` value.

Returns

The greater of `a` and `b`.

Description

This method returns the greater of its two arguments. In other words, it returns the one that is closer to `Long.MAX_VALUE`.

min

`public static double min(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to negative infinity.

If one argument is positive zero and the other is negative zero, the method returns negative zero. If either argument is NaN, the method returns NaN.

`public static float min(float a, float b)`

Parameters

`a`

A `float` value.

`b`

A `float` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to negative infinity.

If one argument is positive zero and the other is negative zero, the method returns negative zero. If either argument is NaN, the method returns NaN.

`public static int min(int a, int b)`

Parameters

`a`

An `int` value.

`b`

An `int` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to `Integer.MIN_VALUE`.

`public static long min(long a, long b)`

Parameters

`a`

A `long` value.

`b`

A `long` value.

Returns

The lesser of `a` and `b`.

Description

This method returns the lesser of its two arguments. In other words, it returns the one that is closer to `Long.MIN_VALUE`.

pow

`public static native double pow(double a, double b)`

Parameters

`a`

A `double` value.

`b`

A `double` value.

Returns

`a^b`

Description

This method computes the value of raising `a` to the power of `b`.

If the second argument is positive or negative zero, the method returns `1.0`. If the second argument is `1.0`, the method returns its first argument. If the second argument is NaN, the method returns NaN. If the first argument is NaN and the second argument is nonzero, the method returns NaN.

If the first argument is positive zero and the second argument is greater than zero, the method returns positive zero. If the first argument is positive zero and the second argument is less than zero, the method returns positive infinity.

If the first argument is positive infinity and the second argument is less than zero, the method returns positive zero. If the first argument is positive infinity and the second argument is greater than zero, the method returns positive infinity.

If the absolute value of the first argument is greater than `1` and the second argument is positive infinity, the method returns positive infinity. If the absolute value of the first argument is greater than `1` and the second argument is negative infinity, the method returns positive zero. If the absolute value of the first argument is less than `1` and the second argument is negative infinity, the method returns positive infinity. If the absolute value of the first argument is less than `1` and the second argument is positive infinity, the method returns positive zero. If the absolute value of the first argument is `1` and the second argument is positive or negative infinity, the method returns NaN.

If the first argument is negative zero and the second argument is greater than zero but not a finite odd integer, the method returns positive zero. If the first argument is negative zero and the second argument is a positive finite odd integer, the method returns negative zero. If the first argument is negative zero and the second argument is less than zero but not a finite odd integer, the method returns positive infinity. If the first argument is negative zero and the second argument is a negative finite odd integer, the method returns negative infinity.

If the first argument is negative infinity and the second argument is less than zero but not a finite odd integer, the method returns positive zero. If the first argument is negative infinity and the second argument is a negative finite odd integer, the method returns negative zero. If the first argument is negative infinity and the second argument is greater than zero but not a finite odd integer, the method returns positive infinity. If the first argument is negative infinity and the second argument is a positive finite odd integer, the method returns negative infinity.

If the first argument is less than zero and the second argument is a finite even integer, the method returns the result of the absolute value of the first argument raised to the power of the second argument. If the first argument is less than zero and the second argument is a finite odd integer, the method returns the negative of the result of the absolute value of the first argument raised to the power of the second argument. If the first argument is finite and less than zero and the second argument is finite and not an integer, the method returns NaN.

If both arguments are integer values, the method returns the first argument raised to the power of the second argument.

random

`public static synchronized double random()`

Returns

A random number between `0.0` and `1.0`.

Description

This method returns a random number greater than or equal to `0.0` and less than `1.0`. The implementation of this method uses the `java.util.Random` class. You may prefer to use the `Random` class directly, in order to gain more control over the distribution, type, and repeatability of the random numbers you are generating.

rint

`public static native double rint(double a)`

Parameters

`a`

A `double` value.

Returns

The value of its argument rounded to the nearest integer.

Description

This method returns its argument rounded to the nearest integer; the result is returned as a `double` value. If the argument is equidistant from two integers (e.g., `1.5`), the method returns the even integer.

If the argument is an infinity value, a zero value, or NaN, the method returns that same value.

round

```
public static long round(double a)
```

Parameters

`a`

A `double` value.

Returns

The value of its argument rounded to the nearest `long`.

Description

This method returns its `double` argument rounded to the nearest integral value and converted to a `long`. If the argument is equidistant from two integers, the method returns the greater of the two integers.

If the argument is positive infinity or any other value greater than `Long.MAX_VALUE`, the method returns `Long.MAX_VALUE`. If the argument is negative infinity or any other value less than `Long.MIN_VALUE`, the method returns `Long.MIN_VALUE`. If the argument is NaN, the method returns `0`.

`public static int round(float a)`

Parameters

`a`

A `float` value.

Returns

The value of its argument rounded to the nearest `int`.

Description

This method returns its `float` argument rounded to the nearest integral value and converted to an `int`. If the argument is equidistant from two integers, the method returns the greater of the two integers.

If the argument is positive infinity or any other value greater than the `Integer.MAX_VALUE`, the method returns `Integer.MAX_VALUE`. If the argument is negative infinity or any other value less than `Integer.MIN_VALUE`, the method returns `Integer.MIN_VALUE`. If the argument is NaN, the method returns `0`.

sin

`public static native double sin(double a)`

Parameters

`a`

A `double` value that's an angle measured in radians.

Returns

The sine of the given angle.

Description

This method returns the sine of the given angle measured in radians.

If the angle is NaN or an infinity value, the method returns NaN. If the angle is positive zero, the method returns positive zero. If the angle is negative zero, the method returns negative zero.

sqrt

`public static native double sqrt(double a)`

Parameters

`a`

A `double` value.

Returns

The square root of its argument.

Description

This method returns the square root of its argument.

If the argument is negative or NaN, the method returns NaN. If the argument is positive infinity, the method returns positive infinity. If the argument is positive or negative zero, the method returns that same value.

tan

`public static native double tan(double a)`

Parameters

`a`

A `double` value that is an angle measured in radians.

Returns

The tangent of the given angle.

Description

This method returns the tangent of the given angle measured in radians.

If the angle is NaN or an infinity value, the method returns NaN. If the angle is positive zero, the method returns positive zero. If the angle is negative zero, the method returns negative zero.

Synopsis

Class Name:

    java.lang.NegativeArraySizeException

Superclass:

    java.lang.RuntimeException

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `NegativeArraySizeException` is thrown in response to an attempt to create an array with a negative size.

Class Summary

```
public class java.lang.NegativeArraySizeException
             extends java.lang.RuntimeException {
  // Constructors
  public NegativeArraySizeException();
  public NegativeArraySizeException(String s);
}
```

Constructors

NegativeArraySizeException

public NegativeArraySizeException()

Description

This constructor creates a `NegativeArraySizeException` with no associated detail message.

public NegativeArraySizeException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `NegativeArraySizeException` with the specified detail message.

NoSuchFieldError

Name

NoSuchFieldError

Synopsis

Class Name:

```
java.lang.NoSuchFieldError
```

Superclass:

```
java.lang.IncompatibleClassChangeError
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `NoSuchFieldError` is thrown in response to an attempt to reference an instance or class variable that is not defined in the current definition of a class. Usually this error is caught by the compiler; it can occur at run-time if the definition of a class is changed after the class that references it was last compiled.

Class Summary

```
public class java.lang.NoSuchFieldError
             extends java.lang.IncompatibleClassChangeError {
  // Constructors
  public NoSuchFieldError();
  public NoSuchFieldError(String s);
}
```

Constructors

NoSuchFieldError

public NoSuchFieldError()

Description

This constructor creates a `NoSuchFieldError` with no associated detail message.

public NoSuchFieldError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `NoSuchFieldError` with the specified detail message.

NullPointerException

Name

NullPointerException

Synopsis

Class Name:

java.lang.NullPointerException

Superclass:

java.lang.RuntimeException

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `NullPointerException` is thrown when there is an attempt to access an object through a `null` object reference. This can occur when there is an attempt to access an instance variable or call a method through a `null` object or when there is an attempt to subscript an array with a `null` object.

Class Summary

```
public class java.lang.NullPointerException
             extends java.lang.RuntimeException {
  // Constructors
  public NullPointerException();
  public NullPointerException(String s);
}

Synopsis

Class Name:

`java.lang.Number`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.lang.Byte`, `java.lang.Double`,

`java.lang.Float`, `java.lang.Integer`,

`java.lang.Long`, `java.lang.Short`,

`java.math.BigDecimal`,

`java.math.BigInteger`

Interfaces Implemented:

java.io.Serializable

Availability:

JDK 1.0 or later

Description

The Number class is an abstract class that serves as the superclass for all of the classes that provide object wrappers for primitive numeric values: byte, short, int, long, float, and double. Wrapping a primitive value is useful when you need to treat such a value as an object. For example, there are a number of utility methods that take a reference to an Object as one of their arguments. You cannot specify a primitive value for one of these arguments, but you can provide a reference to an object that encapsulates the primitive value. Furthermore, as of JDK 1.1, these wrapper classes are necessary to support the Reflection API and class literals.

The Number class defines six methods that must be implemented by its subclasses: byteValue(), shortValue(), intValue(), longValue(), floatValue(), and doubleValue(). This means that a Number object can be fetched as an byte, short, int, long, float, or double value, without regard for its actual class.

Class Summary

```
public abstract class java.lang.Number extends java.lang.Number
                                       implements java.io.Serializable {
    // Instance Methods
    public abstract byte byteValue();                  // New in 1.1
    public abstract double doubleValue();
    public abstract float floatValue();
    public abstract int intValue();
    public abstract long longValue();
    public abstract short shortValue();                // New in 1.1
}
```

Instance Methods

byteValue

public abstract byte byteValue()

Availability

New as of JDK 1.1

Returns

The value of this object as a `byte`.

Description

This method returns the value of this object as a `byte`. If the data type of the value is not `byte`, rounding may occur.

doubleValue

`public abstract double doubleValue()`

Returns

The value of this object as a `double`.

Description

This method returns the value of this object as a `double`. If the data type of the value is not `double`, rounding may occur.

floatValue

`public abstract float floatValue()`

Returns

The value of this object as a `float`.

Description

This method returns the value of this object as a `float`. If the data type of the value is not `float`, rounding may occur.

intValue

`public abstract int intValue()`

Returns

The value of this object as an `int`.

Description

This method returns the value of this object as an `int`. If the type of value is not an `int`, rounding may occur.

longValue

`public abstract long longValue()`

Returns

The value of this object as a `long`.

Description

This method returns the value of this object as a `long`. If the type of value is not a `long`, rounding may occur.

shortValue

`public abstract short shortValue()`

Availability

New as of JDK 1.1

Returns

The value of this object as a `short`.

Description

This method returns the value of this object as a `short`. If the type of value is not a `short`, rounding may occur.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Object

Name

Object

Synopsis

Class Name:

`java.lang.Object`

Superclass:

None

Immediate Subclasses:

Too many to be listed here

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Object` class is the ultimate superclass of all other classes in Java. Because every other class is a subclass of `Object`, all of the methods accessible from `Object` are inherited by every other class. In other words, all objects in Java, including arrays, have access to implementations of the methods in `Object`.

The methods of `Object` provide some basic object functionality. The `equals()` method compares two objects for equality, while the `hashCode()` method returns a hashcode for an object. The `getClass()` method returns the `Class` object associated with an object. The `wait()`, `notify()`, and `notifyAll()` methods support thread synchronization for an object. The `toString()` method provides a string representation of an object.

Some of these methods should be overridden by subclasses of `Object`. For example, every class should provide its own implementation of the `toString()` method, so that it can provide an appropriate string representation.

Although it is possible to create an instance of the `Object` class, this is rarely done because it is more useful to create specialized objects. However, it is often useful to declare a variable that contains a reference to an `Object` because such a variable can contain a reference to an object of any other class.

Class Summary

```
public class java.lang.Object {
    // Constructors
    public Object();
    // Public Instance Methods
    public boolean equals(Object obj);
    public final native Class getClass();
    public native int hashCode();
    public final native void notify();
    public final native void notifyAll();
    public String toString();
    public final native void wait();
    public final native void wait(long millis);
    public final native void wait(long millis, int nanos);
    // Protected Instance Methods
    protected native Object clone();
    protected void finalize() throws Throwable;
}
```

Constructors

Object

`public Object()`

Description

> Creates an instance of the `Object` class.

Public Instance Methods

equals

`public boolean equals(Object obj)`

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Description

The `equals()` method of `Object` returns `true` if the `obj` parameter refers to the same object as the object this method is associated with. This is equivalent to using the == operator to compare two objects.

Some classes, such as `String`, override the `equals()` method to provide a comparison based on the contents of the two objects, rather than on the strict equality of the references. Any subclass can override the `equals()` method to implement an appropriate comparison, as long as the overriding method satisfies the following rules for an equivalence relation:

- The method is *reflexive* : given a reference `x`, `x.equals(x)` returns `true`.
- The method is *symmetric* : given references `x` and `y`, `x.equals(y)` returns `true` if and only if `y.equals(x)` returns `true`.
- The method is *transitive* : given references `x`, `y`, and `z`, if `x.equals(y)` returns `true` and `y.equals(z)` returns `true`, then `x.equals(z)` returns `true`.
- The method is *consistent* : given references `x` and `y`, multiple invocations of `x.equals(y)` consistently return `true` or consistently return `false`, provided that no information contained by the objects referenced by `x` or `y` changes.
- A comparison with `null` returns `false`: given a reference `x` that is non-`null`, `x.equals(null)` returns `false`.

getClass

`public final native Class getClass()`

Returns

A reference to the `Class` object that describes the class of this object.

Description

The `getClass()` method of `Object` returns the `Class` object that describes the class of this object. This method is `final`, so it cannot be overridden by subclasses.

hashCode

`public native int hashCode()`

Returns

A relatively unique value that should be the same for all objects that are considered equal.

Description

The `hashCode()` method of `Object` calculates a hashcode value for this object. The method returns an integer value that should be relatively unique to the object. If the `equals()` method for the object bases its result on the contents of the object, the `hashcode()` method should also base its result on the contents. The `hashCode()` method is provided for the benefit of hashtables, which store and retrieve elements using key values called *hashcodes*. The internal placement of a particular piece of data is determined by its hashcode; hashtables are designed to use hashcodes to provide efficient retrieval.

The `java.util.Hashtable` class provides an implementation of a hashtable that stores values of type `Object`. Each object is stored in the hashtable based on the hash code of its key object. It is important that each object have the most unique hash code possible. If two objects have the same hash code but they are not equal (as determined by `equals()`), a `Hashtable` that stores these two objects may need to spend additional time searching when it is trying to retrieve objects. The implementation of `hashCode()` in `Object` tries to make sure that every object has a distinct hash code by basing its result on the internal representation of a reference to the object.

Some classes, such as `String`, override the `hashCode()` method to produce values based on the contents of individual objects, instead of the objects themselves. In other words, two `String` objects that contain the exact same strings have the same hash code. If `String` did not override the `hashCode()` method inherited from `Object`, these two `String` objects would have different hash code values and it would be impossible to use `String` objects as keys for hashtables.

Any subclass can override the `hashCode()` method to implement an appropriate way of producing hash code values, as long as the overriding method satisfies the following rules:

- If the `hashCode()` method is called on the same object more than once during the execution of a Java application, it must consistently return the same integer value. The integer does not, however, need to be consistent between Java applications, or from one execution of an application to another execution of the same application.
- If two objects compare as equal according to their `equals()` methods, calls to the `hashCode()` methods for the objects must produce the same result.
- If two objects compare as not equal according to their `equals()` methods, calls to the `hashCode()` methods for the two objects are not required to produce distinct results. However, implementations of `hashCode()` that produce distinct results for unequal objects may improve the performance of hashtables.

In general, if a subclass overrides the `equals()` method of `Object`, it should also override the `hashCode()` method.

notify

`public final native void notify()`

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

Description

The `notify()` method wakes up a thread that is waiting to return from a call to this object's `wait()` method. The awakened thread can resume executing as soon as it regains this object's lock. If more than one thread is waiting, the `notify()` method arbitrarily awakens just one of the threads.

The `notify()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

notifyAll

`public final native void notifyAll()`

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

Description

The `notifyAll()` method wakes up all the threads that are waiting to return from a call to this object's `wait()` method. Each awakened thread can resume executing as soon as it regains this object's lock.

The `notifyAll()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

toString

`public String toString()`

Returns

The string representation of this object.

Description

The `toString()` method of `Object` returns a generic string representation of this object. The method returns a `String` that consists of the object's class name, an "at" sign, and the unsigned hexadecimal representation of the value returned by the object's `hashCode()` method.

Many classes override the `toString()` method to provide a string representation that is specific to that type of object. Any subclass can override the `toString()` method; the overriding method should simply return a `String` that represents the contents of the object with which it is associated.

wait

`public final native void wait() throws InterruptedException`

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

`InterruptedException`

If another thread interrupted this thread.

Description

The `wait()` method causes a thread to wait until it is notified by another thread to stop waiting. When `wait()` is called, the thread releases its lock on this object and waits until another thread notifies it to wake up through a call to either `notify()` or `notifyAll()`. After the thread is awakened, it has to regain the lock on this object before it can resume executing.

The `wait()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

`public final native void wait(long timeout) throws InterruptedException`

Parameters

`timeout`

The maximum number of milliseconds to wait.

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

`InterruptedException`

If another thread interrupted this thread.

Description

The `wait()` method causes a thread to wait until it is notified by another thread to stop waiting or until the specified amount of time has elapsed, whichever comes first. When `wait()` is called, the thread releases its lock on this object and waits until another thread notifies it to wake up through a call to either `notify()` or `notifyAll()`. If the thread is not notified within the specified `timeout` period, it is automatically awakened when that amount of time has elapsed. If `timeout` is zero, the thread waits indefinitely, just as if `wait()` had been called without a `timeout` argument. After the thread is awakened, it has to regain the lock on this object before it can resume executing.

The `wait()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized` `static` method of that class.

This method is `final`, so it cannot be overridden by subclasses.

`public final native void wait(long timeout, int nanos) throws InterruptedException`

Parameters

`timeout`

The maximum number of milliseconds to wait.

`nanos`

An additional number of nanoseconds to wait.

Throws

`IllegalMonitorStateException`

If the method is called from a thread that does not hold this object's lock.

`InterruptedException`

If another thread interrupted this thread.

Description

The `wait()` method causes a thread to wait until it is notified by another thread to stop waiting or until the specified amount of time has elapsed, whichever comes first. When `wait()` is called, the thread releases its lock on this object and waits until another thread notifies it to wake up through a call to either `notify()` or `notifyAll()`. If the thread is not notified within the specified time period, it is automatically awakened when that amount of time has elapsed. If `timeout` and `nanos` are zero, the thread waits indefinitely, just as if `wait()` had been called without any arguments. After the thread is awakened, it has to regain the lock on this object before it can resume executing.

The `wait()` method can be called only by a thread that is the current owner of this object's lock. A thread holds the lock on this object while it is executing a `synchronized` instance method of the object or executing the body of a `synchronized` statement that synchronizes on the object. A thread can also hold the lock for a `Class` object if it is executing a `synchronized` `static` method of that class.

Note that Sun's reference implementation of Java does not attempt to implement the precision implied by this method. Instead, it rounds to the nearest millisecond (unless `timeout` is `0`, in which case it rounds up to 1 millisecond) and calls `wait(long)`.

This method is `final`, so it cannot be overridden by subclasses.

Protected Instance Methods

clone

`protected native Object clone() throws CloneNotSupportedException`

Returns

A clone of this object.

Throws

`OutOfMemoryError`

If there is not enough memory to create the new object.

`CloneNotSupportedException`

If the object is of a class that does not support `clone()`.

Description

A *clone* of an object is another object of the same type that has all of its instance variables set to the same values as the object being cloned. In other words, a clone is an exact copy of the original object.

The `clone()` method of `Object` creates a new object that is a clone of this object. No constructor is used in creating the clone. The `clone()` method only clones an object if the class of that object indicates that its instances can be cloned. A class indicates that its objects can be cloned by implementing the `Cloneable` interface.

Although array objects do not implement the `Cloneable` interface, the `clone()` method works for arrays. The clone of an array is an array that has the same number of elements as the original array, and each element in the clone array has the same value as the corresponding element in the original array. Note that if an array element contains an object reference, the clone array contains a reference to the same object, not a copy of the object.

A subclass of `Object` can override the `clone()` method in `Object` to provide any additional functionality that is needed. For example, if an object contains references to other objects, the `clone()` method should recursively call the `clone()` methods of all the referenced objects. An overriding `clone()` method can throw a `CloneNotSupportedException` to indicate that particular objects cannot be cloned.

finalize

`protected void finalize() throws Throwable`

Throws

`Throwable`

For any reason that suits an overriding implementation of this method.

Description

The `finalize()` method is called by the garbage collector when it decides that an object can never be referenced again. The method gives an object a chance to perform any cleanup operations that are necessary before it is destroyed by the garbage collector.

The `finalize()` method of `Object` does nothing. A subclass overrides the `finalize()` method to perform any necessary cleanup operations. The overriding method should call `super.finalize()` as the very last thing it does, so that any `finalize()` method in the superclass is called.

When the garbage collector calls an object's `finalize()` method, the garbage collector does not immediately destroy the object because the `finalize()` method might do something that results in a reference to the object. Thus the garbage collector waits to destroy the object until it can again prove it is safe to do so. The next time the garbage collector decides it is safe to destroy the object, it does so without calling `finalize()` again. In other words, the garbage collector never calls the `finalize()` method more than once for a particular object.

A `finalize()` method can throw any kind of exception. An exception causes the `finalize()` method to stop running. The garbage collector then catches and ignores the exception, so it has no further effect on a program.

Process

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Process

Name

Process

Synopsis

Class Name:

`java.lang.Process`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None that are provided on all platforms. However, a platform-specific version of Java should include at least one operating-system-specific subclass.

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Process` class describes processes that are started by the `exec()` method in the `Runtime` class. A `Process` object controls a process and gets information about it.

The `Process` class is an `abstract` class; therefore, it cannot be instantiated. The actual `Process` objects created by the `exec()` method belong to operating-system-specific subclasses of `Process` that implement the `Process` methods in platform-dependent ways.

Note that losing all references to a `Process` object, thereby making it garbage collectable, does not result in the underlying `Process` object dying. It merely means that there is no longer a Java object to control the process. The process itself continues to run asynchronously. In addition, no guarantees are made as to whether a controlled process will be able to continue after its parent process dies.

Class Summary

```
public abstract class java.lang.Process extends java.lang.Object {
    // Constructors
    public Process();
    // Instance Methods
    public abstract void destroy();
    public abstract int exitValue();
    public abstract InputStream getErrorStream();
    public abstract InputStream getInputStream();
    public abstract OutputStream getOutputStream();
    public abstract int waitFor();
}
```

Constructors

Process

`public Process()`

Description

> Creates a `Process` object.

Instance Methods

destroy

`abstract public void destroy()`

Description

> This method kills the process controlled by this object.

exitValue

`abstract public int exitValue()`

Returns

> The exit value of the process controlled by this object.

Throws

> `IllegalThreadStateException`
>
> > If the process is still running and the exit value is not yet available.

Description

> This method returns the exit value of the process that this object is controlling.
>
> The `waitFor()` method is a similar method that waits for the controlled process to terminate and then returns its exit value.

getErrorStream

`abstract public InputStream getErrorStream()`

Returns

> An `InputStream` object connected to the error stream of the process.

Description

This method returns an `InputStream` object that can read from the error stream of the process.

Although it is suggested that this `InputStream` not be buffered, the Java specification does not forbid such an implementation. In other words, although error output from programs is traditionally unbuffered, there is no guarantee that it won't be buffered. This means that error output written by the process may not be received immediately.

getInputStream

```
abstract public InputStream getInputStream()
```

Returns

An `InputStream` object that is connected to the standard output stream of the process.

Description

This method returns an `InputStream` object that can read from the standard output stream of the process.

This `InputStream` is likely to be buffered, which means that output written by the process may not be received immediately.

getOutputStream

```
abstract public OutputStream getOutputStream()
```

Returns

An `OutputStream` object that is connected to the standard input stream of the process.

Description

This method returns an `OutputStream` object that can write to the standard input stream of the process.

This `OutputStream` is likely to be buffered, which means that input sent to the process may not be received until the buffer fills up or a new line or carriage-return character is sent.

waitFor

`abstract public int waitFor()`

Returns

> The exit value of the process controlled by this object.

Throws

> `InterruptedException`
>
> > If another thread interrupts this thread while it is waiting for the process to exit.

Description

> This method returns the exit value of the process that this object is controlling. If the process is still running, the method waits until the process terminates and its exit value is available.
>
> The `exitValue()` method is a similar method that does not wait for the controlled process to terminate.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`

OutOfMemoryError BOOK INDEX Runnable

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Runnable

Name

Runnable

Synopsis

Interface Name:

`java.lang.Runnable`

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented By:

`java.lang.Thread`

Availability:

JDK 1.0 or later

Description

The `Runnable` interface declares the `run()` method that is required for use with the `Thread` class. Any class that implements the `Runnable` interface must define a `run()` method. This method is the top-level code that is run by a thread.

Interface Declaration

```
public interface java.lang.Runnable {
    // Methods
    public abstract void run();
}
```

Methods

run

`public abstract void run()`

Description

> When a `Thread` object starts running a thread, it associates executable code with the thread by calling a `Runnable` object's `run()` method. The subsequent behavior of the thread is controlled by the `run()` method. Thus, a class that wants to perform certain operations in a separate thread should implement the `Runnable` interface and define an appropriate `run()` method. When the `run()` method called by a `Thread` object returns or throws an exception, the thread dies.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Runtime

Name

Runtime

Synopsis

Class Name:

`java.lang.Runtime`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Runtime` class provides access to various information about the environment in which a program is running. The Java run-time environment creates a single instance of this class that is associated with a program. The

Runtime class does not have any public constructors, so a program cannot create its own instances of the class. A program must call the getRuntime() method to get a reference to the current Runtime object.

Information about operating system features is accessible through the System class.

Class Summary

```
public class java.lang.Runtime extends java.lang.Object {
    // Class Methods
    public static Runtime getRuntime();
    public static void runFinalizersOnExit(boolean value);  // New in 1.1
    // Instance Methods
    public Process exec(String command);
    public Process exec(String command, String envp[]);
    public Process exec(String cmdarray[]);
    public Process exec(String cmdarray[], String envp[]);

    public native void traceMethodCalls(boolean on);
}
```

Class Methods

getRuntime

public static Runtime getRuntime()

Returns

A reference to the current Runtime object.

Description

This method returns a reference to the current Runtime object. Because the other methods of the

`Runtime` class are not `static`, a program must call this method first in order to get a reference to a `Runtime` object that can be used in calling the other methods.

runFinalizersOnExit

`public static void runFinalizersOnExit(boolean value)`

Availability

New as of JDK 1.1

Parameters

`value`

A `boolean` value that specifies whether or not finalization occurs on exit.

Throws

`SecurityException`

If the `checkExit()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method specifies whether or not the `finalize()` methods of all objects that have `finalize()` methods are run before the Java virtual machine exits. By default, the finalizers are not run on exit.

Instance Methods

exec

`public Process exec(String command) throws IOException`

Parameters

`command`

A string that contains the name of an external command and any arguments to be passed to it.

Returns

A `Process` object that controls the process started by this method.

Throws

`IOException`

If there is a problem finding or accessing the specified external command.

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method starts a new process to execute the given external command. The standard input, standard output, and standard error streams from the process are redirected to `OutputStream` and `InputStream` objects that are accessible through the `Process` object returned by this method.

Calling this method is equivalent to:

```
exec(command, null)
```

`public Process exec(String command, String[] envp) throws IOException`

Parameters

`command`

A string that contains the name of an external command and any arguments to be passed to it.

`envp`

An array of strings that specifies the values for the environment variables of the new process. Each `String` in the array should be of the form *variableName =value*. If `envp` is `null`, the values of the environment variables in the current process are copied to the new process.

Returns

A `Process` object that controls the process started by this method.

Throws

`IOException`

If there is a problem finding or accessing the specified external command.

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method starts a new process to execute the given external command. The standard input, standard output, and standard error streams from the process are redirected to `OutputStream` and `InputStream` objects that are accessible through the `Process` object returned by this method.

The method parses the `command` string into words that are separated by whitespace. It creates a `String` object for each word and places word `String` objects into an array. If that array is called `commandArray`, calling this method is equivalent to:

```
exec(commmandArray, envp)
```

`public Process exec(String[] commandArray) throws IOException`

Parameters

`commandArray`

An array of strings that contains separate strings for the name of an external command and any arguments to be passed to it. The first string in the array must be the command name.

Returns

A `Process` object that controls the process started by this method.

Throws

`IOException`

If there is a problem finding or accessing the specified external command.

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method starts a new process to execute the given external command. The standard input, standard output, and standard error streams from the process are redirected to `OutputStream` and `InputStream` objects that are accessible through the `Process` object returned by this method.

Calling this method is equivalent to:

```
exec(commandArray, null)
```

`public Process exec(String[] commandArray, String[] envp) throws IOException`

Parameters

`commandArray`

An array of strings that contains separate strings for the name of an external command and any arguments to be passed to it. The first string in the array must be the command name.

`envp`

An array of strings that specifies the values for the environment variables of the new process. Each `String` in the array should be of the form *variableName =value*. If `envp` is `null`, the values of the environment variables in the current process are copied to the new process.

Returns

A `Process` object that controls the process started by this method.

Throws

`IOException`

If there is a problem finding or accessing the specified external command.

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method starts a new process to execute the given external command. The standard input, standard output, and standard error streams from the process are redirected to `OutputStream` and `InputStream` objects that are accessible through the `Process` object returned by this method.

exit

`public void exit(int status)`

Parameters

`status`

The exit status code to use.

Throws

`SecurityException`

If the `checkExit()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes the Java virtual machine to exit with the given status code. By convention, a nonzero status code indicates abnormal termination. This method never returns.

freeMemory

`public native long freeMemory()`

Returns

An estimate of the number of free bytes in system memory.

Description

This method returns an estimate of the number of free bytes in system memory. The value returned by this method is always less than the value returned by `totalMemory()`. Additional memory may be freed by calling the `gc()` method.

gc

`public native void gc()`

Description

This method causes the Java virtual machine to run the garbage collector in the current thread.

The garbage collector finds objects that will never be used again because there are no live references to them. After it finds these objects, the garbage collector frees the storage occupied by these objects.

The garbage collector is normally run continuously in a thread with the lowest possible priority, so that it works intermittently to reclaim storage. The `gc()` method allows a program to invoke the garbage collector explicitly when necessary.

getLocalizedInputStream

`public InputStream getLocalizedInputStream(InputStream in)`

Availability

Deprecated as of JDK 1.1

Parameters

`in`

An `InputStream` object that is to be localized.

Returns

The localized `InputStream`.

Description

This method returns an `InputStream` object that converts characters from the local character set to Unicode. For example, if the `InputStream` uses an 8-bit character set with values less than 128 representing Cyrillic letters, this method maps those characters to the corresponding Unicode characters in the range `'\u0400'` to `'\u04FF'`.

This method is deprecated as of JDK 1.1. You should instead use the new `InputStreamReader` and `BufferedReader` classes to convert characters from the local character set to Unicode.

getLocalizedOutputStream

`public OutputStream getLocalizedOutputStream(OutputStream out)`

Availability

Deprecated as of JDK 1.1

Parameters

`out`

An `OutputStream` object that is to be localized.

Returns

The localized `OutputStream`.

Description

This method returns an `OutputStream` object that converts characters from Unicode to the local character set. For example, if the local character set is an 8-bit character set with values less than 128 representing Cyrillic letters, this method maps Unicode characters in the range `'\u0400'` to `'\u04FF'` to the appropriate characters in the local character set.

This method is deprecated as of JDK 1.1. You should instead use the new `OutputStreamWriter` and `BufferedWriter` classes to convert characters from Unicode to the local character set.

load

`public synchronized void load(String filename)`

Parameters

`filename`

A string that specifies the complete path of the file to be loaded.

Throws

`SecurityException`

If the `checkLink()` method of the `SecurityManager` throws a `SecurityException`.

`UnsatisfiedLinkError`

If the method is unsuccessful in loading the specified dynamically linked library.

Description

This method loads the specified dynamically linked library.

It is often more convenient to call the `load()` method of the `System` class because it does not require getting a `Runtime` object.

loadLibrary

`public synchronized void loadLibrary(String libname)`

Parameters

`libname`

A string that specifies the name of a dynamically linked library.

Throws

`SecurityException`

If the `checkLink()` method of the `SecurityManager` throws a `SecurityException`.

`UnsatisfiedLinkError`

If the method is unsuccessful in loading the specified dynamically linked library.

Description

This method loads the specified dynamically linked library. It looks for the specified library in a platform-specific way.

It is often more convenient to call the `loadLibrary()` method of the `System` class because it does not require getting a `Runtime` object.

runFinalization

`public native void runFinalization()`

Description

This method causes the Java virtual machine to run the `finalize()` methods of any objects in the finalization queue in the current thread.

When the garbage collector discovers that there are no references to an object, it checks to see if the object has a `finalize()` method that has never been called. If the object has such a `finalize()` method, the object is placed in the finalization queue. While there is a reference to the object in the finalization queue, the object is no longer considered garbage-collectable.

Normally, the objects in the finalization queue are handled by a separate finalization thread that runs continuously at a very low priority. The finalization thread removes an object from the queue and calls its `finalize()` method. As long as the `finalize()` method does not generate a reference to the object, the object again becomes available for garbage collection.

Because the finalization thread runs at a very low priority, there may be a long delay from the time that an object is put on the finalization queue until the time that its `finalize()` method is called. The `runFinalization()` method allows a program to run the `finalize()` methods explicitly. This can be useful when there is a shortage of some resource that is released by a `finalize()` method.

totalMemory

`public native long totalMemory()`

Returns

The total number of bytes in system memory.

Description

This method returns the total number of bytes in system memory in the Java virtual machine. The total includes the number of bytes of memory being used by allocated objects, as well as the number of free bytes available for allocating additional objects. An estimate of the number of free bytes in system memory is available through the `freeMemory()` method.

traceInstructions

`public native void traceInstructions(boolean on)`

Parameters

`on`

A `boolean` value that specifies if instructions are to be traced. `true` if instructions are to be traced; otherwise `false`.

Description

This method controls whether or not the Java virtual machine outputs a detailed trace of each instruction that is executed. The `boolean` parameter causes tracing to be turned on or off. The tracing of instructions is only possible in a Java virtual machine that was compiled with the tracing option enabled. Production releases of the Java virtual machine are generally not compiled with tracing enabled.

traceMethodCalls

`public native void traceMethodCalls(boolean on)`

Parameters

`on`

A `boolean` value that specifies if method calls are to be traced. `true` if instructions are to be traced; otherwise `false`.

Description

This method controls whether or not the Java virtual machine outputs a detailed trace of each method that is invoked. The `boolean` parameter causes tracing to be turned on or off. The tracing of instructions is only possible in a Java virtual machine that was compiled with the tracing option enabled. Production releases of the Java virtual machine are generally not compiled with tracing enabled.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

RuntimeException

Name

RuntimeException

Synopsis

Class Name:

`java.lang.RuntimeException`

Superclass:

`java.lang.Exception`

Immediate Subclasses:

`java.lang.ArithmeticException`,

`java.lang.ArrayStoreException`,

`java.lang.ClassCastException`,

`java.lang.IllegalArgumentException`,

`java.lang.IllegalMonitorStateException`,

`java.lang.IllegalStateException`,

`java.lang.IndexOutOfBoundsException`,

java.lang.NegativeArraySizeException,

java.lang.NullPointerException,

java.lang.SecurityException,

java.util.EmptyStackException,

java.util.MissingResourceException,

java.util.NoSuchElementException

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The RuntimeException class is the superclass of the standard run-time exceptions that can be thrown in Java. The appropriate subclass of RuntimeException is thrown in response to a run-time error detected at the virtual machine level. A run-time exception represents a run-time condition that can occur generally in any Java method, so a method is not required to declare that it throws any of the run-time exceptions.

A Java program should try to handle all of the standard run-time exception classes, since they represent routine abnormal conditions that should be anticipated and caught to prevent program termination.

Class Summary

```
public class java.lang.RuntimeException extends java.lang.Exception {
  // Constructors
  public RuntimeException();
  public RuntimeException(String s);
}
```

Constructors

RuntimeException

public RuntimeException()

Description

This constructor creates a `RuntimeException` with no associated detail message.

public RuntimeException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `RuntimeException` with the specified detail message.

Inherited Methods

RuntimeException BOOK INDEX SecurityManager

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

SecurityManager

Name

SecurityManager

Synopsis

Class Name:

```
java.lang.SecurityManager
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The SecurityManager class provides a way of implementing a comprehensive security policy for a Java program. As of this writing, SecurityManager objects are used primarily by Web browsers to establish security policies for applets. However, the use of a SecurityManager object is appropriate in any situation where a hosting environment wants to limit the actions of hosted programs.

The SecurityManager class contains methods that are called by methods in other classes to ask for permission to do something that can affect the security of the system. These permission methods all have names that begin with check. If a check method does not permit an action, it throws a SecurityException or returns a value that indicates the lack of permission. The SecurityManager class provides default implementations of all of the check methods. These default implementations are the most restrictive possible implementations; they simply deny permission to do anything that can affect the security of the system.

The SecurityManager class is an abstract class. A hosting environment should define a subclass of SecurityManager that implements an appropriate security policy. To give the subclass of SecurityManager control over security, the hosting environment creates an instance of the class and installs it by passing it to the setSecurityManager() method of the System class. Once a SecurityManager object is installed, it cannot be changed. If the setSecurityManager() method is called any additional times, it throws a SecurityException.

The methods in other classes that want to ask the SecurityManager for permission to do something are able to access the SecurityManager object by calling the getSecurityManager() method of the System class. This method returns the SecurityManager object, or null to indicate that there is no SecurityManager installed.

Class Summary

```
public abstract class java.lang.SecurityManager extends java.lang.Object {
    // Constructors
    protected SecurityManager();
    // Variables
    protected boolean inCheck;
    // Instance Methods
    public void checkAccept(String host, int port);
    public void checkAccess(Thread t);
    public void checkAccess(ThreadGroup g);
    public void checkAwtEventQueueAccess();                  // New in 1.1
    public void checkConnect(String host, int port);
    public void checkConnect(String host, int port, Object context);
    public void checkCreateClassLoader();
    public void checkDelete(String file);
    public void checkExec(String cmd);
    public void checkExit(int status);
    public void checkLink(String libname);
    public void checkListen(int port);
    public void checkMemberAccess(Class clazz, int which);   // New in 1.1
    public void checkMulticast(InetAddress maddr);           // New in 1.1
    public void checkMulticast(InetAddress maddr, byte ttl); // New in 1.1
    public void checkPackageAccess();
    public void checkPackageDefinition();
    public void checkPrintJobAccess();                       // New in 1.1
    public void checkPropertiesAccess();
    public void checkPropertyAccess(String key);
    public void checkRead(int fd);
    public void checkRead(String file);
    public void checkRead(String file, Object context);
    public void checkSecurityAccess(String action);          // New in 1.1
    public void checkSetFactory();
    public void checkSystemClipboardAccess();                // New in 1.1
    public boolean checkTopLevelWindow();
    public void checkWrite(int fd);
    public void checkWrite(String file);
    public boolean getInCheck();
    public Object getSecurityContext();
    public ThreadGroup getThreadGroup();                     // New in 1.1
    // Protected Instance Methods
    protected int classDepth(String name);
    protected int classLoaderDepth();
    protected ClassLoader currentClassLoader();
    protected Class currentLoadedClass();                    // New in 1.1
    protected Class[] getClassContext();
    protected boolean inClass(String name);
    protected boolean inClassLoader();
}
```

Variables

inCheck

`protected boolean inCheck = false`

Description

> This variable indicates whether or not a security check is in progress. A subclass of `SecurityManager` should set this variable to `true` while a security check is in progress.
>
> This variable can be useful for security checks that require access to resources that a hosted program may not be permitted to access. For example, a security policy might be based on the contents of a

permissions file. This means that the various `check` methods need to read information from a file to decide what to do. Even though a hosted program may not be allowed to read files, the `check` methods can allow such reads when `inCheck` is `true` to support this style of security policy.

Constructors

SecurityManager

`protected SecurityManager()`

Throws

`SecurityException`

If a `SecurityManager` object already exists. In other words, if `System.getSecurityManager()` returns a value other than `null`.

Description

Creates a new `SecurityManager` object. This constructor cannot be called if there is already a current `SecurityManager` installed for the program.

Public Instance Methods

checkAccept

`public void checkAccept(String host, int port)`

Parameters

`host`

The name of the host machine.

`port`

A port number.

Throws

`SecurityException`

If the caller does not have permission to accept the connection.

Description

This method decides whether or not to allow a connection from the given host on the given port to be accepted. An implementation of the method should throw a `SecurityException` to deny permission to accept the connection. The method is called by the `accept()` method of the `java.net.ServerSocket` class.

The `checkAccept()` method of `SecurityManager` always throws a `SecurityException`.

checkAccess

`public void checkAccess(Thread g)`

Parameters

`g`

A reference to a `Thread` object.

Throws

`SecurityException`

If the current thread does not have permission to modify the specified thread.

Description

This method decides whether or not to allow the current thread to modify the specified `Thread`. An implementation of the method should throw a `SecurityException` to deny permission to modify the thread. Methods of the `Thread` class that call this method include `stop()`, `suspend()`, `resume()`, `setPriority()`, `setName()`, and `setDaemon()`.

The `checkAccess()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkAccess(ThreadGroup g)`

Parameters

`g`

A reference to a `ThreadGroup` object.

Throws

`SecurityException`

If the current thread does not have permission to modify the specified thread group.

Description

This method decides whether or not to allow the current thread to modify the specified `ThreadGroup`. An implementation of the method should throw a `SecurityException` to deny permission to modify the thread group. Methods of the `ThreadGroup` class that call this method include `setDaemon()`, `setMaxPriority()`, `stop()`, `suspend()`, `resume()`, and `destroy()`.

The `checkAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkAwtEventQueueAccess

`public void checkAwtEventQueueAccess()`

Availability

New as of JDK 1.1

Throws

`SecurityException`

If the caller does not have permission to access the AWT event queue.

Description

This method decides whether or not to allow access to the AWT event queue. An implementation of the method should throw a `SecurityException` to deny permission to access the event queue. The method is called by the `getSystemEventQueue()` method of the `java.awt.Toolkit` class.

The `checkAwtEventQueueAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkConnect

`public void checkConnect(String host, int port)`

Parameters

`host`

The name of the host.

`port`

A port number. A value of `-1` indicates an attempt to determine the IP address of given hostname.

Throws

`SecurityException`

If the caller does not have permission to open the socket connection.

Description

This method decides whether or not to allow a socket connection to the given host on the given port to be opened. An implementation of the method should throw a `SecurityException` to deny permission to open the connection. The method is called by the constructors of the `java.net.Socket` class, the `send()` and `receive()` methods of the `java.net.DatagramSocket` class, and the `getByName()` and `getAllByName()` methods of the `java.net.InetAddress` class.

The `checkConnect()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkConnect(String host, int port, Object context)`

Parameters

`host`

The name of the host.

`port`

A port number. A value of `-1` indicates an attempt to determine the IP address of given host name.

`context`

A security context object returned by this object's `getSecurityContext()` method.

Throws

`SecurityException`

If the specified security context does not have permission to open the socket connection.

Description

This method decides whether or not to allow a socket connection to the given host on the given port to be opened for the specified security context. An implementation of the method should throw a `SecurityException` to deny permission to open the connection.

The `checkConnect()` method of `SecurityManager` always throws a `SecurityException`.

checkCreateClassLoader

`public void checkCreateClassLoader()`

Throws

`SecurityException`

If the caller does not have permission to create a `ClassLoader` object.

Description

This method decides whether or not to allow a `ClassLoader` object to be created. An implementation of the method should throw a `SecurityException` to deny permission to create a `ClassLoader`. The method is called by the constructor of the `ClassLoader` class.

The `checkCreateClassLoader()` method of `SecurityManager` always throws a `SecurityException`.

checkDelete

`public void checkDelete(String file)`

Parameters

`file`

The name of a file.

Throws

`SecurityException`

If the caller does not have permission to delete the specified file.

Description

This method decides whether or not to allow a file to be deleted. An implementation of the method should throw a `SecurityException` to deny permission to delete the specified file. The method is called by the `delete()` method of the `java.io.File` class.

The `checkDelete()` method of `SecurityManager` always throws a `SecurityException`.

checkExec

`public void checkExec(String cmd)`

Parameters

`cmd`

The name of an external command.

Throws

`SecurityException`

If the caller does not have permission to execute the specified command.

Description

This method decides whether or not to allow an external command to be executed. An implementation of the method should throw a `SecurityException` to deny permission to execute the specified command. The method is called by the `exec()` methods of the `Runtime` and `System` classes.

The `checkExec()` method of `SecurityManager` always throws a `SecurityException`.

checkExit

`public void checkExit(int status)`

Parameters

`status`

An exit status code.

Throws

`SecurityException`

If the caller does not have permission to exit the Java virtual machine with the given status code.

Description

This method decides whether or not to allow the Java virtual machine to exit with the given status code. An implementation of the method should throw a `SecurityException` to deny permission to exit with the specified status code. The method is called by the `exit()` methods of the `Runtime` and `System` classes.

The `checkExit()` method of `SecurityManager` always throws a `SecurityException`.

checkLink

`public void checkLink(String lib)`

Parameters

`lib`

The name of a library.

Throws

`SecurityException`

If the caller does not have permission to load the specified library.

Description

This method decides whether to allow the specified library to be loaded. An implementation of the method should throw a `SecurityException` to deny permission to load the specified library. The method is called by the `load()` and `loadLibrary()` methods of the `Runtime` and `System` classes.

The `checkLink()` method of `SecurityManager` always throws a `SecurityException`.

checkListen

`public void checkListen(int port)`

Parameters

`port`

A port number.

Throws

`SecurityException`

If the caller does not have permission to listen on the specified port.

Description

This method decides whether or not to allow the caller to listen on the specified port. An implementation of the method should throw a `SecurityException` to deny permission to listen on the specified port. The method is called by the constructors of the `java.net.ServerSocket` class and by the constructor of the `java.net.DatagramSocket` class that takes one argument.

The `checkListen()` method of `SecurityManager` always throws a `SecurityException`.

checkMemberAccess

`public void checkMemberAccess(Class clazz, int which)`

Availability

New as of JDK 1.1

Parameters

`clazz`

A `Class` object.

`which`

The value `Member.PUBLIC` for the set of all `public` members including inherited members or the value `Member.DECLARED` for the set of all declared members of the specified class or interface.

Throws

`SecurityException`

If the caller does not have permission to access the members of the specified class or interface.

Description

This method decides whether or not to allow access to the members of the specified `Class` object. An implementation of the method should throw a `SecurityException` to deny permission to access the members. Methods of the `Class` class that call this method include `getField()`, `getFields()`, `getDeclaredField()`, `getDeclaredFields()`, `getMethod()`, `getMethods()`, `getDeclaredMethod()`, `getDeclaredMethods()`, `getConstructor()`, `getConstructors()`, `getDeclaredConstructor()`, `getDeclaredConstructors()`, and `getDeclaredClasses()`.

The `checkMemberAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkMulticast

`public void checkMulticast(InetAddress maddr)`

Availability

New as of JDK 1.1

Parameters

`maddr`

An `InetAddress` object that represents a multicast address.

Throws

`SecurityException`

If the current thread does not have permission to use the specified multicast address.

Description

This method decides whether or not to allow the current thread to use the specified multicast `InetAddress`. An implementation of the method should throw a `SecurityException` to deny permission to use the multicast address. The method is called by the `send()` method of `java.net.DatagramSocket` if the packet is being sent to a multicast address. The method is also called by the `joinGroup()` and `leaveGroup()` methods of `java.net.MulticastSocket`.

The `checkMulticast()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkMulticast(InetAddress maddr, byte ttl)`

Availability

New as of JDK 1.1

Parameters

`maddr`

An `InetAddress` object that represents a multicast address.

`ttl`

The time-to-live (TTL) value.

Throws

`SecurityException`

If the current thread does not have permission to use the specified multicast address and TTL value.

Description

This method decides whether or not to allow the current thread to use the specified multicast

`InetAddress` and TTL value. An implementation of the method should throw a `SecurityException` to deny permission to use the multicast address. The method is called by the `send()` method of `java.net.MulticastSocket`.

The `checkMulticast()` method of `SecurityManager` always throws a `SecurityException`.

checkPackageAccess

`public void checkPackageAccess(String pkg)`

Parameters

`pkg`

The name of a package.

Throws

`SecurityException`

If the caller does not have permission to access the specified package.

Description

This method decides whether or not to allow the specified package to be accessed. An implementation of the method should throw a `SecurityException` to deny permission to access the specified package. The method is intended to be called by implementations of the `loadClass()` method in subclasses of the `ClassLoader` class.

The `checkPackageAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkPackageDefinition

`public void checkPackageDefinition(String pkg)`

Parameters

`pkg`

The name of a package.

Throws

`SecurityException`

If the caller does not have permission to define classes in the specified package.

Description

This method decides whether or not to allow the caller to define classes in the specified package. An implementation of the method should throw a `SecurityException` to deny permission to create classes in the specified package. The method is intended to be called by implementations of the `loadClass()` method in subclasses of the `ClassLoader` class.

The `checkPackageDefinition()` method of `SecurityManager` always throws a `SecurityException`.

checkPrintJobAccess

`public void checkPrintJobAccess()`

Availability

New as of JDK 1.1

Throws

`SecurityException`

If the caller does not have permission to initiate a print job request.

Description

This method decides whether or not to allow the caller to initiate a print job request. An implementation of the method should throw a `SecurityException` to deny permission to initiate the request.

The `checkPrintJobAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkPropertiesAccess

`public void checkPropertiesAccess()`

Throws

`SecurityException`

If the caller does not have permission to access the system properties.

Description

This method decides whether or not to allow the caller to access and modify the system properties. An implementation of the method should throw a `SecurityException` to deny permission to access and modify the properties. Methods of the `System` class that call this method include `getProperties()` and `setProperties()`.

The `checkPropertiesAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkPropertyAccess

```
public void checkPropertyAccess(String key)
```

Parameters

`key`

The name of an individual system property.

Throws

`SecurityException`

If the caller does not have permission to access the specified system property.

Description

This method decides whether or not to allow the caller to access the specified system property. An implementation of the method should throw a `SecurityException` to deny permission to access the property. The method is called by the `getProperty()` method of the `System` class.

The `checkPropertyAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkRead

`public void checkRead(FileDescriptor fd)`

Parameters

`fd`

A reference to a `FileDescriptor` object.

Throws

`SecurityException`

If the caller does not have permission to read from the given file descriptor.

Description

This method decides whether or not to allow the caller to read from the specified file descriptor. An implementation of the method should throw a `SecurityException` to deny permission to read from the file descriptor. The method is called by the constructor of the `java.io.FileInputStream` class that takes a `FileDescriptor` argument.

The `checkRead()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkRead(String file)`

Parameters

`file`

The name of a file.

Throws

`SecurityException`

If the caller does not have permission to read from the named file.

Description

This method decides whether or not to allow the caller to read from the named file. An implementation of the method should throw a `SecurityException` to deny permission to read from the file. The method is called by constructors of the `java.io.FileInputStream` and `java.io.RandomAccessFile` classes, as well as by the `canRead()`, `exists()`, `isDirectory()`, `isFile()`, `lastModified()`, `length()`, and `list()` methods of the `java.io.File` class.

The `checkRead()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkRead(String file, Object context)`

Parameters

`file`

The name of a file.

`context`

A security context object returned by this object's `getSecurityContext()` method.

Throws

`SecurityException`

If the specified security context does not have permission to read from the named file.

Description

This method decides whether or not to allow the specified security context to read from the named file. An implementation of the method should throw a `SecurityException` to deny permission to read from the file.

The `checkRead()` method of `SecurityManager` always throws a `SecurityException`.

checkSecurityAccess

`public void checkSecurityAccess(String action)`

Availability

New as of JDK 1.1

Parameters

`action`

A string that specifies a security action.

Throws

`SecurityException`

If the caller does not have permission to perform the specified security action.

Description

This method decides whether to allow the caller to perform the specified security action. An implementation of the method should throw a `SecurityException` to deny permission to perform the action. The method is called by many of the methods in the `java.security.Identity` and `java.security.Security` classes.

The `checkSecurityAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkSetFactory

`public void checkSetFactory()`

Throws

`SecurityException`

If the caller does not have permission to set the factory class to be used by another class.

Description

This method decides whether to allow the caller to set the factory class to be used by another class. An implementation of the method should throw a `SecurityException` to deny permission to set the factory class. The method is called by the `setSocketFactory()` method of the `java.net.ServerSocket` class, the `setSocketImplFactory()` method of the `java.net.Socket` class, the `setURLStreamHandlerFactory()` method of the `java.net.URL` class, and the `setContentHandlerFactory()` method of the `java.net.URLConnection` class.

The `checkSetFactory()` method of `SecurityManager` always throws a `SecurityException`.

checkSystemClipboardAccess

`public void checkSystemClipboardAccess()`

Availability

New as of JDK 1.1

Throws

`SecurityException`

If the caller does not have permission to access the system clipboard.

Description

This method decides whether or not to allow the caller to access the system clipboard. An implementation of the method should throw a `SecurityException` to deny permission to access the system clipboard.

The `checkSystemClipboardAccess()` method of `SecurityManager` always throws a `SecurityException`.

checkTopLevelWindow

`public boolean checkTopLevelWindow(Object window)`

Parameters

`window`

A window object.

Returns

`true` if the caller is trusted to put up the specified top-level window; otherwise `false`.

Description

This method decides whether or not to trust the caller to put up the specified top-level window. An implementation of the method should return `false` to indicate that the caller is not trusted. In this case, the hosting environment can still decide to display the window, but the window should include a visual indication that it is not trusted. If the caller is trusted, the method should return `true`, and the window can be displayed without any special indication.

The `checkTopLevelWindow()` method of `SecurityManager` always returns `false`.

checkWrite

`public void checkWrite(FileDescriptor fd)`

Parameters

`fd`

A `FileDescriptor` object.

Throws

`SecurityException`

If the caller does not have permission to write to the given file descriptor.

Description

This method decides whether or not to allow the caller to write to the specified file descriptor. An implementation of the method should throw a `SecurityException` to deny permission to write to the file descriptor. The method is called by the constructor of the `java.io.FileOutputStream` class that takes a `FileDescriptor` argument.

The `checkWrite()` method of `SecurityManager` always throws a `SecurityException`.

`public void checkWrite(String file)`

Parameters

`file`

The name of a file.

Throws

`SecurityException`

If the caller does not have permission to read from the named file.

Description

This method decides whether or not to allow the caller to write to the named file. An implementation of the method should throw a `SecurityException` to deny permission to write to the file. The method is called by constructors of the `java.io.FileOutputStream` and `java.io.RandomAccessFile` classes, as well as by the `canWrite()`, `mkdir()`, and `renameTo()` methods of the `java.io.File` class.

The `checkWrite()` method of `SecurityManager` always throws a `SecurityException`.

getInCheck

`public boolean getInCheck()`

Returns

`true` if a security check is in progress; otherwise `false`.

Description

This method returns the value of the `SecurityManager` object's `inCheck` variable, which is `true` if a security check is in progress and `false` otherwise.

getSecurityContext

`public Object getSecurityContext()`

Returns

An implementation-dependent object that contains enough information about the current execution environment to perform security checks at a later time.

Description

This method is meant to create an object that encapsulates information about the current execution environment. The resulting security context object is used by specific versions of the `checkConnect()` and `checkRead()` methods. The intent is that such a security context object can be used by a trusted method to determine whether or not another, untrusted method can perform a particular operation.

The `getSecurityContext()` method of `SecurityManager` simply returns `null`. This method should be overridden to return an appropriate security context object for the security policy that is being implemented.

getThreadGroup

`public ThreadGroup getThreadGroup()`

Availability

New as of JDK 1.1

Returns

A `ThreadGroup` in which to place any threads that are created when this method is called.

Description

This method returns the appropriate parent `ThreadGroup` for any threads that are created when the method is called. The `getThreadGroup()` method of `SecurityManager` simply returns the `ThreadGroup` of the current thread. This method should be overridden to return an appropriate `ThreadGroup`.

Protected Instance Methods

classDepth

`protected native int classDepth(String name)`

Parameters

`name`

The fully qualified name of a class.

Returns

The number of pending method invocations from the top of the stack to a call to a method of the given class; `-1` if no stack frame in the current thread is associated with a call to a method in the given class.

Description

This method returns the number of pending method invocations between this method invocation and an invocation of a method associated with the named class.

classLoaderDepth

`protected native int classLoaderDepth()`

Returns

> The number of pending method invocations from the top of the stack to a call to a method that is associated with a class that was loaded by a `ClassLoader` object; `-1` if no stack frame in the current thread is associated with a call to such a method.

Description

> This method returns the number of pending method invocations between this method invocation and an invocation of a method associated with a class that was loaded by a `ClassLoader` object.

currentClassLoader

`protected native ClassLoader currentClassLoader()`

Returns

> The most recent `ClassLoader` object executing on the stack.

Description

> This method finds the most recent pending invocation of a method associated with a class that was loaded by a `ClassLoader` object. The method then returns the `ClassLoader` object that loaded that class.

currentLoadedClass

`protected Class currentLoadedClass()`

Availability

> New as of JDK 1.1

Returns

> The most recent `Class` object loaded by a `ClassLoader`.

Description

This method finds the most recent pending invocation of a method associated with a class that was loaded by a `ClassLoader` object. The method then returns the `Class` object for that class.

getClassContext

`protected native Class[] getClassContext()`

Returns

An array of `Class` objects that represents the current execution stack.

Description

This method returns an array of `Class` objects that represents the current execution stack. The length of the array is the number of pending method calls on the current thread's stack, not including the call to `getClassContext()`. Each element of the array references a `Class` object that describes the class associated with the corresponding method call. The first element of the array corresponds to the most recently called method, the second element is that method's caller, and so on.

inClass

`protected boolean inClass(String name)`

Parameters

`name`

The fully qualified name of a class.

Returns

`true` if there is a pending method invocation on the stack for a method of the given class; otherwise `false`.

Description

This method determines whether or not there is a pending method invocation that is associated with the named class.

inClassLoader

`protected boolean inClassLoader()`

Returns

> `true` if there is a pending method invocation on the stack for a method of a class that was loaded by a `ClassLoader` object; otherwise `false`.

Description

> This method determines whether or not there is a pending method invocation that is associated with a class that was loaded by a `ClassLoader` object. The method returns `true` only if the `currentClassLoader()` method does not return `null`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Short

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Short

Name

Short

Synopsis

Class Name:

`java.lang.Short`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `Short` class provides an object wrapper for a `short` value. This is useful when you need to treat a `short` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `short` value for one of these arguments, but you can provide a reference to a `Short` object that encapsulates the `byte` value. Furthermore, the `Short` class is necessary as of JDK 1.1 to support the

Reflection API and class literals.

The `Short` class also provides a number of utility methods for converting `short` values to other primitive types and for converting `short` values to strings and vice-versa.

Class Summary

```
public final class java.lang.Short extends java.lang.Number {
  // Constants
  public static final short MAX_VALUE;
  public static final short MIN_VALUE;
  public static final Class TYPE;
  // Constructors
  public Short(short value);
  public Short(String s);
  // Class Methods
  public static Short decode(String nm);
  public static short parseShort(String s);
  public static short parseShort(String s, int radix);
  public static String toString(short s);
  public static Short valueOf(String s, int radix);
  public static Short valueOf(String s);
  // Instance Methods
  public byte byteValue();
  public double doubleValue();
  public boolean equals(Object obj);
  public float floatValue();
  public int hashCode();
  public int intValue();
  public long longValue();
  public short shortValue();
  public String toString();
}
```

Constants

MAX_VALUE

public static final short MAX_VALUE= 32767

The largest value that can be represented by a `short`.

MIN_VALUE

public static final byte MIN_VALUE= -32768

The smallest value that can be represented by a `short`.

TYPE

public static final Class TYPE

The `Class` object that represents the primitive type `short`. It is always true that `Short.TYPE` == `short.class`.

Constructors

Short

public Short(short value)

Parameters

> `value`
>
> > The `short` value to be encapsulated by this object.

Description

> Creates a `Short` object with the specified `short` value.

public Short(String s) throws NumberFormatException

Parameters

> `s`
>
> > The string to be made into a `Short` object.

Throws

> `NumberFormatException`
>
> > If the sequence of characters in the given `String` does not form a valid `short` literal.

Description

> Constructs a `Short` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `` `-' `` character. If the string contains any other characters, the constructor throws a `NumberFormatException`.

Class Methods

decode

public static Short decode(String nm) throws NumberFormatException

Parameters

`nm`

A `String` representation of the value to be encapsulated by a `Short` object. If the string begins with # or `0x`, it is a radix 16 representation of the value. If the string begins with `0`, it is a radix 8 representation of the value. Otherwise, it is assumed to be a radix 10 representation of the value.

Returns

A `Short` object that encapsulates the given value.

Throws

`NumberFormatException`

If the `String` contains any non-digit characters other than a leading minus sign or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

This method returns a `Short` object that encapsulates the given value.

parseByte

```
public static short parseShort(String s) throws NumberFormatException
```

Parameters

`s`

The `String` to be converted to a `short` value.

Returns

The numeric value of the `short` represented by the `String` object.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short` or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

This method returns the numeric value of the `short` represented by the contents of the given `String` object. The `String` must contain only decimal digits, except that the first character may be a minus sign.

`public static short parseShort(String s, int radix) throws NumberFormatException`

Parameters

`s`

The `String` to be converted to a short value.

`radix`

The radix used in interpreting the characters in the `String` as digits. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`. If radix is in the range 2 through 10, only characters for which the `Character.isDigit()` method returns `true` are considered to be valid digits. If `radix` is in the range 11 through 36, characters in the ranges `A' through `Z' and `a' through `z' are considered valid digits.

Returns

The numeric value of the `short` represented by the `String` object in the specified radix.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short`, radix is not in the appropriate range, or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

This method returns the numeric value of the `short` represented by the contents of the given `String` object in the specified radix. The `String` must contain only valid digits of the specified radix, except that the first character may be a minus sign. The digits are parsed in the specified radix to produce the numeric value.

toString

public String toString(short s)

Parameters

`s`

The `short` value to be converted to a string.

Returns

The `string` representation of the given value.

Description

This method returns a `String` object that contains the decimal representation of the given value.

This method returns a string that begins with `` `- ``' if the given value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if its argument is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

valueOf

public static Short valueOf(String s) throws NumberFormatException

Parameters

`s`

The string to be made into a `Short` object.

Returns

The `Short` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short` or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

Constructs a `Short` object with the value specified by the given string. The string should consist of one or more digit characters. The digit characters can be preceded by a single `` `- ``'. If the string contains any other characters, the method throws a `NumberFormatException`.

`public static Short valueOf(String s, int radix) throws NumberFormatException`

Parameters

`s`

The string to be made into a `Short` object.

`radix`

The radix used in converting the string to a value. This value must be in the range `Character.MIN_RADIX` to `Character.MAX_RADIX`.

Returns

The `Short` object constructed from the string.

Throws

`NumberFormatException`

If the `String` does not contain a valid representation of a `short`, `radix` is not in the appropriate range, or the value represented by the `String` is less than `Short.MIN_VALUE` or greater than `Short.MAX_VALUE`.

Description

Constructs a `Short` object with the value specified by the given string in the specified radix. The string should consist of one or more digit characters or characters in the range `A' to `Z' or `a' to `z' that are considered digits in the given radix. The digit characters can be preceded by a single `-' character. If the string contains any other characters, the method throws a `NumberFormatException`.

Instance Methods

byteValue

public byte byteValue()

Returns

The value of this object as a `byte`. The high order bits of the value are discarded.

Overrides

`Number.byteValue()`

Description

This method returns the value of this object as a `byte`.

doubleValue

public double doubleValue()

Returns

The value of this object as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this object as a `double`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Short` and it contains the same value as the object this method is associated with.

floatValue

public float floatValue()

Returns

The value of this object as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this object as a `float`.

hashCode

public int hashCode()

Returns

A hashcode based on the `short` value of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hash code computed from the value of this object.

intValue

public int intValue()

Returns

The value of this object as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this object as an `int`.

longValue

public long longValue()

Returns

The value of this object as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this object as a `long`.

shortValue

public short shortValue()

Returns

The value of this object as a `short`.

Overrides

`Number.shortValue()`

Description

This method returns the value of this object as a `short`.

toString

public String toString()

Returns

The string representation of the value of this object.

Overrides

`Object.toString()`

Description

This method returns a `String` object that contains the decimal representation of the value of this object.

This method returns a string that begins with `` `- ``' if the value is negative. The rest of the string is a sequence of one or more of the characters `0', `1', `2', `3', `4', `5', `6', `7', `8', and `9'. This method returns "0" if the value of the object is `0`. Otherwise, the string returned by this method does not begin with "0" or "-0".

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

StackOverflowError

Name

StackOverflowError

Synopsis

Class Name:

`java.lang.StackOverflowError`

Superclass:

`java.lang.VirtualMachineError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `StackOverflowError` is thrown when a stack overflow error occurs within the virtual machine.

Class Summary

```
public class java.lang.StackOverflowError
             extends java.lang.VirtualMachineError {
  // Constructors
  public StackOverflowError();
  public StackOverflowError(String s);
}
```

Constructors

StackOverflowError

public StackOverflowError()

Description

This constructor creates a `StackOverflowError` with no associated detail message.

public StackOverflowError(String s)<

Parameters

`s`

The detail message.

Description

This constructor creates a `StackOverflowError` with the specified detail message.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

String

Name

String

Synopsis

Class Name:

`java.lang.String`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `String` class represents sequences of characters. Once a `String` object is created, it is immutable. In other words, the sequence of characters that a `String` represents cannot be changed after it is created. The `StringBuffer` class, on the other hand, represents a sequence of characters that can be changed. `StringBuffer` objects are used to perform computations on `String` objects.

The `String` class includes a number of utility methods, such as methods for fetching individual characters or ranges of contiguous characters, for translating characters to upper- or lowercase, for searching strings, and for parsing numeric values in strings.

`String` literals are compiled into `String` objects. Where a `String` literal appears in an expression, the compiled code contains a `String` object. If `s` is declared as `String`, the following two expressions are identical:

```
s.equals("ABC")
"ABC".equals(s)
```

The string concatenation operator implicitly creates `String` objects.

Class Summary

```
public final class java.lang.String extends java.lang.Object {
    // Constructors
    public String();
    public String(byte[] bytes);                           // New in 1.1
    public String(byte[] bytes, String enc);               // New in 1.1
    public String(byte[] bytes, int offset, int length);  // New in 1.1
    public String(byte[] bytes, int offset,
                  int length, String enc);                 // New in 1.1
    public String(byte[] lowbytes, int hibyte);        // Deprecated in 1.1
    public String(byte[] lowbytes, int hibyte,
                  int offset, int count);              // Deprecated in 1.1
    public String(char[] value);
    public String(char[] value, int offset, int;
    public String(String value);
    public String(StringBuffer buffer);
    // Class Methods
    public static String copyValueOf(char data[]);
    public static String copyValueOf(char data[], int offset, int count);
    public static String valueOf(boolean b);
    public static String valueOf(char c);
    public static String valueOf(char[] data);
    public static String valueOf(char[] data, int offset, int count);
    public static String valueOf(double d);
    public static String valueOf(float f);
    public static String valueOf(int i);
    public static String valueOf(long l);
    public static String valueOf(Object obj);
    // Instance Methods
    public char charAt(int index);
    public int compareTo(String anotherString);
    public String concat(String str);
    public boolean endsWith(String suffix);
    public boolean equals(Object anObject);
    public boolean equalsIgnoreCase(String anotherString);
    public byte[] getBytes();                             // New in 1.1
    public byte[] getBytes(String enc);                   // New in 1.1
    public void getBytes(int srcBegin, int srcEnd,
                         byte[] dst, int dstBegin);     // Deprecated in 1.1

    public String toUpperCase(Locale locale);             // New in 1.1
    public String trim();
}
```

Constructors

String

`public String()`

Description

> Creates a new `String` object that represents the empty string (i.e., a string with zero characters).

`public String(byte[] bytes)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

Description

Creates a new `String` object that represents the sequence of characters stored in the given `bytes` array. The bytes in the array are converted to characters using the system's default character encoding scheme.

`public String(byte[] bytes, String enc)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

`enc`

The name of an encoding scheme.

Throws

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

Creates a new `String` object that represents the sequence of characters stored in the given `bytes` array. The bytes in the array are converted to characters using the specified character encoding scheme.

`public String(byte[] bytes, int offset, int length)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

`offset`

An offset into the array.

`length`

The number of bytes to be included.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `length` indexes an element that is outside the bounds of the `bytes` array.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the given `bytes` array. The bytes in the array are converted to characters using the system's default character encoding scheme.

`public String(byte[] bytes, int offset, int length, String enc)`

Availability

New as of JDK 1.1

Parameters

`bytes`

An array of `byte` values.

`offset`

An offset into the array.

`length`

The number of bytes to be included.

`enc`

The name of an encoding scheme.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `length` indexes an element that is outside the bounds of the `bytes` array.

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the given `bytes` array. The bytes in the array are converted to characters using the specified character encoding scheme.

`public String(byte[] lowbytes, int hibyte)`

Availability

Deprecated as of JDK 1.1

Parameters

`lowbytes`

An array of `byte` values.

`hibyte`

The value to be put in the high-order byte of each 16-bit character.

Description

Creates a new `String` object that represents the sequence of characters stored in the given `lowbytes` array. The type of the array elements is `byte`, which is an 8-bit data type, so each element must be converted to a `char`, which is a 16-bit data type. The value of the `hibyte` argument is used to provide the value of the high-order byte when the `byte` values in the array are converted to `char` values.

More specifically, for each element `i` in the array `lowbytes`, the character at position `i` in the created `String` object is:

```
((hibyte & 0xff)<<8) | lowbytes[i]
```

This method is deprecated as of JDK 1.1 because it does not convert bytes into characters properly. You should instead use one of the constructors that takes a specific character encoding argument or that uses the default encoding.

`public String(byte[] lowbytes, int hibyte, int offset, int count)`

Availability

Deprecated as of JDK 1.1

Parameters

`lowbytes`

An array of `byte` values.

`hibyte`

The value to be put in the high-order byte of each 16-bit character.

`offset`

An offset into the array.

`count`

The number of bytes from the array to be included in the string.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `lowbytes` array.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the `lowbytes` array. That is, the portion of the array that starts at `offset` elements from the beginning of the array and is `count` elements long.

The type of the array elements is `byte`, which is an 8-bit data type, so each element must be converted to a `char`, which is a 16-bit data type. The value of the `hibyte` argument is used to provide the value of the high-order byte when the `byte` values in the array are converted to `char` values.

More specifically, for each element `i` in the array `lowbytes` that is included in the `String` object, the character at position `i` in the created `String` is:

```
 ((hibyte & 0xff)<<8) | lowbytes[I]
```

This method is deprecated as of JDK 1.1 because it does not convert bytes into characters properly. You should instead use one of the constructors that takes a specific character encoding argument or that uses the default encoding.

`public String(char[] value)`

Parameters

`value`

An array of `char` values.

Description

Creates a new `String` object that represents the sequence of characters stored in the given array.

`public String(char[] value, int offset, int count)`

Parameters

`value`

An array of `char` values.

`offset`

An offset into the array.

`count`

The number of characters from the array to be included in the string.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `value` array.

Description

Creates a new `String` object that represents the sequence of characters stored in the specified portion of the given array. That is, the portion of the given array that starts at `offset` elements from the beginning of the array and is `count` elements long.

`public String(String value)`

Parameters

`value`

A `String` object.

Description

Creates a new `String` object that represents the same sequence of characters as the given `String` object.

`public String(StringBuffer value)`

Parameters

`value`

A `StringBuffer` object.

Description

Creates a new `String` object that represents the same sequence of characters as the given object.

Class Methods

copyValueOf

`public static String copyValueOf(char data[])`

Parameters

`data`

An array of `char` values.

Returns

A new `String` object that represents the sequence of characters stored in the given array.

Description

This method returns a new `String` object that represents the character sequence contained in the given array. The `String` object produced by this method is guaranteed not to refer to the given array, but instead to use a copy. Because the `String` object uses a copy of the array, subsequent changes to the array do not change the contents of this `String` object.

This method is now obsolete. The same result can be obtained using the `valueOf()` method that takes an array of `char` values.

`public static String copyValueOf(char data[], int offset, int count)`

Parameters

`data`

An array of `char` values.

`offset`

An offset into the array.

`count`

The number of characters from the array to be included in the string.

Returns

A new `String` object that represents the sequence of characters stored in the specified portion of the given array.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `data` array.

Description

This method returns a new `String` object that represents the character sequence contained in the specified portion of the given array. That is, the portion of the given array that starts at `offset` elements from the beginning of the array and is `count` elements long. The `String` object produced by this method is guaranteed not to refer to the given array, but instead to use a copy. Because the `String` object uses a copy of the array, subsequent changes to the array do not change the contents of this `String` object.

This method is obsolete. The same result can be obtained by using the `valueOf()` method that takes an array of `char` values, an offset, and a count.

valueOf

`public static String valueOf(boolean b)`

Parameters

`b`

A `boolean` value.

Returns

A new `String` object that contains `'true'` if `b` is `true` or `'false'` if `b` is `false`.

Description

This method returns a string representation of a `boolean` value. In other words, it returns `'true'` if `b` is `true` or `'false'` if `b` is `false`.

`public static String valueOf(char c)`

Parameters

`c`

A `char` value.

Returns

A new `String` object that contains just the given character.

Description

This method returns a string representation of a `char` value. In other words, it returns a `String` object that contains just the given character.

`public static String valueOf(char[] data)`

Parameters

`data`

An array of `char` values.

Returns

A new `String` object that contains the sequence of characters stored in the given array.

Description

This method returns a string representation of an array of `char` values. In other words, it returns a `String` object that contains the sequence of characters stored in the given array.

`public static String valueOf(char[] data, int offset, int count)`

Parameters

`data`

An array of `char` values.

`offset`

An offset into the array.

`count`

The number of characters from the array to be included in the string.

Returns

A new `String` object that contains the sequence of characters stored in the specified portion of the given array.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `count` indexes an element that is outside the bounds of the `data` array.

Description

This method returns a string representation of the specified portion of an array of char values. In other words, it returns a `String` object that contains the sequence of characters in the given array that starts `offset` elements from the beginning of the array and is `count` elements long.

`public static String valueOf(double d)`

Parameters

`d`

A `double` value.

Returns

A new `String` object that contains a string representation of the given `double` value.

Description

This method returns a string representation of a `double` value. In other words, it returns the `String` object returned by `Double.toString(d)`.

`public static String valueOf(float f)`

Parameters

`f`

A `float` value.

Returns

A new `String` object that contains a string representation of the given `float` value.

Description

This method returns a string representation of a `float` value. In other words, it returns the `String` object returned by `Float.toString(f)`.

`public static String valueOf(int i)`

Parameters

`i`

An `int` value.

Returns

A new `String` object that contains a string representation of the given `int` value.

Description

This method returns a string representation of an `int` value. In other words, it returns the `String` object returned by `Integer.toString(i)`.

`public static String valueOf(long l)`

Parameters

`l`

A `long` value.

Returns

A new `String` object that contains a string representation of the given `long` value.

Description

This method returns a string representation of a `long` value. In other words, it returns the `String` object returned by `Long.toString(l)`.

`public static String valueOf (Object obj)`

Parameters

`obj`

A reference to an object.

Returns

A new `String` that contains a string representation of the given object.

Description

This method returns a string representation of the given object. If `obj` is `null`, the method returns`'null'`. Otherwise, the method returns the `String` object returned by the `toString()` method of the object.

Instance Methods

charAt

`public char charAt(int index)`

Parameters

`index`

An index into the string.

Returns

The character at the specified position in this string.

Throws

`StringIndexOutOfBoundsException`

If `index` is less than zero or greater than or equal to the length of the string.

Description

This method returns the character at the specified position in the `String` object; the first character in the string is at position `0`.

compareTo

`public int compareTo(String anotherString)`

Parameters

`anotherString`

The `String` object to be compared.

Returns

A positive value if this string is greater than `anotherString`, `0` if the two strings are the same, or a negative value if this string is less than `anotherString`.

Description

This method lexicographically compares this `String` object to `anotherString`.

Here is how the comparison works: the two `String` objects are compared character-by-character, starting at index `0` and continuing until a position is found in which the two strings contain different characters or until all of the characters in the shorter string have been compared. If the characters at `k` are different, the method returns:

```
this.charAt(k)-anotherString.charAt(k)
```

Otherwise, the comparison is based on the lengths of the strings and the method returns:

```
this.length()-anotherString.length()
```

concat

`public String concat(String str)`

Parameters

`str`

The `String` object to be concatenated.

Returns

A new `String` object that contains the character sequences of this string and `str` concatenated together.

Description

This method returns a new `String` object that concatenates the characters from the argument string `str` onto the characters from this `String` object. Although this is a good way to concatenate two strings, concatenating more than two strings can be done more efficiently using a `StringBuffer` object.

endsWith

`public boolean endsWith(String suffix)`

Parameters

`suffix`

The `String` object suffix to be tested.

Returns

`true` if this string ends with the sequence of characters specified by `suffix`; otherwise `false`.

Description

This method determines whether or not this `String` object ends with the specified `suffix`.

equals

`public boolean equals(Object anObject)`

Parameters

`anObject`

The `Object` to be compared.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `anObject` is an instance of `String` and it contains the same sequence of characters as this `String` object.

Note the difference between this method and the `==` operator, which only returns `true` if both of its arguments are references to the same object.

equalsIgnoreCase

`public boolean equalsIgnoreCase(String anotherString)`

Parameters

`anotherString`

The `String` object to be compared.

Returns

`true` if the strings are equal, ignoring case; otherwise `false`.

Description

This method determines whether or not this `String` object contains the same sequence of characters, ignoring case, as `anotherString`. More specifically, corresponding characters in the two strings are considered equal if any of the following conditions are true:

- The two characters compare as equal using the `==` operator.
- The `Character.toUppercase()` method returns the same result for both characters.
- The `Character.toLowercase()` method returns the same result for both characters.

getBytes

`public byte[] getBytes()`

Availability

New as of JDK 1.1

Returns

A `byte` array that contains the characters of this `String`.

Description

This method converts the characters in this `String` object to an array of `byte` values. The characters in the string are converted to bytes using the system's default character encoding scheme.

`public byte[] getBytes(String enc)`

Availability

New as of JDK 1.1

Parameters

`enc`

The name of an encoding scheme.

Returns

A `byte` array that contains the characters of this `String`.

Throws

`UnsupportedEncodingException`

If `enc` is not a supported encoding scheme.

Description

This method converts the characters in this `String` object to an array of `byte` values. The characters in the string are converted to bytes using the specified character encoding scheme.

`public void getBytes(int srcBegin, int srcEnd, byte[] dst, int dstBegin)`

Availability

Deprecated as of JDK 1.1

Parameters

`srcBegin`

The index of the first character to be copied.

`srcEnd`

The index after the last character to be copied.

`dst`

The destination `byte` array.

`dstBegin`

An offset into the destination array.

Throws

`StringIndexOutOfBoundsException`

If `srcBegin`, `srcEnd`, or `dstBegin` is out of range.

Description

This method copies the low-order byte of each character in the specified range of this `String` object to the given array of `byte` values. More specifically, the first character to be copied is at index `srcBegin`; the last character to be copied is at index `srcEnd-1`. The low-order bytes of these characters are copied into `dst`, starting at index `dstBegin` and ending at index:

```
dstBegin + (srcEnd-srcBegin) - 1
```

This method is deprecated as of JDK 1.1 because it does not convert characters into bytes properly. You should instead use the `getBytes()` method that takes a specific character encoding argument or the one that uses the default encoding.

getChars

```
public void getChars(int srcBegin, int srcEnd, char[] dst, int dstBegin)
```

Parameters

`srcBegin`

The index of the first character to be copied.

`srcEnd`

The index after the last character to be copied.

`dst`

The destination `char` array.

`dstBegin`

An offset into the destination array.

Throws

`StringIndexOutOfBoundsException`

If `srcBegin`, `srcEnd`, or `dstBegin` is out of range.

Description

This method copies each character in the specified range of this `String` object to the given array of `char` values. More specifically, the first character to be copied is at index `srcBegin`; the last character to be copied is at index `srcEnd-1`. These characters are copied into `dst`, starting at index `dstBegin` and ending at index:

```
dstBegin + (srcEnd-srcBegin) - 1
```

hashCode

`public int hashCode()`

Returns

A hashcode based on the sequence of characters in this string.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode based on the sequence of characters this `String` object represents.

More specifically, one of two algorithms is used to compute a hash code for the string, depending on its length. If *n* is the length of the string and *S_i* is the character at position *i* in the string, then if *n* = 15 the method returns:

Mathematical Equation

If *n* > 15, the method returns:

Mathematical Equation

indexOf

`public int indexOf(int ch)`

Parameters

`ch`

A `char` value.

Returns

The index of the first occurrence of the given character in this string or `-1` if the character does not occur.

Description

This method returns the index of the first occurrence of the given character in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int indexOf(int ch, int fromIndex)`

Parameters

`ch`

A `char` value.

`fromIndex`

The index where the search is to begin.

Returns

The index of the first occurrence of the given character in this string after `fromIndex` or `-1` if the character does not occur.

Description

This method returns the index of the first occurrence of the given character in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

`public int indexOf(String str)`

Parameters

`str`

A `String` object.

Returns

The index of the first occurrence of `str` in this string or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the first occurrence of the substring `str` in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int indexOf(String str, int fromIndex)`

Parameters

`str`

A `String` object.

`fromIndex`

The index where the search is to begin.

Returns

The index of the first occurrence of `str` in this string after `fromIndex` or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the first occurrence of the substring `str` in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

intern

`public native String intern()`

Returns

A `String` object that is guaranteed to be the same object for every `String` that contains the same character sequence.

Description

This method returns a canonical representation for this `String` object. The returned `String` object is guaranteed to be the same `String` object for every `String` object that contains the same character sequence. In other words, if:

```
s1.equals(s2)
```

then:

```
s1.intern() == s2.intern()
```

The `intern`() method is used by the Java environment to ensure that `String` literals and constant-value `String` expressions that contain the same sequence of characters are all represented by a single `String` object.

lastIndexOf

`public int lastIndexOf(int ch)`

Parameters

`ch`

A `char` value.

Returns

The index of the last occurrence of the given character in this string or `-1` if the character does not occur.

Description

This method returns the index of the last occurrence of the given character in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int lastIndexOf(int ch, int fromIndex)`

Parameters

`ch`

A `char` value.

`fromIndex`

The index where the search is to begin.

Returns

The index of the last occurrence of the given character in this string after `fromIndex` or `-1` if the character does not occur.

Description

This method returns the index of the last occurrence of the given character in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

`public int lastIndexOf(String str)`

Parameters

`str`

A `String` object.

Returns

The index of the last occurrence of `str` in this string or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the last occurrence of the substring `str` in this `String` object. If there is no such occurrence, the method returns the value `-1`.

`public int lastIndexOf(String str, int fromIndex)`

Parameters

`str`

A `String` object.

`fromIndex`

The index where the search is to begin.

Returns

The index of the last occurrence of `str` in this string after `fromIndex` or `-1` if the substring does not occur.

Description

This method returns the index of the first character of the last occurrence of the substring `str` in this `String` object after ignoring the first `fromIndex` characters. If there is no such occurrence, the method returns the value `-1`.

length

`public int length()`

Returns

The length of the character sequence represented by this string.

Description

This method returns the number of characters in the character sequence represented by this `String` object.

regionMatches

`public boolean regionMatches(int toffset, String other, int ooffset, int len)`

Parameters

`toffset`

The index of the first character in this string.

`other`

The `String` object to be used in the comparison.

`ooffset`

The index of the first character in `other`.

`len`

The length of the sub-sequences to be compared.

Returns

`true` if the sub-sequences are identical; otherwise `false`.

Description

This method determines whether or not the specified sub-sequences in this `String` object and `other` are identical. The method returns false if `toffset` is negative, if `ooffset` is negative, if `toffset+len` is greater than the length of this string, or if `ooffset+len` is greater than the length of `other`. Otherwise, the method returns `true` if for all nonnegative integers `k` less than `len` it is true that:

```
this.charAt(toffset+k) == other.charAt(ooffset+k)
```

`public boolean regionMatches(boolean ignoreCase, int toffset, String other, int ooffset, int len)`

Parameters

`ignoreCase`

A `boolean` value that indicates whether case should be ignored.

`toffset`

The index of the first character in this string.

`other`

The `String` object to be used in the comparison.

`ooffset`

The index of the first character in `other`.

`len`

The length of the sub-sequences to be compared.

Returns

`true` if the sub-sequences are identical; otherwise `false`. The `ignoreCase` argument controls whether or not case is ignored in the comparison.

Description

This method determines whether or not the specified sub-sequences in this `String` object and `other` are identical. The method returns false if `toffset` is negative, if `ooffset` is negative, if `toffset+len` is greater than the length of this string, or if `ooffset+len` is greater than the length of `other`. Otherwise, if `ignoreCase` is `false`, the method returns `true` if for all nonnegative integers `k` less than `len` it is true that:

```
this.charAt(toffset+k) == other.charAt(ooffset+k)
```

If `ignoreCase` is `true`, the method returns `true` if for all nonnegative integers `k` less than `len` it is true that:

```
Character.toLowerCase(this.charAt(toffset+k))
== Character.toLowerCase(other.charAt(ooffset+k))
```

or:

```
Character.toUpperCase(this.charAt(toffset+k))
== Character.toUpperCase(other.charAt(ooffset+k))
```

replace

`public String replace(char oldChar, char newChar)`

Parameters

`oldChar`

The character to be replaced.

`newChar`

The replacement character.

Returns

A new `String` object that results from replacing every occurrence of `oldChar` in the string with `newChar`.

Description

This method returns a new `String` object that results from replacing every occurrence of `oldChar` in this `String` object with `newChar`. If there are no occurrences of `oldChar`, the method simply returns this `String` object.

startsWith

`public boolean startsWith(String prefix)`

Parameters

`prefix`

The `String` object prefix to be tested.

Returns

`true` if this string begins with the sequence of characters specified by `prefix`; otherwise `false`.

Description

This method determines whether or not this `String` object begins with the specified `prefix`.

`public boolean startsWith(String prefix, int toffset)`

Parameters

`prefix`

The `String` object prefix to be tested.

`toffset`

The index where the search is to begin.

Returns

`true` if this string contains the sequence of characters specified by `prefix` starting at the index `toffset`; otherwise `false`.

Description

This method determines whether or not this `String` object contains the specified `prefix` at the index specified by `toffset`.

substring

`public String substring(int beginIndex)`

Parameters

`beginIndex`

The index of the first character in the substring.

Returns

A new `String` object that contains the sub-sequence of this string that starts at `beginIndex` and extends to the end of the string.

Throws

`StringIndexOutOfBoundsException`

If `beginIndex` is less than zero or greater than or equal to the length of the string.

Description

This method returns a new `String` object that represents a sub-sequence of this `String` object. The sub-sequence consists of the characters starting at `beginIndex` and extending through the end of this `String` object.

`public String substring(int beginIndex, int endIndex)`

Parameters

`beginIndex`

The index of the first character in the substring.

`endIndex`

The index after the last character in the substring.

Returns

A new `String` object that contains the sub-sequence of this string that starts at `beginIndex` and extends to the character at `endindex-1`.

Throws

`StringIndexOutOfBoundsException`

If `beginIndex` or `endIndex` is less than zero or greater than or equal to the length of the string.

Description

This method returns a new `String` object that represents a sub-sequence of this `String` object. The sub-sequence consists of the characters starting at `beginIndex` and extending through `endIndex-1` of this `String` object.

toCharArray

`public char[] toCharArray()`

Returns

A new `char` array that contains the same sequence of characters as this string.

Description

This method returns a new `char` array that contains the same sequence of characters as this `String`object. The length of the array is the same as the length of this `String` object.

toLowerCase

`public String toLowerCase()`

Returns

A new `String` object that contains the characters of this string converted to lowercase.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its lowercase equivalent if it has one. If no character in the string has a lowercase equivalent, the method returns this `String` object.

`public String toLowerCase(Locale locale)`

Availability

New as of JDK 1.1

Parameters

`locale`

The `Locale` to use.

Returns

A new `String` object that contains the characters of this string converted to lowercase using the rules of the specified locale.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its lowercase equivalent if it has one according to the rules of the specified locale. If no character in the string has a lowercase equivalent, the method returns this `String` object.

toString

`public String toString()`

Returns

This `String` object.

Overrides

`Object.toString()`

Description

This method returns this `String` object.

toUpperCase

`public String toUpperCase()`

Returns

A new `String` object that contains the characters of this string converted to uppercase.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its uppercase equivalent if it has one. If no character in the string has an uppercase equivalent, the method returns this `String` object.

`public String toUpperCase(Locale locale)`

Availability

New as of JDK 1.1

Parameters

`locale`

The `Locale` to use.

Returns

A new `String` object that contains the characters of this string converted to uppercase using the rules of the specified locale.

Description

This method returns a new `String` that represents a character sequence of the same length as this `String` object, but with each character replaced by its uppercase equivalent if it has one according to the rules of the specified locale. If no character in the string has an uppercase equivalent, the method returns this `String` object.

trim

```
public String trim()
```

Returns

> A new `String` object that represents the same character sequence as this string, but with leading and trailing whitespace and control characters removed.

Description

> If the first and last character in this `String` object are greater than `'\u0020'` (the space character), the method returns this `String` object. Otherwise, the method returns a new `String` object that contains the same character sequence as this `String` object, but with leading and trailing characters that are less than `'\u0020''` removed.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

StringBuffer

Name

StringBuffer

Synopsis

Class Name:

`java.lang.StringBuffer`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `StringBuffer` class represents a variable-length sequence of characters. `StringBuffer` objects are used in computations that involve creating new `String` objects. The `StringBuffer` class provides a number of utility methods for working with `StringBuffer` objects, including `append()` and `insert()` methods that add characters to a `StringBuffer` and methods that fetch the contents of `StringBuffer` objects.

When a `StringBuffer` object is created, the constructor determines the initial contents and capacity of the `StringBuffer`. The capacity of a `StringBuffer` is the number of characters that its internal data structure can hold. This is distinct from the length of the contents of a `StringBuffer`, which is the number of characters that are actually stored in the `StringBuffer` object. The capacity of a `StringBuffer` can vary. When a `StringBuffer` object is asked to hold more characters than its current capacity allows, the `StringBuffer` enlarges its internal data structure. However, it is more costly in terms of execution time and memory when a `StringBuffer` has to repeatedly increase its capacity than when a `StringBuffer` object is created with sufficient capacity.

Because the intended use of `StringBuffer` objects involves modifying their contents, all methods of the `StringBuffer` class that modify `StringBuffer` objects are `synchronized`. This means that is it safe for multiple threads to try to modify a `StringBuffer` object at the same time.

`StringBuffer` objects are used implicitly by the string concatenation operator. Consider the following code:

```
String s, s1, s2;
s = s1 + s2;
```

To compute the string concatenation, the Java compiler generates code like:

```
s = new StringBuffer().append(s1).append(s2).toString();
```

Class Summary

```
public class java.lang.StringBuffer extends java.lang.Object {
    // Constructors
    public StringBuffer();
    public StringBuffer(int length);
    public StringBuffer(String str);
    // Instance Methods
    public StringBuffer append(boolean b);
    public synchronized StringBuffer append(char c);
    public synchronized StringBuffer append(char[] str);
    public synchronized StringBuffer append(char[] str, int offset, int len);
    public StringBuffer append(double d);
    public StringBuffer append(float f);
    public StringBuffer append(int i);
    public StringBuffer append(long l);
    public synchronized StringBuffer append(Object obj);
    public synchronized StringBuffer append(String str);
    public int capacity();
    public synchronized char charAt(int index);
    public synchronized void ensureCapacity(int minimumCapacity);
    public synchronized void getChars(int srcBegin, int srcEnd,
                             char[] dst, int dstBegin);
    public StringBuffer insert(int offset, boolean b);
    public synchronized StringBuffer insert(int offset, char c);
    public synchronized StringBuffer insert(int offset, char[] str);
    public StringBuffer insert(int offset, double d);
    public StringBuffer insert(int offset, float f);
    public StringBuffer insert(int offset, int i);
    public StringBuffer insert(int offset, long l);
    public synchronized StringBuffer insert(int offset, Object obj);
    public synchronized StringBuffer insert(int offset, String str);
    public int length();
    public synchronized StringBuffer reverse();
    public synchronized void setCharAt(int index, char ch);
    public synchronized void setLength(int newLength);
    public String toString();
}
```

Constructors

StringBuffer

`public StringBuffer()`

Description

Creates a `StringBuffer` object that does not contain any characters and has a capacity of 16 characters.

`public StringBuffer(int capacity)`

Parameters

`capacity`

The initial capacity of this `StringBufffer` object.

Throws

`NegativeArraySizeException`

If `capacity` is negative.

Description

Creates a `StringBuffer` object that does not contain any characters and has the specified capacity.

`public StringBuffer(String str)`

Parameters

`str`

A `String` object.

Description

Creates a `StringBuffer` object that contains the same sequence of characters as the given `String` object and has a capacity 16 greater than the length of the `String`.

Instance Methods

append

`public StringBuffer append(boolean b)`

Parameters

`b`

A `boolean` value.

Returns

This `StringBuffer` object.

Description

This method appends either `"true"` or `"false"` to the end of the sequence of characters stored in ths `StringBuffer` object, depending on the value of `b`.

`public synchronized StringBuffer append(char c)`

Parameters

`c`

A `char` value.

Returns

This `StringBuffer` object.

Description

This method appends the given character to the end of the sequence of characters stored in this `StringBuffer` object.

`public synchronized StringBuffer append(char str[])`

Parameters

`str`

An array of `char` values.

Returns

This `StringBuffer` object.

Description

This method appends the characters in the given array to the end of the sequence of characters stored in this `StringBuffer` object.

`public synchronized StringBuffer append(char str[], int offset, int len)`

Parameters

`str`

An array of `char` values.

`offset`

An offset into the array.

`len`

The number of characters from the array to be appended.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` or `len` are out of range.

Description

This method appends the specified portion of the given array to the end of the character sequence stored in this `StringBuffer` object. The portion of the array that is appended starts `offset` elements from the beginning of the array and is `len` elements long.

`public StringBuffer append(double d)`

Parameters

`d`

A `double` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `double` value to a string using `Double.toString(d)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public StringBuffer append(float f)`

Parameters

`f`

A `float` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `float` value to a string using `Float.toString(f)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public StringBuffer append(int i)`

Parameters

`i`

An `int` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `int` value to a string using `Integer.toString(i)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public StringBuffer append(long l)`

Parameters

`l`

A `long` value.

Returns

This `StringBuffer` object.

Description

This method converts the given `long` value to a string using `Long.toString(l)` and appends the resulting string to the end of the sequence of characters stored in this `StringBuffer` object.

`public synchronized StringBuffer append(Object obj)`

Parameters

`obj`

A reference to an object.

Returns

This `StringBuffer` object.

Description

This method gets the string representation of the given object by calling `String.valueOf(obj)` and appends the resulting string to the end of the character sequence stored in this `StringBuffer` object.

`public synchronized StringBuffer append(String str)`

Parameters

`str`

A `String` object.

Returns

This `StringBuffer` object.

Description

This method appends the sequence of characters represented by the given `String` to the characters in this `StringBuffer` object. If `str` is `null`, the string `"null"` is appended.

capacity

`public int capacity()`

Returns

The capacity of this `StringBuffer` object.

Description

This method returns the current capacity of this object. The capacity of a `StringBuffer` object is the number of characters that its internal data structure can hold. A `StringBuffer` object automatically increases its capacity when it is asked to hold more characters than its current capacity allows.

charAt

`public synchronized char charAt(int index)`

Parameters

`index`

An index into the `StringBuffer`.

Returns

The character stored at the specified position in this `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `index` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method returns the character at the specified position in the `StringBuffer` object. The first character in the `StringBuffer` is at index `0`.

ensureCapacity

```
public synchronized void ensureCapacity(int minimumCapacity)
```

Parameters

`minimumCapacity`

The minimum desired capacity.

Description

This method ensures that the capacity of this `StringBuffer` object is at least the specified number of characters. If necessary, the capacity of this object is increased to the greater of `minimumCapacity` or double its current capacity plus two.

It is more efficient to ensure that the capacity of a `StringBuffer` object is sufficient to hold all of the additions that will be made to its contents, rather than let the `StringBuffer` increase its capacity in multiple increments.

getChars

```
 public synchronized void getChars(int srcBegin, int srcEnd, char dst[], int
```

`dstBegin)`

Parameters

`srcBegin`

The index of the first character to be copied.

`srcEnd`

The index after the last character to be copied.

`dst`

The destination `char` array.

`dstBegin`

An offset into the destination array.

Throws

`StringIndexOutOfBoundsException`

If `srcBegin`, `srcEnd`, or `dstBegin` is out of range.

Description

This method copies each character in the specified range of this `StringBuffer` object to the given array of `char` values. More specifically, the first character to be copied is at index `srcBegin`; the last character to be copied is at index `srcEnd-1`.

These characters are copied into `dst`, starting at index `dstBegin` and ending at index:

```
dstBegin + (srcEnd-srcBegin) - 1
```

insert

public StringBuffer insert(int offset, boolean b)

Parameters

`offset`

An offset into the `StringBuffer`.

`b`

A `boolean` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is out of range.

Description

This method inserts either `"true"` or `"false"` into the sequence of characters stored in this `StringBuffer` object, depending on the value of `b`. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public synchronized StringBuffer insert(int offset, char c)`

Parameters

`offset`

An offset into the `StringBuffer`.

`c`

A `char` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method inserts the given character into the sequence of characters stored in this `StringBuffer` object. The character is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the character is inserted before the first character in the `StringBuffer`.

public synchronized StringBuffer insert(int offset, char str[])

Parameters

`offset`

An offset into the `StringBuffer`.

`str`

An array of `char` values.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method inserts the characters in the given array into the sequence of characters stored in this `StringBuffer` object. The characters are inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the characters are inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, double d)`

Parameters

`offset`

An offset into the `StringBuffer`.

`d`

A `double` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `double` value to a string using `Double.toString(d)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, float f)`

Parameters

`offset`

An offset into the `StringBuffer`.

`f`

A `float` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `float` value to a string using `Float.toString(f)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, int i)`

Parameters

`offset`

An offset into the `StringBuffer`.

`i`

An `int` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `int` value to a string using `Integer.toString(i)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

`public StringBuffer insert(int offset, long l)`

Parameters

`offset`

An offset into the `StringBuffer`.

`l`

A `long` value.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method converts the given `long` value to a string using `Long.toString(l)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

public synchronized StringBuffer insert(int offset, Object obj)

Parameters

`offset`

An offset into the `StringBuffer`.

`obj`

A reference to an object.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method gets the string representation of the given object by calling `String.valueOf(obj)` and inserts the resulting string into the sequence of characters stored in this `StringBuffer` object. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

public synchronized StringBuffer insert(int offset, String str)

Parameters

`offset`

An offset into the `StringBuffer`.

`str`

A `String` object.

Returns

This `StringBuffer` object.

Throws

`StringIndexOutOfBoundsException`

If `offset` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

This method inserts the sequence of characters represented by the given `String` into the sequence of characters stored in this `StringBuffer` object. If `str` is `null`, the string `"null"` is inserted. The string is inserted at a position `offset` characters from the beginning of the sequence. If `offset` is `0`, the string is inserted before the first character in the `StringBuffer`.

length

`public int length()`

Returns

The number of characters stored in this `StringBuffer` object.

Description

This method returns the number of characters stored in this `StringBuffer` object. The length is distinct from the capacity of a `StringBuffer`, which is the number of characters that its internal data structure can hold.

reverse

`public synchronized StringBuffer reverse()`

Returns

> This `StringBuffer` object.

Description

> This method reverses the sequence of characters stored in this `StringBuffer` object.

setCharAt

`public synchronized void setCharAt(int index, char ch)`

Parameters

> `index`
>
> > The index of the character to be set.
>
> `ch`
>
> > A `char` value.

Throws

> `StringIndexOutOfBoundsException`
>
> > If `index` is less than zero or greater than or equal to the length of the `StringBuffer` object.

Description

> This method modifies the character located `index` characters from the beginning of the sequence of characters stored in this `StringBuffer` object. The current character at this position is replaced by the character `ch`.

setLength

`public synchronized void setLength(int newLength)`

Parameters

> `newLength`

The new length for this `StringBuffer`.

Throws

`StringIndexOutOfBoundsException`

If `index` is less than zero.

Description

This method sets the length of the sequence of characters stored in this `StringBuffer` object. If the length is set to be less than the current length, characters are lost from the end of the character sequence. If the length is set to be more than the current length, NUL characters (`\u0000`) are added to the end of the character sequence.

toString

`public String toString()`

Returns

A new `String` object that represents the same sequence of characters as the sequence of characters stored in this `StringBuffer` object.

Overrides

`Object.toString()`

Description

This method returns a new `String` object that represents the same sequence of characters as the sequence of characters stored in this `StringBuffer` object. Note that any subsequent changes to the contents of this `StringBuffer` object do not affect the contents of the `String` object created by this method.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

StringIndexOutOfBoundsException

Name

StringIndexOutOfBoundsException

Synopsis

Class Name:

`java.lang.StringIndexOutOfBoundsException`

Superclass:

`java.lang.IndexOutOfBoundsException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `StringIndexOutOfBoundsException` is thrown when a `String` or `StringBuffer` object detects an out-of-range index. An out-of-range index occurs when the index is less than zero, or greater than or equal to the length of the string.

Class Summary

```
public class java.lang.StringIndexOutOfBoundsException
             extends java.lang.IndexOutOfBoundsException {
  // Constructors
  public StringIndexOutOfBoundsException();
  public StringIndexOutOfBoundsException(int index);
  public StringIndexOutOfBoundsException(String s);
}
```

Constructors

StringIndexOutOfBoundsException

public StringIndexOutOfBoundsException()

Description

> This constructor creates a `StringIndexOutOfBoundsException` with no associated detail message.

public StringIndexOutOfBoundsException(int index)

Parameters

> `index`
>
> > The index value that was out of bounds

Description

> This constructor creates an `StringIndexOutOfBoundsException` with an associated message that mentions the specified index.

public StringIndexOutOfBoundsException(String s)

Parameters

> `s`

The detail message.

Description

This constructor creates a `StringIndexOutOfBoundsException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

System

Name

System

Synopsis

Class Name:

  `java.lang.System`

Superclass:

  `java.lang.Object`

Immediate Subclasses:

  None

Interfaces Implemented:

  None

Availability:

  JDK 1.0 or later

Description

The `System` class provides access to various information about the operating system environment in which a program is running. For example, the `System` class defines variables that allow access to the standard I/O streams and methods that allow a program to run the garbage collector and stop the Java virtual machine.

All of the variables and methods in the `System` class are `static`. In other words, it is not necessary to create an instance of the `System` class in order to use its variables and methods. In fact, the `System` class does not define any `public` constructors, so it cannot be instantiated.

The `System` class supports the concept of system properties that can be queried and set. The following properties are guaranteed always to be defined:

Property Name	**Description**
`file.encoding`	The character encoding for the default locale (Java 1.1 only)
`file.encoding.pkg`	The package that contains converters between local encodings and Unicode (Java 1.1 only)
`file.separator`	File separator (`'/'` on UNIX, `' \'` on Windows)
`java.class.path`	The class path
`java.class.version`	Java class version number
`java.compiler`	The just-in-time compiler to use, if any (Java 1.1 only)
`java.home`	Java installation directory
`java.vendor`	Java vendor-specific string
`java.vendor.url`	Java vendor URL
`java.version`	Java version number
`line.separator`	Line separator(`' \n'` on UNIX, `' \r\n'` on Windows)
`os.arch`	Operating system architecture
`os.name`	Operating system name
`os.version`	Operating system version
`path.separator`	Path separator (`':'` on UNIX, `','` on Windows)
`user.dir`	User's current working directory when the properties were initialized
`user.home`	User's home directory
`user.language`	The two-letter language code of the default locale (Java 1.1 only)
`user.name`	User's account name
`user.region`	The two-letter country code of the default locale (Java 1.1 only)
`user.timezone`	The default time zone (Java 1.1 only)

Additional properties may be defined by the run-time environment. The `-D` command-line option can be used to define system properties when a program is run.

The `Runtime` class is related to the `System` class; it provides access to information about the environment in which a program is running.

Class Summary

```
public final class java.lang.System extends java.lang.Object {
    // Constants
    public static final PrintStream err;
    public static final InputStream in;
    public static final PrintStream out;
    // Class Methods
    public static void arraycopy(Object src, int srcOffset,
                                 Object dst, int dstOffset, int length);
    public static long currentTimeMillis();
    public static void exit(int status);
    public static void gc();
    public static Properties getProperties();
    public static String getProperty(String key);
    public static String getProperty(String key, String default);
    public static SecurityManager getSecurityManager();
    public static String getenv(String name);           // Deprecated in 1.1
    public static native int identityHashCode(Object x);   // New in 1.1
    public static void load(String filename);
    public static void loadLibrary(String libname);
    public static void runFinalization();
    public static void runFinalizersOnExit(boolean value); // New in 1.1
    public static void setErr(PrintStream err);            // New in 1.1
    public static void setIn(InputStream in);              // New in 1.1
    public static void setOut(PrintStream out);            // New in 1.1
    public static void setProperties(Properties props);
    public static void setSecurityManager(SecurityManager s);
}
```

Variables

err

`public static final PrintStream err`

Description

> The standard error stream. In an application environment, this variable refers to a `java.io.PrintStream` object that is associated with the standard error output for the process running the Java virtual machine. In an applet environment, the `PrintStream` is likely to be associated with a separate window, although this is not guaranteed.
>
> The value of `err` can be set using the `setErr()` method. The value of `err` can only be set if the

currenly installed SecurityManager does not throw a SecurityException when the request is made.

Prior to to Java 1.1, err was not final. It has been made final as of Java 1.1 because the unchecked ability to set err is a security hole.

in

public static final InputStream in

Description

The standard input stream. In an application environment, this variable refers to a java.io.InputStream object that is associated with the standard input for the process running the Java virtual machine.

The value of in can be set using the setIn() method. The value of in can only be set if the currenly installed SecurityManager does not throw a SecurityException when the request is made.

Prior to to Java 1.1, in was not final. It has been made final as of Java 1.1 because the unchecked ability to set in is a security hole.

out

public static final PrintStream out

Description

The standard output stream. In an application environment, this variable refers to a java.io.PrintStream object that is associated with the standard output for the process running the Java virtual machine. In an applet environment, the PrintStream is likely to be associated with a separate window, although this is not guaranteed.

out is the most commonly used of the three I/O streams provided by the System class. Even in GUI-based applications, sending output to this stream can be useful for debugging. The usual idiom for sending output to this stream is:

```
System.out.println("Some text");
```

The value of out can be set using the setOut() method. The value of out can only be set if the currenly installed SecurityManager does not throw a SecurityException when the request is made.

Prior to to Java 1.1, out was not final. It has been made final as of Java 1.1 because the unchecked ability to set `out` is a security hole.

Class Methods

arraycopy

`public static void arraycopy(Object src, int src_position, Object dst, int dst_position, int length)`

Parameters

`src`

The source array.

`src_position`

An index into the source array.

`dst`

The destination array.

`dst_position`

An index into the destination array.

`length`

The number of elements to be copied.

Throws

`ArrayIndexOutOfBoundsException`

If the values of the `src_position`, `dst_position`, and `length` arguments imply accessing either array with an index that is less than zero or an index greater than or equal to the number of elements in the array.

`ArrayStoreException`

If the type of value stored in the `src` array cannot be stored in the `dst` array.

`NullPointerException`

If `src` or `dst` is `null`.

Description

This method copies a range of array elements from the `src` array to the `dst` array. The number of elements that are copied is specified by `length`. The elements at positions `src_position` through `src_position+length-1` in `src` are copied to the positions `dst_position` through `dst_position+length-1` in `dst`, respectively.

If `src` and `dst` refer to the same array, the copying is done as if the array elements were first copied to a temporary array and then copied to the destination array.

Before this method does any copying, it performs a number of checks. If either `src` or `dst` are `null`, the method throws a `NullPointerException` and `dst` is not modified.

If any of the following conditions are true, the method throws an `ArrayStoreException`, and `dst` is not modified:

- Either `src` or `dst` refers to an object that is not an array.
- `src` and `dst` refer to arrays whose element types are different primitive types.
- `src` refers to an array that has elements that contain a primitive type, while `dst` refers to an array that has elements that contain a reference type, or vice versa.

If any of the following conditions are true, the method throws an `ArrayIndexOutOfBoundsException`, and `dst` is not modified:

- `srcOffset`, `dstOffset`, or `length` is negative.
- `srcOffset+length` is greater than `src.length()`.
- `dstOffset+length` is greater than `dst.length()`.

Otherwise, if an element in the source array being copied cannot be converted to the type of the destination array using the rules of the assignment operator, the method throws an `ArrayStoreException` when the problem occurs. Since the problem is discovered during the copy operation, the state of the `dst` array reflects the incomplete copy operation.

currentTimeMillis

```
public static native long currentTimeMillis()
```

Returns

The current time as the number of milliseconds since 00:00:00 UTC, January 1, 1970.

Description

This method returns the current time as the number of milliseconds since 00:00:00 UTC, January 1, 1970. It will not overflow until the year 292280995.

The `java.util.Date` class provides more extensive facilities for dealing with times and dates.

exit

`public static void exit(int status)`

Parameters

`status`

The exit status code to use.

Throws

`SecurityException`

If the `checkExit()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes the Java virtual machine to exit with the given status code. This method works by calling the `exit()` method of the current `Runtime` object. By convention, a nonzero status code indicates abnormal termination. This method never returns.

gc

`public static void gc()`

Description

This method causes the Java virtual machine to run the garbage collector in the current thread. This method works by calling the `gc()` method of the current `Runtime` object.

The garbage collector finds objects that will never be used again because there are no live references to them. After it finds these objects, the garbage collector frees the storage occupied by these objects.

The garbage collector is normally run continuously in a thread with the lowest possible priority, so that it works intermittently to reclaim storage. The `gc()` method allows a program to invoke the garbage collector explicitly when necessary.

getProperties

`public static Properties getProperties()`

Returns

A `Properties` object that contains the values of all the system properies.

Throws

`SecurityException`

If the `checkPropertiesAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method returns all of the defined system properties encapsulated in a `java.util.Properties` object. If there are no system properties currently defined, a set of default system properties is created and initialized. As discussed in the description of the `System` class, some system properties are guaranteed always to be defined.

getProperty

`public static String getProperty(String key)`

Parameters

`key`

The name of a system property.

Returns

The value of the named system property or `null` if the named property is not defined.

Throws

`SecurityException`

If the `checkPropertyAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method returns the value of the named system property. If there is no definition for the named property, the method returns `null`. If there are no system properties currently defined, a set of default system properties is created and initialized. As discussed in the description of the `System` class, some system properties are guaranteed always to be defined.

`public static String getProperty(String key, String def)`

Parameters

`key`

The name of a system property.

`def`

A default value for the property.

Returns

The value of the named system property, or the default value if the named property is not defined.

Throws

`SecurityException`

If the `checkPropertyAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method returns the value of the named system property. If there is no definition for the named property, the method returns the default value as specified by the `def` parameter. If there are no system properties currently defined, a set of default system properties is created and initialized. As discussed earlier in the description of the `System` class, some system properties are guaranteed to always be defined.

getSecurityManager

`public static SecurityManager getSecurityManager()`

Returns

> A reference to the installed `SecurityManager` object or `null` if there is no `SecurityManager` object installed.

Description

> This method returns a reference to the installed `SecurityManager` object. If there is no `SecurityManager` object installed, the method returns `null`.

getenv

`public static String getenv(String name)`

Availability

> Deprecated as of JDK 1.1

Parameters

> `name`
>
> > The name of a system-dependent environment variable.

Returns

> The value of the environment variable or `null` if the variable is not defined.

Description

> This method is obsolete; it always throws an error. Use `getProperties()` and the `-D` option instead.

identityHashCode

`public static native int identityHashCode(Object x)`

Availability

> New as of JDK 1.1

Parameters

`x`

An object.

Returns

The identity hashcode value for the specified object.

Description

This method returns the same hashcode value for the specified object as would be returned by the default `hashCode()` method of `Object`, regardless of whether or not the object's class overrides `hashCode()`.

load

`public void load(String filename)`

Parameters

`filename`

A string that specifies the complete path of the file to be loaded.

Throws

`SecurityException`

If the `checkLink()` method of the `SecurityManager` throws a `SecurityException`.

`UnsatisfiedLinkError`

If the method is unsuccessful in loading the specified dynamically linked library.

Description

This method loads the specified dynamically linked library. This method works by calling the `load()` method of the current `Runtime` object.

loadLibrary

`public void loadLibrary(String libname)`

Parameters

`libname`

A string that specifies the name of a dynamically linked library.

Throws

`SecurityException`

If the `checkLink()` method of the `SecurityManager` throws a `SecurityException`.

`UnsatisfiedLinkError`

If the method is unsuccessful in loading the specified dynamically linked library.

Description

This method loads the specified dynamically linked library. It looks for the specified library in a platform-specific way. This method works by calling the `loadLibrary()` method of the current `Runtime` object.

runFinalization

`public static void runFinalization()`

Description

This method causes the Java virtual machine to run the `finalize()` methods of any objects in the finalization queue in the current thread. This method works by calling the `runFinalization()` method of the current `Runtime` object.

When the garbage collector discovers that there are no references to an object, it checks to see if the object has a `finalize()` method that has never been called. If the object has such a `finalize()` method, the object is placed in the finalization queue. While there is a reference to the object in the finalization queue, the object is no longer considered garbage collectable.

Normally, the objects in the finalization queue are handled by a separate finalization thread that runs continuously at a very low priority. The finalization thread removes an object from the queue and calls its `finalize()` method. As long as the `finalize()` method does not generate a reference to the object, the object again becomes available for garbage collection.

Because the finalization thread runs at a very low priority, there may be a long delay from the time that an object is put on the finalization queue until the time that its `finalize()` method is called. The `runFinalization()` method allows a program to run the `finalize()` methods explicitly. This can be useful when there is a shortage of some resource that is released by a `finalize()` method.

runFinalizersOnExit

`public static void runFinalizersOnExit(boolean value)`

Availability

New as of JDK 1.1

Parameters

`value`

A `boolean` value that specifies whether or not finalization occurs on exit.

Throws

`SecurityException`

If the `checkExit()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method specifies whether or not the `finalize()` methods of all objects that have `finalize()` methods are run before the Java virtual machine exits. By default, the finalizers are not run on exit. This method works by calling the `runFinalizersOnExit()` method of the current `Runtime` object.

setErr

`public static void setErr(PrintStream err)`

Availability

New as of JDK 1.1

Parameters

`err`

A `PrintStream` object to use for the standard error stream.

Throws

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the standard error stream to be this `PrintStream` object.

setIn

`public static void setIn(InputStream in)`

Availability

New as of JDK 1.1

Parameters

`in`

A `InputStream` object to use for the standard input stream.

Throws

`SecurityException`

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the standard input stream to be this `InputStream` object.

setOut

`public static void setOut(PrintStream out)`

Availability

New as of JDK 1.1

Parameters

out

A `PrintStream` object to use for the standard output stream.

Throws

SecurityException

If the `checkExec()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the standard output stream to be this `PrintStream` object.

setProperties

`public static void setProperties(Properties props)`

Parameters

props

A reference to a `Properties` object.

Throws

SecurityException

If the `checkPropertiesAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method replaces the current set of system property definitions with a new set of system property definitions that are encapsulated by the given `Properties` object. As discussed in the description of the `System` class, some system properties are guaranteed to always be defined.

setSecurityManager

`public static void setSecurityManager(SecurityManager s)`

Parameters

s

A reference to a SecurityManager object.

Throws

SecurityException

If a SecurityManager object has already been installed.

Description

This method installs the given SecurityManager object. If s is null, then no SecurityManager object is installed. Once a SecurityManager object is installed, any subsequent calls to this method throw a SecurityException.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	equals(Object)	Object
finalize()	Object	getClass()	Object
hashCode()	Object	notify()	Object
notifyAll()	Object	toString()	Object
wait()	Object	wait(long)	Object
wait(long, int)	Object

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Thread

Name

Thread

Synopsis

Class Name:

`java.lang.Thread`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Runnable`

Availability:

JDK 1.0 or later

Description

The `Thread` class encapsulates all of the information about a single thread of control running in a Java environment. `Thread` objects are used to control threads in a multithreaded program.

The execution of Java code is always under the control of a `Thread` object. The `Thread` class provides a `static` method called `currentThread()` that can be used to get a reference to the `Thread` object that controls the current thread of execution.

In order for a `Thread` object to be useful, it must be associated with a method that it is supposed to run. Java provides two ways of associating a `Thread` object with a method:

- Declare a subclass of `Thread` that defines a `run()` method. When such a class is instantiated and the object's `start()` method is called, the thread invokes this `run()` method.

- Pass a reference to an object that implements the `Runnable` interface to a `Thread` constructor. When the `start()` method of such a `Thread` object is called, the thread invokes the `run()` method of the `Runnable` object.

After a thread is started, it dies when one of the following things happens:

- The `run()` method called by the `Thread` returns.

- An exception is thrown that causes the `run()` method to be exited.

- The `stop()` method of the `Thread` is called.

Class Summary

```
public class java.lang.Thread extends java.lang.Object
                              implements java.lang.Runnable {
    // Constants
    public final static int MAX_PRIORITY;
    public final static int MIN_PRIORITY;
    public final static int NORM_PRIORITY;
    // Constructors
    public Thread();
    public Thread(Runnable target);
    public Thread(Runnable target, String name);
    public Thread(String name);
    public Thread(ThreadGroup group, Runnable target);
    public Thread(ThreadGroup group, Runnable target, String name);
    public Thread(ThreadGroup group, String name);
    // Class Methods
    public static int activeCount();
    public static native Thread currentThread();
    public static void dumpStack();
    public static int enumerate(Thread tarray[]);
    public static boolean interrupted();
    public static native void sleep(long millis);
    public static void sleep(long millis, int nanos);
    public static native void yield();
    // Instance Methods
    public void checkAccess();
    public native int countStackFrames();
    public void destroy();
    public final String getName();
    public final int getPriority();
    public final ThreadGroup getThreadGroup();
    public void interrupt();
    public final native boolean isAlive();
    public final boolean isDaemon();
    public boolean isInterrupted();
    public final void join();
    public final synchronized void join(long millis);
    public final synchronized void join(long millis, int nanos);
    public final void resume();
    public void run();
    public final void setDaemon(boolean on);
    public final void setName(String name);
    public final void setPriority(int newPriority);
    public synchronized native void start();
    public final void stop();
    public final synchronized void stop(Throwable o);
    public final void suspend();
    public String toString();
}
```

Constants

MAX_PRIORITY

`public final static int MAX_PRIORITY = 10`

Description

The highest priority a thread can have.

MIN_PRIORITY

`public final static int MIN_PRIORITY = 1`

Description

The lowest priority a thread can have.

NORM_PRIORITY

`public final static int NORM_PRIORITY = 5`

Description

The default priority assigned to a thread.

Constructors

Thread

`public Thread()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the same `ThreadGroup` object as the current thread, has the same daemon attribute as the current thread, has the same priority as the current thread, and has a default name.

A `Thread` object created with this constructor invokes its own `run()` method when the `Thread` object's `start()` method is called. This is not useful unless the object belongs to a subclass of the `Thread` class that overrides the `run()` method.

Calling this constructor is equivalent to:

```
Thread(null, null, genName)
```

`genName` is an automatically generated name of the form `"Thread-"+n`, where `n` is an integer incremented each time a `Thread` object is created.

public Thread(String name)

Parameters

`name`

The name of this `Thread` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the same `ThreadGroup` object as the current thread, has the same daemon attribute as the current thread, has the same priority as the current thread, and has the specified name.

A `Thread` object created with this constructor invokes its own `run()` method when the `Thread` object's `start()` method is called. This is not useful unless the object belongs to a subclass of the `Thread` class that overrides the `run()` method.

Calling this constructor is equivalent to:

```
Thread(null, null, name)
```

The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their name.

`public Thread(ThreadGroup group, Runnable target)`

Parameters

`group`

The `ThreadGroup` object that this `Thread` object is to be added to.

`target`

A reference to an object that implements the `Runnable` interface.

Throws

SecurityException

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the specified `ThreadGroup` object, has the same daemon attribute as the current thread, has the same priority as the current thread, and has a default name.

A `Thread` object created with this constructor invokes the `run()` method of the specified `Runnable` object when the `Thread` object's `start()` method is called.

Calling this constructor is equivalent to:

```
Thread(group, target, genName)
```

`genName` is an automatically generated name of the form `"Thread-"+n`, where `n` is an integer that is incremented each time a `Thread` object is created.

`public Thread(ThreadGroup group, Runnable target, String name)`

Parameters

`group`

The `ThreadGroup` object that this `Thread` object is to be added to.

`target`

A reference to an object that implements the `Runnable` interface.

`name`

The name of this `Thread` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the specified `ThreadGroup` object, has the same daemon attribute as the current thread, has the same priority as the current thread, and has the specified name.

A `Thread` object created with this constructor invokes the `run()` method of the specified `Runnable` object when the `Thread` object's `start()` method is called.

The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their names.

`public Thread(ThreadGroup group, String name)`

Parameters

`group`

The `ThreadGroup` object that this `Thread` object is to be added to.

`name`

The name of this `Thread` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `Thread` object that belongs to the specified `ThreadGroup` object, has the same daemon attribute as the current thread, has the same priority as the current thread, and has the specified name.

A `Thread` object created with this constructor invokes its own `run()` method when the `Thread` object's `start()` method is called. This is not useful unless the object belongs to a subclass of the `Thread` class that overrides the `run()` method. Calling this constructor is equivalent to:

```
Thread(group, null, name)
```

The uniqueness of the specified `Thread` object's name is not checked, which may be a problem for programs that attempt to identify `Thread` objects by their name.

Class Methods

activeCount

`public static int activeCount()`

Returns

The current number of threads in the `ThreadGroup` of the currently running thread.

Description

This method returns the number of threads in the `ThreadGroup` of the currently running thread for which the `isAlive()` method returns `true`.

currentThread

`public static native Thread currentThread()`

Returns

A reference to the `Thread` object that controls the currently executing thread.

Description

This method returns a reference to the `Thread` object that controls the currently executing thread.

dumpStack

`public static void dumpStack()`

Description

This method outputs a stack trace of the currently running thread.

enumerate

`public static int enumerate(Thread tarray[])`

Parameters

`tarray`

A reference to an array of `Thread` objects.

Returns

The number of `Thread` objects stored in the array.

Description

This method stores a reference in the array for each of the `Thread` objects in the `ThreadGroup` of the currently running thread for which the `isAlive()` method returns `true`.

Calling this method is equivalent to:

```
currentThread().getThreadGroup().enumerate(tarray)
```

If the array is not big enough to contain references to all the `Thread` objects, only as many references as will fit are put into the array. No indication is given that some `Thread` objects were left out, so it is a good idea to call `activeCount()` before calling this method, to get an idea of how large to make the array.

interrupted

`public static boolean interrupted()`

Returns

`true` if the currently running thread has been interrupted; otherwise `false`.

Description

This method determines whether or not the currently running thread has been interrupted.

sleep

`public static native void sleep(long millis)`

Parameters

`millis`

The number of milliseconds that the currently running thread should sleep.

Throws

`InterruptedException`

If another thread interrupts the currently running thread.

Description

This method causes the currently running thread to sleep. The method does not return until at least the specified number of milliseconds have elapsed.

While a thread is sleeping, it retains ownership of all locks. The `Object` class defines a method called `wait()` that is similar to `sleep()` but causes the currently running thread to temporarily relinquish its locks.

public static void sleep(long millis, int nanos)

Parameters

`millis`

The number of milliseconds that the currently running thread should sleep.

`nanos`

An additional number of nanoseconds to sleep.

Throws

`InterruptedException`

If another thread interrupts the currently running thread.

Description

This method causes the currently running thread to sleep. The method does not return until at least the specified number of milliseconds have elapsed.

While a thread is sleeping, it retains ownership of all locks. The `Object` class defines a method called `wait()` that is similar to `sleep()` but causes the currently running thread to temporarily relinquish its locks.

Note that Sun's reference implementation of Java does not attempt to implement the precision implied by this method. Instead, it rounds to the nearest millisecond (unless `millis` is `0`, in which case it rounds up to 1 millisecond) and calls `sleep(long)`.

yield

`public static native void yield()`

Description

> This method causes the currently running thread to yield control of the processor so that another thread can be scheduled.

Instance Methods

checkAccess

`public void checkAccess()`

Throws

> `SecurityException`
>
> > If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

> This method determines if the currently running thread has permission to modify this `Thread` object.

countStackFrames

`public native int countStackFrames()`

Returns

> The number of pending method invocations on this thread's stack.

Description

> This method returns the number of pending method invocations on this thread's stack.

destroy

`public void destroy()`

Description

> This method is meant to terminate this thread without any of the usual cleanup (i.e., any locks held by the thread are not released). This method provides a last-resort way to terminate a thread. While a thread can defeat its `stop()` method by catching objects thrown from it, there is nothing that a thread can do to stop itself from being destroyed.
>
> Note that Sun's reference implementation of Java does not implement the documented functionality of this method. Instead, the implementation of this method just throws a `NoSuchMethodError`.

getName

`public final String getName()`

Returns

> The name of this thread.

Description

> This method returns the name of this `Thread` object.

getPriority

`public final int getPriority()`

Returns

> The priority of this thread.

Description

> This method returns the priority of this `Thread` object.

getThreadGroup

`public final ThreadGroup getThreadGroup()`

Returns

The `ThreadGroup` of this thread.

Description

This method returns a reference to the `ThreadGroup` that this `Thread` object belongs to.

interrupt

`public void interrupt()`

Description

This method interrupts this `Thread` object.

Note that prior to version 1.1, Sun's reference implementation of Java does not implement the documented functionality of this method. Instead, the method just sets a `private` flag that indicates that an interrupt has been requested. None of the methods that should throw an `InterruptedException` currently do. However, the `interrupted()` and `isInterrupted()` methods do return `true` after this method has been called.

isAlive

`public final native boolean isAlive()`

Returns

`true` if this thread is alive; otherwise `false`.

Description

This method determines whether or not this `Thread` object is alive. A `Thread` object is alive if it has been started and has not yet died. In other words, it has been scheduled to run before and can still be scheduled to run again. A thread is generally alive after its `start()` method is called and until its `stop()` method is called.

isDaemon

`public final boolean isDaemon()`

Returns

> `true` if the thread is a daemon thread; otherwise `false`.

Description

> This method determines whether or not this thread is a daemon thread, based on the value of the daemon attribute of this `Thread` object.

isInterrupted

`public boolean isInterrupted()`

Returns

> `true` if this thread has been interrupted; otherwise `false`.

Description

> This method determines whether or not this `Thread` object has been interrupted.

join

`public final void join()`

Throws

> `InterruptedException`
>
> > If another thread interrupts this thread.

Description

> This method allows the thread that calls it to wait for the `Thread` associated with this method to die. The method returns when the `Thread` dies. If this thread is already dead, then this method returns immediately.

`public final synchronized void join(long millis)`

Parameters

`millis`

The maximum number of milliseconds to wait for this thread to die.

Throws

`InterruptedException`

If another thread interrupts this thread.

Description

This method causes a thread to wait to die. The method returns when this `Thread` object dies or after the specified number of milliseconds has elapsed, whichever comes first. However, if the specified number of milliseconds is zero, the method will wait forever for this thread to die. If this thread is already dead, the method returns immediately.

`public final synchronized void join(long millis, int nanos)`

Parameters

`millis`

The maximum number of milliseconds to wait for this thread to die.

`nanos`

An additional number of nanoseconds to wait.

Throws

`InterruptedException`

If another thread interrupts this thread.

Description

This method causes a thread to wait to die. The method returns when this `Thread` object dies or after the specified amount of time has elapsed, whichever comes first. However, if `millis` and `nanos` are zero, the method will wait forever for this thread to die. If this thread is already dead, the method returns immediately.

Note that Sun's reference implementation of Java does not attempt to implement the precision implied by this method. Instead, it rounds to the nearest millisecond (unless `millis` is `0`, in which case it rounds up to 1 millisecond) and calls `join(long)`.

resume

`public final void resume()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method resumes a suspended thread. The method causes this `Thread` object to once again be eligible to be run. Calling this method for a thread that is not suspended has no effect.

run

`public void run()`

Implements

`Runnable.run()`

Description

A `Thread` object's `start()` method causes the thread to invoke a `run()` method. If this `Thread` object was created without a specified `Runnable` object, the `Thread` object's own `run()` method is executed. This behavior is only useful in a subclass of `Thread` that overrides this `run()` method, since the `run()` method of the `Thread` class does not do anything.

setDaemon

`public final void setDaemon(boolean on)`

Parameters

`on`

The new value for this thread's daemon attribute.

Throws

`IllegalThreadStateException`

If this method is called after this thread has been started and while it is still alive.

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the daemon attribute of this `Thread` object to the given value. This method must be called before the thread is started. If a thread dies and there are no other threads except daemon threads alive, the Java virtual machine stops.

setName

`public final void setName(String name)`

Parameters

`name`

The new name for this thread.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a

SecurityException.

Description

This method sets the name of this Thread object to the given value. The uniqueness of the specified Thread object's name is not checked, which may be a problem for programs that attempt to identify Thread objects by their name.

setPriority

public final void setPriority(int newPriority)

Parameters

newPriority

The new priority for this thread.

Throws

IllegalArgumentException

If the given priority is less than MIN_PRIORITY or greater than MAX_PRIORITY.

SecurityException

If the checkAccess() method of the SecurityManager throws a SecurityException.

Description

This method sets the priority of this Thread to the given value.

start

public synchronized native void start()

Throws

IllegalThreadStateException

If this `Thread` object's `start()` method has been called before.

Description

This method starts this `Thread` object, allowing it to be scheduled for execution. The top-level code that is executed by the thread is the `run()` method of the `Runnable` object specified in the constructor that was used to create this object. If no such object was specified, the top-level code executed by the thread is this object's `run()` method.

It is not permitted to start a thread more than once.

stop

`public final void stop()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes this `Thread` object to stop executing by throwing a `ThreadDeath` object. The object is thrown in this thread, even if the method is called from a different thread. This thread is forced to stop whatever it is doing and throw a newly created `ThreadDeath` object. If this thread was suspended, it is resumed; if it was sleeping, it is awakened. Normally, you should not catch `ThreadDeath` objects in a `try` statement. If you need to catch `ThreadDeath` objects to detect a `Thread` is about to die, the `try` statement that catches `ThreadDeath` objects should rethrow them.

When an object is thrown out of the `run()` method associated with a `Thread`, the `uncaughtException()` method of the `ThreadGroup` for that `Thread` is called. The `uncaughtException()` method normally outputs a stack trace. However, `uncaughtException()` treats a `ThreadDeath` object as a special case by not outputting a stack trace. When the `uncaughtException()` method returns, the thread is dead. The thread is never scheduled to run again.

If this `Thread` object's `stop()` method is called before this thread is started, the `ThreadDeath` object is thrown as soon as the thread is started.

`public final synchronized void stop(Throwable o)`

Parameters

`o`

The object to be thrown.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method causes this `Thread` object to stop executing by throwing the given object. Normally, the `stop()` method that takes no arguments and throws a `ThreadDeath` object should be called instead of this method. However, if it is necessary to stop a thread by throwing some other type of object, this method can be used.

The object is thrown in this thread, even if the method is called from a different thread. This thread is forced to stop whatever it is doing and throw the `Throwable` object `o`. If this thread was suspended, it is resumed; if it was sleeping, it is awakened.

When an object is thrown out of the `run()` method associated with a `Thread`, the `uncaughtException()` method of the `ThreadGroup` for that `Thread` is called. If the thrown object is not an instance of the `ThreadDeath` class, `uncaughtException()` calls the thrown object's `printStackTrace()` method and then the thread dies. The thread is never scheduled to run again.

If this `Thread` object's `stop()` method is called before this thread is started, the `ThreadDeath` object is thrown as soon as the thread is started.

suspend

`public final void suspend()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method suspends a thread. The method causes this `Thread` object to temporarily be ineligible to be run. The thread becomes eligible to be run again after its `resume()` method is called. Calling this method for a thread that is already suspended has no effect.

toString

`public String toString()`

Returns

A string representation of this `Thread` object.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Thread` object.

Inherited Methods

ThreadDeath

Name

ThreadDeath

Synopsis

Class Name:

`java.lang.ThreadDeath`

Superclass:

`java.lang.Error`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `ThreadDeath` object is thown by the `stop()` method of a `Thread` object to kill the thread. Catching

ThreadDeath objects is not recommended. If it is necessary to catch a ThreadDeath object, it is important to rethrow the object so that it is possible to cleanly stop the catching thread.

Class Summary

```
public class java.lang.ThreadDeath extends java.lang.Error {
  // Constructors
  public ThreadDeath();
}
```

Constructors

ThreadDeath

public ThreadDeath()

Description

> This constructor creates a ThreadDeath object with no associated detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	equals(Object)	Object

ThreadGroup

Name

ThreadGroup

Synopsis

Class Name:

```
java.lang.ThreadGroup
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The ThreadGroup class implements a grouping scheme for threads. A ThreadGroup object can own Thread objects and other ThreadGroup objects. The ThreadGroup class provides methods that allow a ThreadGroup object to control its Thread and ThreadGroup objects as a group. For example, suspend() and resume() methods of a ThreadGroup object call the suspend() and resume() methods of each of the Thread and ThreadGroup objects that belong to the particular ThreadGroup.

When a Java program starts, a ThreadGroup object is created to own the first Thread. Any additional ThreadGroup objects are explicitly created by the program.

Class Summary

```
public class java.lang.ThreadGroup extends java.lang.Object {
    // Constructors
    public ThreadGroup(String name);
    public ThreadGroup(ThreadGroup parent, String name;
    // Instance Methods
    public int activeCount();
    public int activeGroupCount();
    public boolean allowThreadSuspension(boolean b);       // New in 1.1
    public final void checkAccess();
    public final void destroy();
    public int enumerate(Thread list[]);
    public int enumerate(Thread list[], boolean recurse);
    public int enumerate(ThreadGroup list[]);
    public int enumerate(ThreadGroup list[], boolean recurse);
    public final int getMaxPriority();
    public final String getName();
    public final ThreadGroup getParent();
    public final boolean isDaemon();
    public synchronized boolean isDestroyed();             // New in 1.1
    public void list();
    public final boolean parentOf(ThreadGroup g);
    public final void resume();
    public final void setDaemon(boolean daemon);
    public final void setMaxPriority(int pri);
    public final void stop();
    public final void suspend();
    public String toString();
    public void uncaughtException(Thread t, Throwable e);
}
```

Constructors

ThreadGroup

`public ThreadGroup(String name)`

Parameters

`name`

The name of this `ThreadGroup` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

Creates a `ThreadGroup` object that has the specified name and the same parent `ThreadGroup` as the current thread.

`public ThreadGroup(ThreadGroup parent, String name)`

Parameters

`parent`

The `ThreadGroup` object that this `ThreadGroup` object is to be added to.

`name`

The name of this `ThreadGroup` object.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a

SecurityException.

Description

Creates a ThreadGroup object with the specified name and parent ThreadGroup object.

Instance Methods

activeCount

public int activeCount()

Returns

An approximation of the current number of threads in this ThreadGroup object and any child ThreadGroup objects.

Description

This method returns an approximation of the number of threads that belong to this ThreadGroup object and any child ThreadGroup objects. The count is approximate because a thread can die after it is counted, but before the complete count is returned. Also, after a child ThreadGroup is counted but before the total count is returned, additional Thread and ThreadGroup objects can be added to a child ThreadGroup.

activeGroupCount

public int activeGroupCount()

Returns

An approximation of the current number of child ThreadGroup objects in this ThreadGroup object.

Description

This method returns an approximation of the number of child ThreadGroup objects that belong to this ThreadGroup object. The count is approximate because after a child ThreadGroup is counted but before the total count is returned, additional ThreadGroup objects can be added to a child ThreadGroup.

allowThreadSuspension

`public boolean allowThreadSuspension(boolean b)`

Availability

New as of JDK 1.1

Parameters

`b`

A `boolean` value that specifies whether or not the run-time system is allowed to suspend threads due to low memory.

Returns

The `boolean` value `true`.

Description

This method specifies whether or not the Java virtual machine is allowed to suspend threads due to low memory.

checkAccess

`public final void checkAccess()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method determines if the currently running thread has permission to modify this `ThreadGroup` object.

destroy

`public final void destroy()`

Throws

`IllegalThreadStateException`

If this `ThreadGroup` object is not empty, or if it has already been destroyed.

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method destroys this `ThreadGroup` object and any child `ThreadGroup` objects. The `ThreadGroup` must not contain any `Thread` objects. This method also removes the `ThreadGroup` object from its parent `ThreadGroup` object.

enumerate

`public int enumerate(Thread list[])`

Parameters

`list`

A reference to an array of `Thread` objects.

Returns

The number of `Thread` objects stored in the array.

Description

This method stores a reference in the array for each of the `Thread` objects that belongs to this `ThreadGroup` or any of its child `ThreadGroup` objects.

If the array is not big enough to contain references to all the `Thread` objects, only as many references as will fit are put into the array. No indication is given that some `Thread` objects were left out, so it is a good idea to call `activeCount()` before calling this method, to get an idea of how large to make the array.

`public int enumerate(Thread list[], boolean recurse)`

Parameters

`list`

A reference to an array of `Thread` objects.

`recurse`

A `boolean` value that specifies whether or not to include `Thread` objects that belong to child `ThreadGroup` objects of this `ThreadGroup` object.

Returns

The number of `Thread` objects stored in the array.

Description

This method stores a reference in the array for each of the `Thread` objects that belongs to this `ThreadGroup` object. If `recurse` is `true`, the method also stores a reference for each of the `Thread` objects that belongs to a child `ThreadGroup` object of this `ThreadGroup`.

If the array is not big enough to contain references to all the `Thread` objects, only as many references as will fit are put into the array. No indication is given that some `Thread` objects were left out, so it is a good idea to call `activeCount()` before calling this method, to get an idea of how large to make the array.

`public int enumerate(ThreadGroup list[])`

Parameters

`list`

A reference to an array of `ThreadGroup` objects.

Returns

The number of `ThreadGroup` objects stored in the array.

Description

This method stores a reference in the array for each `ThreadGroup` object that belongs to this `ThreadGroup` or any of its child `ThreadGroup` objects.

If the array is not big enough to contain references to all the `ThreadGroup` objects, only as many references as will fit are put into the array. No indication is given that some `ThreadGroup` objects were left out, so it is a good idea to call `activeGroupCount()` before calling this method, to get an idea of how large to make the array.

`public int enumerate(Thread list[], boolean recurse)`

Parameters

`list`

A reference to an array of `ThreadGroup` objects.

`recurse`

A `boolean` value that specifies whether or not to include `ThreadGroup` objects that belong to child `ThreadGroup` objects of this `ThreadGroup` object.

Returns

The number of `ThreadGroup` objects stored in the array.

Description

This method stores a reference in the array for each of the `ThreadGroup` objects that belongs to this `ThreadGroup` object. If `recurse` is `true`, the method also stores a reference for each of the `ThreadGroup` objects that belongs to a child `ThreadGroup` object of this `ThreadGroup`.

If the array is not big enough to contain references to all the `ThreadGroup` objects, only as many references as will fit are put into the array. No indication is given that some `ThreadGroup` objects were left out, so it is a good idea to call `activeGroupCount()` before calling this method, to get an idea of how large to make the array.

getMaxPriority

`public final int getMaxPriority()`

Returns

> The maximum priority that can be assigned to `Thread` objects that belong to this `ThreadGroup` object.

Description

> This method returns the maximum priority that can be assigned to `Thread` objects that belong to this `ThreadGroup` object.
>
> It is possible for a `ThreadGroup` to contain `Thread` objects that have higher priorities than this maximum, if they were given that higher priority before the maximum was set to a lower value.

getName

`public final String getName()`

Returns

> The name of this `ThreadGroup` object.

Description

> This method returns the name of this `ThreadGroup` object.

getParent

`public final ThreadGroup getParent()`

Returns

> The parent `ThreadGroup` object of this `ThreadGroup`, or `null` if this `ThreadGroup` is the root of the thread group hierarchy.

Description

> This method returns the parent `ThreadGroup` object of this `ThreadGroup` object. If this `ThreadGroup` is at the root of the thread group hierarchy and has no parent, the method returns `null`.

isDaemon

`public final boolean isDaemon()`

Returns

> `true` if this `ThreadGroup` is a daemon thread group; otherwise `false`.

Description

> This method determines whether or not this `ThreadGroup` is a daemon thread group, based on the value of daemon attribute of this `ThreadGroup` object. A daemon thread group is destroyed when the last `Thread` in it is stopped, or the last `ThreadGroup` in it is destroyed.

isDestroyed

`public synchronized boolean isDestroyed()`

Availability

> New as of JDK 1.1

Returns

> `true` if this `ThreadGroup` has been destroyed; otherwise `false`.

Description

> This method determines whether or not this `ThreadGroup` has been destroyed.

list

`public void list()`

Description

> This method outputs a listing of the contents of this `ThreadGroup` object to `System.out`.

parentOf

`public final boolean parentOf(ThreadGroup g)`

Parameters

`g`

A `ThreadGroup` object.

Returns

`true` if this `ThreadGroup` object is the same `ThreadGroup`, or a direct or indirect parent of the specified `ThreadGroup`; otherwise `false`.

Description

This method determines if this `ThreadGroup` object is the same as the specified `ThreadGroup` or one of its ancestors in the thread-group hierarchy.

resume

`public final void resume()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method resumes each `Thread` object that directly or indirectly belongs to this `ThreadGroup` object by calling its `resume()` method.

setDaemon

`public final void setDaemon(boolean daemon)`

Parameters

`daemon`

The new value for this `ThreadGroup` object's daemon attribute.

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method sets the daemon attribute of this `ThreadGroup` object to the given value. A daemon thread group is destroyed when the last `Thread` in it is stopped, or the last `ThreadGroup` in it is destroyed.

setMaxPriority

`public final void setMaxPriority(int pri)`

Parameters

`pri`

The new maximum priority for `Thread` objects that belong to this `ThreadGroup` object.

Description

This method sets the maximum priority that can be assigned to `Thread` objects that belong to this `ThreadGroup` object.

It is possible for a `ThreadGroup` to contain `Thread` objects that have higher priorities than this maximum, if they were given that higher priority before the maximum was set to a lower value.

stop

`public final void stop()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method stops each `Thread` object that directly or indirectly belongs to this `ThreadGroup` object by calling its `stop()` method.

suspend

`public final void suspend()`

Throws

`SecurityException`

If the `checkAccess()` method of the `SecurityManager` throws a `SecurityException`.

Description

This method suspends each `Thread` object that directly or indirectly belongs to this `ThreadGroup` object by calling its `suspend()` method.

toString

`public String toString()`

Returns

A string representation of this `ThreadGroup` object.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `ThreadGroup` object.

uncaughtException

`public void uncaughtException(Thread t, Throwable e)`

Parameters

`t`

A reference to a `Thread` that just died because of an uncaught exception.

`e`

The uncaught exception.

Description

This method is called when a `Thread` object that belongs to this `ThreadGroup` object dies because of an uncaught exception. If this `ThreadGroup` object has a parent `ThreadGroup` object, this method just calls the parent's `uncaughtException()` method. Otherwise, this method must determine whether the uncaught exception is an instance of `ThreadDeath`. If it is, nothing is done. If it is not, the method calls the `printStackTrace()` method of the exception object.

If this method is overridden, the overriding method should end with a call to `super.uncaughtException()`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Throwable

Name

Throwable

Synopsis

Class Name:

```
java.lang.Throwable
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

```
java.lang.Error, java.lang.Exception
```

Interfaces Implemented:

```
java.io.Serializable
```

Availability:

JDK 1.0 or later

Description

The `Throwable` class is the superclass of all objects that can be thrown by the `throw` statement in Java. This is a requirement of the `throw` statement.

A `Throwable` object can have an associated message that provides more detail about the particular error or exception that is being thrown.

The `Throwable` class provides a method that outputs information about the state of the system when an exception object is created. This method can be useful in debugging Java programs.

The subclasses of `Throwable` that are provided with Java do not add functionality to `Throwable`. Instead, they offer more specific classifications of errors and exceptions.

Class Summary

```
public class java.lang.Throwable extends java.lang.Object
                                 implements java.lang.Serializable {
    // Constructors
    public Throwable();
    public Throwable(String message);
    // Instance Methods
    public native Throwable fillInStackTrace();
    public String getLocalizedMessage();              // New in 1.1
    public String getMessage();
    public void printStackTrace();
    public void printStackTrace(PrintStream s);
    public void printStackTrace(PrintWriter s);       // New in 1.1
    public String toString();
}
```

Constructors

Throwable

`public Throwable()`

Description

Creates a `Throwable` object with no associated message. This constructor calls `fillInStackTrace()` so that information is available for `printStackTrace()`.

`public Throwable(String message)`

Parameters

`message`

A message string to be associated with the object.

Description

Create a `Throwable` object with an associated message. This constructor calls `fillInStackTrace()` so that information is available for `printStackTrace()`.

Instance Methods

fillInStackTrace

`public native Throwable fillInStackTrace()`

Returns

A reference to this object.

Description

This method puts stack trace information in this `Throwable` object. It is not usually necessary to explicitly call this method, since it is called by the constructors of the class. However, this method can be useful when rethrowing an object. If the stack trace information in the object needs to reflect the location that the object is rethrows from, `fillInStackTrace()` should be called.

getLocalizedMessage

`public String getLocalizedMessage()`

Availability

New as of JDK 1.1

Returns

A localized version of the `String` object associated with this `Throwable` object, or `null` if there is no message associated with this object.

Description

This method creates a localized version of the message that was associated with this object by its constructor.

The `getLocalizedMessage()` method in `Throwable` always returns the same result as `getMessage()`. A subclass must override this method to produce a locale-specific message.

getMessage

`public String getMessage()`

Returns

The `String` object associated with this `Throwable` object, or `null` if there is no message associated with this object.

Description

This method returns any string message that was associated with this object by its constructor.

printStackTrace

`public void printStackTrace()`

Description

This method outputs the string representation of this `Throwable` object and a stack trace to `System.err`.

`public void printStackTrace(PrintStream s)`

Parameters

s

A `java.io.PrintStream` object.

Description

This method outputs the string representation of this `Throwable` object and a stack trace to the specified `PrintStream` object.

`public void printStackTrace(PrintStream w)`

Availability

New as of JDK 1.1

Parameters

s

A `java.io.PrintWriter` object.

Description

This method outputs the string representation of this `Throwable` object and a stack trace to the specified `PrintWriter` object.

toString

`public String toString()`

Returns

A string representation of this object.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Throwable` object.

Synopsis

Class Name:

`java.lang.UnknownError`

Superclass:

`java.lang.VirtualMachineError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `UnknownError` is thrown when an error of unknown origins is detected in the run-time system.

Class Summary

```
public class java.lang.UnknownError
             extends java.lang.VirtualMachineError {
  // Constructors
  public UnknownError();
  public UnknownError(String s);
}
```

Constructors

UnknownError

public UnknownError()

Description

This constructor creates an `UnknownError` with no associated detail message.

public UnknownError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `UnknownError` with the specified detail message.

VerifyError

Name

VerifyError

Synopsis

Class Name:

`java.lang.VerifyError`

Superclass:

`java.lang.LinkageError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `VerifyError` is thrown when the byte-code verifier detects that a class file, though well-formed, contains some sort of internal inconsistency or security problem.

As part of loading the byte-codes for a class, the Java virtual machine may run the *.class* file through the byte-code verifier. The default mode of the virtual machine causes it not to verify classes that are found locally, however. Thus, after compiling an applet and running it locally, you may still get a `VerifyError` when you put it on a web server.

Class Summary

```
public class java.lang.VerifyError extends java.lang.LinkageError {
  // Constructors
  public VerifyError();
  public VerifyError(String s);
}
```

Constructors

VerifyError

public VerifyError()

Description

This constructor creates a `VerifyError` with no associated detail message.

public VerifyError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `VerifyError` with the specified detail message.

VerifyError BOOK INDEX Void

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Void

Name

Void

Synopsis

Class Name:

`java.lang.Void`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability

New as of JDK 1.1

Description

The `Void` class is an uninstantiable wrapper for the primitive type `void`. The class contains simply a reference to the `Class` object that represents the primitive type `void`. The `Void` class is necessary as of JDK 1.1 to support the Reflection API and class literals.

Class Summary

```
public final class java.lang.Void extends java.lang.Object {
  // Constants
  public static final Class TYPE;
}
```

Constants

TYPE

public static final Class TYPE

The `Class` object that represents the primitive type `void`. It is always true that `Void.TYPE == void.class`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Constructor

Name

Constructor

Synopsis

Class Name:

    `java.lang.reflect.Constructor`

Superclass:

    `java.lang.Object`

Immediate Subclasses:

    None

Interfaces Implemented:

    `java.lang.reflect.Member`

Availability:

    New as of JDK 1.1

Description

The `Constructor` class represents a constructor of a class. A `Constructor` object can be obtained by calling the `getConstructor()` method of a `Class` object. `Constructor` provides methods for getting the name, modifiers, parameters, exceptions, and declaring class of a constructor. The `newInstance()` method can create a new instance of the class that declares a constructor.

Class Summary

```
public final class java.lang.reflect.Constructor extends java.lang.Object
                   implements java.lang.reflect.Member {
  // Instance Methods
  public boolean equals(Object obj);
  public Class getDeclaringClass();
  public Class[] getExceptionTypes();
  public native int getModifiers();
  public String getName();
  public Class[] getParameterTypes();
  public int hashCode();
  public native Object newInstance(Object[] initargs);
  public String toString();
}
```

Instance Methods

equals

public boolean equals(Object obj)

Parameters

obj

The object to be compared with this object.

Returns

true if the objects are equal; false if they are not.

Overrides

Object.equals()

Description

This method returns true if obj is an instance of Constructor, and it is equivalent to this Constructor.

getDeclaringClass

public Class getDeclaringClass()

Returns

The Class object that represents the class that declared this constructor.

Implements

`Member.getDeclaringClass()`

Description

This method returns the `Class` object for the class in which this constructor is declared.

getExceptionTypes

public Class[] getExceptionTypes()

Returns

An array that contains the `Class` objects that describe the exceptions that can be thrown by this constructor.

Description

This method returns an array of `Class` objects that represents the `throws` clause of this constructor. If the constructor does not throw any exceptions, an array of length `0` is returned. As of Java 1.1.2, this method is not properly supported: it always returns an empty array.

getModifiers

public native int getModifiers()

Returns

An integer that represents the modifier keywords used to declare this constructor.

Implements

`Member.getModifiers()`

Description

This method returns an integer value that represents the modifiers of this constructor. The `Modifier` class should decode the returned value.

getName

public String getName()

Returns

The name of this constructor as a `String`.

Implements

`Member.getName()`

Description

This method returns the name of this constructor, which is always the same as the name of the declaring class.

getParameterTypes

public Class[] getParameterTypes()

Returns

An array that contains the `Class` objects that describe the parameter types that this constructor accepts.

Description

This method returns an array of `Class` objects that represents the parameter types this constructor accepts. The parameter types are listed in the order in which they are declared. If the constructor does not take any parameters, an array of length `0` is returned.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `Constructor`.

newInstance

`public native Object newInstance(Object[] initargs) throws InstantiationException, IllegalAccessException, IllegalArgumentException, InvocationTargetException`

Parameters

`initargs`

An array of arguments to be passed to this constructor.

Returns

The newly created object.

Throws

`InstantiationException`

If the declaring class of this constructor is `abstract`.

`IllegalAccessException`

If the constructor is inaccessible.

`IllegalArgumentException`

If `initargs` is the wrong length or contains any value of the wrong type.

`InvocationTargetException`

If the constructor itself throws an exception.

Description

This method executes the constructor represented by this object using the given array of arguments. Thus, it creates and initializes a new instance of the declaring class of the constructor. If a particular parameter is of a primitive type, the corresponding argument is automatically unwrapped and converted to the appropriate type, if possible. If that is not possible, an `IllegalArgumentException` is thrown. If the constructor itself throws an exception, the exception is placed in an `InvocationTargetException`, which is then thrown to the caller of `newInstance()`. If the constructor completes normally, the newly created instance is returned.

toString

public String toString()

Returns

A string representation of this object.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Constructor`. This string contains the access modifiers of the constructor, if any, followed by the fully qualified name of the declaring class and a list of the parameters of the constructor, if any. The list is enclosed by parentheses, and the individual parameters are separated by commas. If the constructor does not have any parameters, just the parentheses are included in the string.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

BigInteger

Name

BigInteger

Synopsis

Class Name:

`java.math.BigInteger`

Superclass:

`java.lang.Number`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `BigInteger` class represents an arbitrary-precision integer value. You should use this class if a `long` is not big enough for your purposes. The number in a `BigInteger` is represented by a sign value and a magnitude, which is an arbitrarily large array of bytes. A `BigInteger` cannot overflow.

Most of the methods in `BigInteger` perform mathematical operations or make comparisons with other `BigInteger` objects. BigInteger also defines some methods for handling modular arithmetic and determining primality that are needed for cryptographic purposes.

Class Summary

```
public class java.math.BigInteger extends java.lang.Number {
  // Constructors
  public BigInteger(byte[] val);
  public BigInteger(int signum, byte[] magnitude);
  public BigInteger(String val);
  public BigInteger(String val, int radix);
  public BigInteger(int numBits, Random rndSrc);
  public BigInteger(int bitLength, int certainty, Random rnd);
  // Class Methods
  public static BigInteger valueOf(long val);
  // Instance Methods
  public BigInteger abs();
  public BigInteger add(BigInteger val);
  public BigInteger and(BigInteger val);
  public BigInteger andNot(BigInteger val);
  public int bitCount();
  public int bitLength();
  public BigInteger clearBit(int n);
  public int compareTo(BigInteger val);
  public BigInteger divide(BigInteger val);
  public BigInteger[] divideAndRemainder(BigInteger val);
  public double doubleValue();
  public boolean equals(Object x);
  public BigInteger flipBit(int n);
  public float floatValue();
  public BigInteger gcd(BigInteger val);
  public int getLowestSetBit();
  public int hashCode();
  public int intValue();
  public boolean isProbablePrime(int certainty);
  public long longValue();
  public BigInteger max(BigInteger val);
  public BigInteger min(BigInteger val);
  public BigInteger mod(BigInteger m);
  public BigInteger modInverse(BigInteger m);
  public BigInteger modPow(BigInteger exponent, BigInteger m);
  public BigInteger multiply(BigInteger val);
  public BigInteger negate();
  public BigInteger not();
  public BigInteger or(BigInteger val);
  public BigInteger pow(int exponent);
  public BigInteger remainder(BigInteger val);
  public BigInteger setBit(int n);
  public BigInteger shiftLeft(int n);
  public BigInteger shiftRight(int n);
  public int signum();
  public BigInteger subtract(BigInteger val);
  public boolean testBit(int n);
  public byte[] toByteArray();
  public String toString();
  public String toString(int radix);
  public BigInteger xor(BigInteger val);
}
```

Constructors

BigInteger

public BigInteger(byte[] val) throws NumberFormatException

Parameters

`val`

The initial value.

Throws

`NumberFormatException`

If the array does not contain any bytes.

Description

This constructor creates a `BigInteger` with the given initial value. The value is expressed as a two's complement signed integer, with the most significant byte in the first position (`val[0]`) of the array (big-endian). The most significant bit of the most significant byte is the sign bit.

`public BigInteger(int signum, byte[] magnitude) throws NumberFormatException`

Parameters

`signum`

The sign of the value: `-1` indicates negative, `0` indicates zero, and `1` indicates positive.

`magnitude`

The initial magnitude of the value.

Throws

`NumberFormatException`

If `signum` is invalid or if `signum` is 0 but `magnitude` is not 0.

Description

This constructor creates a `BigInteger` with the given initial value and sign. The magnitude is expressed as a big-endian byte array.

public BigInteger(String val) throws NumberFormatException

Parameters

`val`

The initial value.

Throws

`NumberFormatException`

If the string cannot be parsed into a valid `BigInteger`.

Description

This constructor creates a `BigInteger` with the initial value specified by the `String`. The string can contain an optional minus sign followed by zero or more decimal digits. The mapping from characters to digits is provided by the `Character.digit()` method.

`public BigInteger(String val, int radix) throws NumberFormatException`

Parameters

`val`

The initial value.

`radix`

The radix to use to parse the given string.

Throws

`NumberFormatException`

If the string cannot be parsed, or if the radix is not in the allowed range (`Character.MIN_RADIX` through `Character.MAX_RADIX`).

Description

This constructor creates a `BigInteger` with the initial value specified by the `String` using the given radix. The string can contain an optional minus sign followed by zero or more digits in the specified radix. The mapping from characters to digits is provided by the `Character.digit()` method.

`public BigInteger(int numBits, Random rndSrc) throws IllegalArgumentException`

Parameters

`numBits`

The maximum number of bits in the returned number.

`rndSrc`

The source of the random bits.

Throws

`IllegalArgumentException`

If `numBits` is less than zero.

Description

This constructor creates a random `BigInteger` in the range `0` to `2^numBits -1`.

public BigInteger(int bitLength, int certainty, Random rnd)

Parameters

`bitLength`

The maximum number of bits in the returned number.

`certainty`

The certainty that the returned value is a prime number.

`rnd`

The source of the random bits.

Throws

`ArithmeticException`

If numBits is less than 2.

Description

This constructor creates a random BigInteger in the range 0 to 2^numBits-1 that is probably a prime number. The probability that the returned number is prime is greater than 1-.5^certainty. In other words, the higher the value of certainty, the more likely the BigInteger is to be prime, and also the longer it takes for the constructor to create the BigInteger.

Class Methods

valueOf

public static BigInteger valueOf(long val)

Parameters

val

The initial value.

Returns

A BigInteger that represents the given value.

Description

This method creates a BigInteger from the given long value.

Instance Methods

abs

public BigInteger abs()

Returns

A BigInteger that contains the absolute value of this number.

Description

This method returns the absolute value of this BigInteger. If this BigInteger is nonnegative, it is returned. Otherwise, a new BigInteger that contains the absolute value of this BigInteger is returned.

add

public BigInteger add(BigInteger val) throws ArithmeticException

Parameters

`val`

The number to be added.

Returns

A new `BigInteger` that contains the sum of this number and the given value.

Throws

`ArithmeticException`

If any kind of arithmetic error occurs.

Description

This method returns the sum of this `BigInteger` and the given `BigInteger` as a new `BigInteger`.

and

public BigInteger and(BigInteger val)

Parameters

`val`

The number to be ANDed.

Returns

A new `BigInteger` that contains the bitwise AND of this number and the given value.

Description

This method returns the bitwise AND of this `BigInteger` and the supplied `BigInteger` as a new `BigInteger`.

andNot

public BigInteger andNot(BigInteger val)

Parameters

`val`

The number to be combined with this `BigInteger`.

Returns

A new `BigInteger` that contains the bitwise AND of this number and the bitwise negation of the given value.

Description

This method returns the bitwise AND of this `BigInteger` and the bitwise negation of the given `BigInteger` as a new `BigInteger`. Calling this method is equivalent to calling `and(val.not())`.

bitCount

public int bitCount()

Returns

The number of bits that differ from this `BigInteger`'s sign bit.

Description

This method returns the number of bits in the two's complement representation of this `BigInteger` that differ from the sign bit of this `BigInteger`.

bitLength

public int bitLength()

Returns

The number of bits needed to represent this number, excluding a sign bit.

Description

This method returns the minimum number of bits needed to represent this number, not counting a sign bit.

clearBit

public BigInteger clearBit(int n) throws ArithmeticException

Parameters

`n`

The bit to clear.

Returns

A new `BigInteger` that contains the value of this `BigInteger` with the given bit cleared.

Throws

`ArithmeticException`

If `n` is less than 0.

Description

This method returns a new `BigInteger` that is equal to this `BigInteger`, except that the given bit is cleared, or set to zero.

compareTo

public int compareTo(BigInteger val)

Parameters

`val`

The value to be compared.

Returns

`-1` if this number is less than `val`, `0` if this number is equal to `val`, or `1` if this number is greater than `val`.

Description

This method compares this `BigInteger` to the given `BigInteger` and returns a value that indicates the result of the comparison. This method can be used to implement all six of the standard boolean comparison operators: `==`, `!=`, `<=`, `<`, `>=`, and `>`.

divide

public BigInteger divide(BigInteger val) throws ArithmeticException

Parameters

`val`

The divisor.

Returns

A new `BigInteger` that contains the result (quotient) of dividing this number by the given value.

Throws

`ArithmeticException`

If `val` is zero.

Description

This method returns the quotient that results from dividing this `BigInteger` by the given `BigInteger` as a new `BigInteger`. Any fractional remainder is discarded.

divideAndRemainder

```
public BigInteger[] divideAndRemainder(BigInteger val) throws ArithmeticException
```

Parameters

`val`

The divisor.

Returns

An array of `BigInteger` objects that contains the quotient and remainder (in that order) that result from dividing this number by the given value.

Throws

`ArithmeticException`

If `val` is zero.

Description

This method returns the quotient and remainder that results from dividing this `BigInteger` by the given `BigInteger` as an array of new `BigInteger` objects. The first element of the array is equal to `divide(val)`; the second element is equal to `remainder(val)`.

doubleValue

public double doubleValue()

Returns

The value of this `BigInteger` as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this `BigInteger` as a `double`. If the value exceeds the limits of a `double`, `Double.POSITIVE_INFINITY` or `Double.NEGATIVE_INFINITY` is returned.

equals

public boolean equals(Object x)

Parameters

`x`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `x` is an instance of `BigInteger`, and it represents the same value as this `BigInteger`.

flipBit

public BigInteger flipBit(int n)

Parameters

`n`

The bit to toggle.

Returns

A new `BigInteger` that contains the value of this `BigInteger` with the given bit toggled.

Throws

`ArithmeticException`

If `n` is less than 0.

Description

This method returns a new `BigInteger` that is equal to this `BigInteger`, except that the given bit is toggled. In other words, if the given bit is `0`, it is set to one, or if it is `1`, it is set to zero.

floatValue

public float floatValue()

Returns

The value of this `BigInteger` as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this `BigInteger` as a `float`. If the value exceeds the limits of a `float`, `Float.POSITIVE_INFINITY` or `Float.NEGATIVE_INFINITY` is returned.

gcd

public BigInteger gcd(BigInteger val)

Parameters

`val`

The number to be compared.

Returns

A new `BigInteger` that contains the greatest common denominator of this number and the given number.

Description

This method calculates the greatest common denominator of the absolute value of this `BigInteger` and the absolute value of the given `BigInteger`, and returns it as a new `BigInteger`. If both values are `0`, the method returns a `BigInteger` that contains the value `0`.

getLowestSetBit

public int getLowestSetBit()

Returns

> The index of the lowest-order bit with a value of `1`, or `-1` if there are no bits that are `1`.

Description

> This method returns the index of the lowest-order, or rightmost, bit with a value of `1`.

hashCode

public int hashCode()

Returns

> A hashcode for this object.

Overrides

> `Object.hashCode()`

Description

> This method returns a hashcode for this `BigInteger`.

intValue

public int intValue()

Returns

> The value of this `BigInteger` as an `int`.

Overrides

> `Number.intValue()`

Description

> This method returns the value of this `BigInteger` as an `int`. If the value exceeds the limits of an `int`, the excessive high-order bits are discarded.

isProbablePrime

public boolean isProbablePrime(int certainty)

Parameters

`certainty`

The "certainty" that this number is prime, where a higher value indicates more certainty.

Returns

`true` if this number is probably prime; `false` if it is definitely not prime.

Description

This method returns `true` if this number has a probability of being prime that is greater than `1-.5^certainty`. If the number is definitely not prime, `false` is returned.

longValue

public long longValue()

Returns

The value of this `BigInteger` as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this `BigInteger` as a `long`. If the value exceeds the limits of a `long`, the excessive high-order bits are discarded.

max

public BigInteger max(BigInteger val)

Parameters

`val`

The number to be compared.

Returns

The `BigInteger` that represents the greater of this number and the given value.

Description

This method returns the greater of this `BigInteger` and the given `BigInteger`.

min

public BigInteger min(BigInteger val)

Parameters

`val`

The number to be compared.

Returns

The `BigInteger` that represents the lesser of this number and the given value.

Description

This method returns the lesser of this `BigInteger` and the given `BigInteger`.

mod

public BigInteger mod(BigInteger m)

Parameters

`m`

The number to use.

Returns

A new `BigInteger` that contains the modulus of this number and the given number.

Throws

`ArithmeticException`

If `m` is less than or equal to zero.

Description

This method returns a new `BigInteger` that contains the value of this `BigInteger` mod `m`.

modInverse

```
public BigInteger modInverse(BigInteger m) throws ArithmeticException
```

Parameters

`m`

The number to use.

Returns

A new `BigInteger` that contains the multiplicative inverse of the modulus of this number and the given number.

Throws

`ArithmeticException`

If `m` is less than or equal to zero, or if the result cannot be calculated.

Description

This method returns a new `BigInteger` that contains the multiplicative inverse of the value of this `BigInteger` mod `m`.

modPow

public BigInteger modInverse(BigInteger exponent, BigInteger m)

Parameters

`exponent`

The exponent.

`m`

The number to use.

Returns

A new `BigInteger` that contains the modulus of this number raised to the given power and the given number.

Throws

`ArithmeticException`

If `m` is less than or equal to zero.

Description

This method returns a new `BigInteger` that contains the value of this `BigInteger` raised to the given power mod `m`.

multiply

public BigInteger multiply(BigInteger val)

Parameters

`val`

The number to be multiplied.

Returns

A new `BigInteger` that contains the product of this number and the given number.

Description

This method multiplies this `BigInteger` by the given `BigInteger` and returns the product as a new `BigInteger`.

negate

public BigInteger negate()

Returns

A new `BigInteger` that contains the negative of this number.

Description

This method returns a new `BigInteger` that is identical to this `BigInteger` except that its sign is reversed.

not

public BigInteger not()

Returns

A new `BigInteger` that contains the bitwise negation of this number.

Description

This method returns a new `BigInteger` that is calculated by inverting every bit of this `BigInteger`.

or

public BigInteger or(BigInteger val)

Parameters

`val`

The value to be ORed.

Returns

A new `BigInteger` that contains the bitwise OR of this number and the given value.

Description

This method returns the bitwise OR of this `BigInteger` and the given `BigInteger` as a new `BigInteger`.

pow

public BigInteger pow(int exponent) throws ArithmeticException

Parameters

`exponent`

The exponent.

Returns

A new `BigInteger` that contains the result of raising this number to the given power.

Throws

`ArithmeticException`

If `exponent` is less than zero.

Description

This method raises this `BigInteger` to the given power and returns the result as a new `BigInteger`.

remainder

```
public BigInteger remainder(BigInteger val) throws ArithmeticException
```

Parameters

`val`

The divisor.

Returns

A new `BigInteger` that contains the remainder that results from dividing this number by the given value.

Throws

`ArithmeticException`

If `val` is zero.

Description

This method returns the remainder that results from dividing this `BigInteger` by the given `BigInteger` as a new `BigInteger`.

setBit

public BigInteger setBit(int n) throws ArithmeticException

Parameters

`n`

The bit to set.

Returns

A new `BigInteger` that contains the value of this `BigInteger` with the given bit set.

Throws

`ArithmeticException`

If `n` is less than zero.

Description

This method returns a new `BigInteger` that is equal to this `BigInteger`, except that the given bit is set to `1`.

shiftLeft

public BigInteger shiftLeft(int n)

Parameters

`n`

The number of bits to shift.

Returns

A new `BigInteger` that contains the result of shifting the bits of this number left by the given number of bits.

Description

This method returns a new `BigInteger` that contains the value of this `BigInteger` left-shifted by the given number of bits.

shiftRight

public BigInteger shiftRight(int n)

Parameters

`n`

The number of bits to shift.

Returns

A new `BigInteger` that contains the result of shifting the bits of this number right by the given number of bits with sign extension.

Description

This method returns a new `BigInteger` that contains the value of this `BigInteger` right-shifted by the given number of bits with sign extension.

signum

public int signum()

Returns

`-1` is this number is negative, `0` if this number is zero, or `1` if this number is positive.

Description

This method returns a value that indicates the sign of this `BigInteger`.

subtract

public BigInteger subtract(BigInteger val)

Parameters

`val`

The number to be subtracted.

Returns

A new `BigDecimal` that contains the result of subtracting the given number from this number.

Description

This method subtracts the given `BigInteger` from this `BigInteger` and returns the result as a new `BigInteger`.

testBit

public boolean testBit(int n) throws ArithmeticException

Parameters

`n`

The bit to test.

Returns

`true` if the specified bit is `1`; `false` if the specified bit is `0`.

Throws

`ArithmeticException`

If `n` is less than zero.

Description

This method returns `true` if the specified bit in this `BigInteger` is `1`. Otherwise the method returns `false`.

toByteArray

public byte[] toByteArray()

Returns

An array of bytes that represents this object.

Description

This method returns an array of bytes that contains the two's complement representation of this `BigInteger`. The most significant byte is in the first position (`val[0]`) of the array. The array can be used with the `BigInteger(byte[])` constructor to reconstruct the number.

toString

public String toString()

Returns

A string representation of this object in decimal form.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `BigInteger` in decimal form. A minus sign represents the sign if necessary. The mapping from digits to characters is provided by the `Character.forDigit()` method.

public String toString(int radix)

Parameters

`radix`

The radix to use.

Returns

A string representation of this object in the given radix.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `BigInteger` for the given radix. A minus sign is used to represent the sign if necessary. The mapping from digits to characters is provided by the `Character.forDigit()` method.

xor

public BigInteger xor(BigInteger val)

Parameters

`val`

The value to be XORed.

Returns

A new `BigInteger` that contains the bitwise XOR of this number and the given value.

Description

This method returns the bitwise XOR of this `BigInteger` and the given `BigInteger` as a new `BigInteger`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`byteValue()`	`Number`	`clone()`	`Object`
`getClass()`	`Object`	`finalize()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`shortValue()`	`Number`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Name

ConnectException

Synopsis

Class Name:

`java.net.ConnectException`

Superclass:

`java.net.SocketException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `ConnectException` is thrown when a socket connection cannot be established with a remote machine. This type of exception usually indicates that there is no listening process on the remote machine.

Class Summary

```
public class java.net.ConnectException extends java.net.SocketException {
  // Constructors
  public ConnectException();
  public ConnectException(String msg);
}
```

Constructors

ConnectException

public ConnectException()

Description

This constructor `create`s a `ConnectException` with no associated detail message.

public ConnectException(String msg)

Parameters

`msg`

The detail message.

Description

This constructor create a `ConnectException` with the specified detail message.

BindException | BOOK INDEX | ContentHandler

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ContentHandler

Name

ContentHandler

Synopsis

Class Name:

```
java.net.ContentHandler
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `ContentHandler` class is an `abstract` class that defines a method to read data from a

URLConnection and then create an Object appropriate for the type of content it has read. Each subclass of ContentHandler handles a specific type of content (i.e., MIME type).

You do not create ContentHandler objects directly; they are created by an object that implements the ContentHandlerFactory interface. A ContentHandlerFactory object selects and creates an appropriate ContentHandler for the content type. If you write your own ContentHandler subclasses, you should also write your own ContentHandlerFactory. The content handler factory for an application is set by a call to URLConnection.setContentHandlerFactory().

An application does not normally call the getContent() method of a ContentHandler directly; it should call URL.getContent() or URLConnection.getContent() instead.

A ContentHandler works in conjunction with a URLStreamHandler, but their roles do not overlap. The URLStreamHandler deals with the specifics of a protocol, such as negotiating with a server to retrieve a resource, while the ContentHandler expects a data stream from which it can construct an object.

Class Summary

```
public abstract class java.net.ContentHandler extends java.lang.Object {
  // Instance Methods
  public abstract Object getContent(URLConnection urlc) throws IOException;
}
```

Instance Methods

getContent

public abstract Object getContent(URLConnection urlc) throws IOException

Parameters

urlc

A URLConnection that is the data source.

Returns

The Object created from the data source.

Throws

IOException

If any kind of I/O error occurs.

Description

This method reads data from the given `URLConnection` and returns the object that is represented by the data.

ContentHandlerFactory

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ContentHandlerFactory

Name

ContentHandlerFactory

Synopsis

Interface Name:

```
java.net.ContentHandlerFactory
```

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented By:

None

Availability:

JDK 1.0 or later

Description

The `ContentHandlerFactory` interface defines a method that creates and returns an appropriate `ContentHandler` object for a given MIME type. The interface is implemented by classes that select `ContentHandler` subclasses to process content.

The `URLStreamHandler` class uses a `ContentHandlerFactory` to create `ContentHandler` objects. The content type is usually implied by the portion of the URL following the last period. For example, given the following URL:

```
http://www.tolstoi.org/anna.html
```

the MIME content type is `text/html`. A `ContentHandlerFactory` that recognizes `text/html` returns a `ContentHandler` object that can process that kind of content.

Interface Declaration

```
public abstract interface java.net.ContentHandlerFactory {
  // Methods
  public abstract ContentHandler createContentHandler(String mimetype);
}
```

Methods

createContentHandler

`public abstract ContentHandler createContentHandler( String mimetype)`

Parameters

`mimetype`

A `String` that represents a MIME type.

Returns

A `ContentHandler` object that can read the specified type of content.

Description

This method creates an object of the appropriate subclass of `ContentHandler` that can read and process data for the given MIME type.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

DatagramPacket

Name

DatagramPacket

Synopsis

Class Name:

`java.net.DatagramPacket`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `DatagramPacket` class represents a packet of data that can be sent and received over the network using a `DatagramSocket`. The class is used to implement connectionless data communication.

Class Summary

```
public final class java.net.DatagramPacket extends java.lang.Object {
  // Constructors
  public DatagramPacket(byte[] ibuf, int ilength);
  public DatagramPacket(byte[] ibuf, int ilength,
                        InetAddress iaddr, int iport);
  // Instance Methods
  public synchronized InetAddress getAddress();
  public synchronized byte[] getData();
  public synchronized int getLength();
  public synchronized int getPort();
  public synchronized void setAddress(InetAddress iaddr);   // New in 1.1
  public synchronized void setData(byte[] ibuf);            // New in 1.1
  public synchronized void setLength(int ilength);          // New in 1.1
  public synchronized void setPort(int iport);              // New in 1.1
}
```

Constructors

DatagramPacket

public DatagramPacket(byte ibuf[], int ilength)

Parameters

`ibuf`

The data buffer for receiving incoming bytes.

`ilength`

The number of bytes to read.

Description

This constructor creates a `DatagramPacket` that receives data. The value of `ilength` must be less than or equal to `ibuf.length`. This `DatagramPacket` can be passed to `DatagramSocket.receive()`.

public DatagramPacket(byte ibuf[], int ilength, InetAddress iaddr, int iport)

Parameters

`ibuf`

The data buffer for the packet.

`ilength`

The number of bytes to send.

`iaddr`

The destination address.

`iport`

The destination port number.

Description

This constructor creates a `DatagramPacket` that sends packets of length `ilength` to the given port of the specified address. The value of `ilength` must be less than or equal to `ibuf.length`. The packets are sent using `DatagramSocket.send()`.

Instance Methods

getAddress

public synchronized InetAddress getAddress()

Returns

The IP address of the packet.

Description

If this packet has been received, the method returns the address of the machine that sent it. If the packet is being sent, the method returns the destination address.

getData

public synchronized byte[] getData()

Returns

The packet data.

Description

This method returns the data buffer associated with this `DatagramPacket` object. This data is either the data being sent or the data that has been received.

getLength

public synchronized int getLength()

Returns

The packet length.

Description

This method returns the length of the message in the buffer associated with this `DatagramPacket`. This length is either the length of the data being sent or the length of the data that has been received.

getPort

public synchronized int getPort()

Returns

The `port` number of the packet.

Description

If this packet has been received, the method returns the port number of the machine that sent it. If the packet is being sent, the method returns the destination port number.

setAddress

public synchronized void setAddress(InetAddress iaddr)

Availability

New as of JDK 1.1

Parameters

`iaddr`

The destination address for the packet.

Description

This method sets the destination address for this packet. When the packet is sent using `DatagramSocket.send()`, it is sent to the specified address.

setData

public synchronized void setData(byte[] ibuf)

Availability

New as of JDK 1.1

Parameters

`ibuf`

The data buffer for the packet.

Description

This method sets the data for this packet. When the packet is sent using `DatagramSocket.send()`, the specified data is sent.

setLength

public synchronized void setLength(int ilength)

Availability

New as of JDK 1.1

Parameters

`ilength`

The number of bytes to send.

Description

This method sets the length of the data to be sent for this packet. When the packet is sent using `DatagramSocket.send()`, the specified amount of data is sent.

setPort

public synchronized void setPort(int iport)

Availability

New as of JDK 1.1

Parameters

`iport`

The port number for the packet.

Description

This method sets the destination port number for this packet. When the packet is sent using `DatagramSocket.send()`, it is sent to the specified port.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

DatagramSocket

Name

DatagramSocket

Synopsis

Class Name:

`java.net.DatagramSocket`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.net.MulticastSocket`

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The DatagramSocket class implements packet-oriented, connectionless data communication. In Internet parlance, this is the User Datagram Protocol, commonly known as UDP (see RFC 768). Each packet wanders through the network, routed by its destination address. Different packets can take different paths through the network and may arrive in a different order than they were sent. Furthermore, packets are not even guaranteed to reach their destination. It is up to an application that uses DatagramSocket to determine if data is out of order or missing. While these features may seem like disadvantages of DatagramSocket, there is also some advantage to using this class. Primarily, communication using DatagramSocket is faster than Socket stream communication because of the lack of overhead involved.

Class Summary

```
public class java.net.DatagramSocket extends java.lang.Object {
  // Constructors
  public DatagramSocket();
  public DatagramSocket(int port);
  public DatagramSocket(int port, InetAddress laddr);     // New in 1.1
  // Instance Methods
  public void close();
  public InetAddress getLocalAddress();                   // New in 1.1
  public int getLocalPort();
  public synchronized int getSoTimeout();                 // New in 1.1
  public synchronized void receive(DatagramPacket p);
  public void send(DatagramPacket p);
  public synchronized void setSoTimeout(int timeout);     // New in 1.1
}
```

Constructors

DatagramSocket

public DatagramSocket() throws SocketException

Throws

SocketException

If any kind of socket error occurs.

SecurityException

If the application is not allowed to listen on the port.

Description

This constructor creates a `DatagramSocket` that is bound to any available port on the local host machine.

public DatagramSocket(int port) throws SocketException

Parameters

`port`

A port number.

Throws

`SocketException`

If any kind of socket error occurs.

`SecurityException`

If the application is not allowed to listen on the given port.

Description

This constructor creates a `DatagramSocket` that is bound to the given port on the local host machine.

`public DatagramSocket(int port, InetAddress laddr) throws SocketException`

Availability

New as of JDK 1.1

Parameters

`port`

A port number.

`laddr`

A local address.

Throws

> `SocketException`
>
> > If any kind of socket error occurs.
>
> `SecurityException`
>
> > If the application is not allowed to listen on the given port on the specified host.

Description

> This constructor creates a `DatagramSocket` that is bound to the given port on the specified local host machine.

Instance Methods

close

public void close()

Description

> This method closes the socket, releasing any system resources it holds.

getLocalAddress

public InetAddress getLocalAddress()

Availability

> New as of JDK 1.1

Returns

> The local address of the socket.

Throws

> `SecurityException`

If the application is not allowed to retrieve the address.

Description

This method returns the local address to which this `DatagramSocket` is bound.

getLocalPort

public int getLocalPort()

Returns

`The port` number of the socket.

Description

This method returns the local port to which this `DatagramSocket` is bound.

getSoTimeout

public synchronized int getSoTimeout() throws SocketException

Availability

New as of JDK 1.1

Returns

The receive time-out value for the socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method returns the receive time-out value for this socket. A value of zero indicates that the socket waits indefinitely for an incoming packet, while a non-zero value indicates the number of milliseconds it waits.

receive

`public synchronized void receive(DatagramPacket p) throws IOException`

Parameters

`p`

The `DatagramPacket` that receives incoming data.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to receive data from the packet's source.

`InterruptedIOException`

If a packet does not arrive before the time-out period expires.

Description

This method receives a datagram packet on this socket. After this method returns, the given `DatagramPacket` contains the packet's data and length, and the sender's address and port number. If the data that was sent is longer that the given packet's data buffer, the data is truncated.

If a time-out value is specified using the `setSoTimeout()` method, the method either returns with the received packet or times out, throwing an `InterruptedIOException`. If no time-out value is specified, the method blocks until it receives a packet.

send

public void send(DatagramPacket p) throws IOException

Parameters

`p`

The `DatagramPacket` to be sent.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to send data to the packet's destination.

Description

This method sends a packet from this socket. The packet data, packet length, destination address, and destination port number are specified by the given `DatagramPacket`.

setSoTimeout

`public synchronized void setSoTimeout(int timeout) throws SocketException`

Availability

New as of JDK 1.1

Parameters

`timeout`

The new time-out value, in milliseconds, for this socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method is used to set the time-out value that is used for `receive()`. A non-zero value specifies the length of time, in milliseconds, that the `DatagramSocket` should wait for an incoming packet. A value of zero indicates that the `DatagramSocket` should wait indefinitely for an incoming packet. If a time-out value is needed, this method must be called before `receive()`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

DatagramSocketImpl

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

DatagramSocketImpl

Name

DatagramSocketImpl

Synopsis

Class Name:

`java.net.DatagramSocketImpl`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `DatagramSocketImpl` class is an `abstract` class that defines the bulk of the methods that make the `DatagramSocket` and `MulticastSocket` classes work. Non-`public` subclasses of `DatagramSocketImpl` provide platform-specific implementations of datagram socket communication.

Class Summary

```
public abstract class java.net.DatagramSocketImpl
                      extends java.lang.Object {
  // Variables
  protected FileDescriptor fd;
  protected int localPort;
  // Protected Instance Methods
  protected abstract void bind(int lport, InetAddress laddr);
  protected abstract void close();
  protected abstract void create();
  protected FileDescriptor getFileDescriptor();
  protected int getLocalPort();
  protected abstract byte getTTL();
  protected abstract void join(InetAddress inetaddr);
  protected abstract void leave(InetAddress inetaddr);
  protected abstract int peek(InetAddress i);
  protected abstract void receive(DatagramPacket p);
  protected abstract void send(DatagramPacket p);
  protected abstract void setTTL(byte ttl);
}
```

Variables

fd

protected FileDescriptor fd

Description

> The file descriptor that represents this socket.

localPort

protected int localPort

Description

> The local port number of this socket.

Protected Instance Methods

bind

`protected abstract void bind(int lport, InetAddress laddr) throws SocketException`

Parameters

`lport`

A port number.

`laddr`

A local address.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method binds the socket to the given address and port. If the address or the port is unavailable, an exception is thrown.

close

protected void close()

Description

This method closes the socket, releasing any system resources it holds.

create

protected abstract void create() throws SocketException

Throws

`SocketException`

If a socket error occurs.

Description

This method creates a socket that is not bound to an address and port.

getFileDescriptor

protected FileDescriptor getFileDescriptor()

Returns

The file descriptor for this socket.

Description

This method returns the file descriptor associated with this `DatagramSocketImpl`.

getLocalPort

protected int getLocalPort()

Returns

The port number for this socket.

Description

This method returns the local port to which this `DatagramSocketImpl` is bound.

getTTL

protected abstract byte getTTL() throws IOException

Returns

The time-to-live (TTL) value for this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns the TTL value for this socket. This value is the number of hops that an outgoing packet can traverse before it is discarded.

join

`protected abstract void join(InetAddress inetaddr) throws IOException`

Parameters

`inetaddr`

The IP address of the group to join.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is used by `MulticastSocket` to join a multicast group. An exception is thrown if the given address is not a multicast address. While the socket is part of a group, it receives all packets that are sent to the group.

leave

```
protected abstract void leave(InetAddress inetaddr) throws IOException
```

Parameters

`inetaddr`

The IP address of the group to leave.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is used by `MulticastSocket` to leave a multicast group. An exception is thrown if the given address is not a multicast address.

peek

protected abstract int peek(InetAddress i) throws IOException

Parameters

`i`

A reference to an `InetAddress` object.

Returns

The port number of the next incoming packet.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method places the address of the next incoming packet in the given `InetAddress` object. The method also returns the port number of the next incoming packet. The method looks at the address of an incoming packet to determine if it should be accepted.

receive

`protected abstract void receive(DatagramPacket p) throws IOException`

Parameters

`p`

The `DatagramPacket` that receives incoming data.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method receives a datagram packet on this socket. After this method returns, the given `DatagramPacket` contains the packet's data and length, and the sender's address and port number. If the data that was sent is longer that the given packet's data buffer, the data is truncated.

send

protected abstract void send(DatagramPacket p) throws IOException

Parameters

`p`

The `DatagramPacket` to be sent.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method sends a packet from this socket. The packet data, packet length, destination address, and destination port number are specified by the given `DatagramPacket`.

setTTL

protected abstract void setTTL(byte ttl) throws IOException

Parameters

`ttl`

The new TTL value for this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is used to set the TTL value of the socket. The TTL value is the number of hops that an outgoing packet can traverse before it is discarded.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

FileNameMap

Name

FileNameMap

Synopsis

Interface Name:

`java.net.FileNameMap`

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented By:

None

Availability:

New as of JDK 1.1

Description

The `FileNameMap` interface defines a method that maps filenames to MIME types. The interface is implemented by classes that provide this mapping. The mapping is typically done by examining the file extension of the filename, or in other words, the part of the filename that follows the final period.

Interface Declaration

```
public abstract interface java.net.FileNameMap {
  // Methods
  public abstract String getContentTypeFor(String fileName);
}
```

Methods

getContentTypeFor

public abstract String getContentTypeFor(String fileName)

Parameters

> `fileName`
>
> > A `String` that contains a filename.

Returns

> The `String` that contains the MIME type that corresponds to the filename.

Description

> This method attempts to determine the MIME type of a file by examining its filename.

HttpURLConnection

Name

HttpURLConnection

Synopsis

Class Name:

`java.net.HttpURLConnection`

Superclass:

`java.net.URLConnection`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `HttpURLConnection` class is an `abstract` class that is a subclass of `URLConnection`. `HttpURLConnection` defines many of the HTTP server response codes as constants and provides methods for parsing server responses.

An `HttpURLConnection` object defines a network connection to a resource specified by a URL. Essentially, the `HttpURLConnection` object represents the HTTP request for that resource.

Class Summary

```
public abstract class java.net.HttpURLConnection
                      extends java.net.URLConnection {
  // Constants
  public final static int HTTP_ACCEPTED;
  public final static int HTTP_BAD_GATEWAY;
  public final static int HTTP_BAD_METHOD;

  public static void setFollowRedirects(boolean set);
  // Instance Methods
  public abstract void disconnect();
  public String getRequestMethod();
  public int getResponseCode();
  public String getResponseMessage();
  public void setRequestMethod(String method);
  public abstract boolean usingProxy();
}
```

Constants

HTTP_ACCEPTED

public final static int HTTP_ACCEPTED = 202

Description

> The HTTP response code that means the request has been accepted by the server.

HTTP_BAD_GATEWAY

public final static int HTTP_BAD_GATEWAY = 502

Description

> The HTTP response code that means the server, acting as a gateway, has received a bad response from another server.

HTTP_BAD_METHOD

public final static int HTTP_BAD_METHOD = 405

Description

> The HTTP response code that means the requested method is not allowed for the requested resource.

HTTP_BAD_REQUEST

public final static int HTTP_BAD_REQUEST = 400

Description

> The HTTP response code that means the request was syntactically incorrect.

HTTP_CLIENT_TIMEOUT

public final static int HTTP_CLIENT_TIMEOUT = 408

Description

> The HTTP response code that means the server has not received a request from the client in the time it expected.

HTTP_CONFLICT

public final static int HTTP_CONFLICT = 409

Description

The HTTP response code that means there is a conflict with the state of the requested resource.

HTTP_CREATED

public final static int HTTP_CREATED = 201

Description

The HTTP response code that means a new resource has been created as the result of the request.

HTTP_ENTITY_TOO_LARGE

public final static int HTTP_ENTITY_TOO_LARGE = 413

Description

The HTTP response code that means the request contains an entity that is too large for the server.

HTTP_FORBIDDEN

public final static int HTTP_FORBIDDEN = 403

Description

The HTTP response code that means the client does not have permission to access the requested resource.

HTTP_GATEWAY_TIMEOUT

public final static int HTTP_GATEWAY_TIMEOUT = 504

Description

The HTTP response code that means the server, acting as a gateway, has not received a response from an upstream server in the time it expected.

HTTP_GONE

public final static int HTTP_GONE = 410

Description

The HTTP response code that means the requested resource is no longer available.

HTTP_INTERNAL_ERROR

public final static int HTTP_INTERNAL_ERROR = 501

Description

The HTTP response code that means the server does not or cannot support the client's request.

HTTP_LENGTH_REQUIRED

public final static int HTTP_LENGTH_REQUIRED = 411

Description

> The HTTP response code that means the server won't accept the request without a length indication.

HTTP_MOVED_PERM

public final static int HTTP_MOVED_PERM = 301

Description

> The HTTP response code that means the requested resource has moved permanently.

HTTP_MOVED_TEMP

public final static int HTTP_MOVED_TEMP = 302

Description

> The HTTP response code that means the requested resource has moved temporarily.

HTTP_MULT_CHOICE

public final static int HTTP_MULT_CHOICE = 300

Description

> The HTTP response code that means the requested resource is available in multiple representations.

HTTP_NOT_ACCEPTABLE

public final static int HTTP_NOT_ACCEPTABLE = 406

Description

> The HTTP response code that means the requested resource is not available in a representation that is acceptable to the client.

HTTP_NOT_AUTHORITATIVE

public final static int HTTP_NOT_AUTHORITATIVE = 203

Description

> The HTTP response code that means the information returned may be a copy.

HTTP_NOT_FOUND

public final static int HTTP_NOT_FOUND = 404

Description

The HTTP response code that means the server could not find the requested resource.

HTTP_NOT_MODIFIED

public final static int HTTP_NOT_MODIFIED = 304

Description

The HTTP response code that means the requested resource has not been modified.

HTTP_NO_CONTENT

public final static int HTTP_NO_CONTENT = 204

Description

The HTTP response code that means the request has been processed, but there is no new information.

HTTP_OK

public final static int HTTP_OK = 200

Description

The HTTP response code that means the request succeeded.

HTTP_PARTIAL

public final static int HTTP_PARTIAL = 206

Description

The HTTP response code that means the partial request has been fulfilled.

HTTP_PAYMENT_REQUIRED

public final static int HTTP_PAYMENT_REQUIRED = 402

Description

An HTTP response code that is reserved for future use.

HTTP_PRECON_FAILED

public final static int HTTP_PRECON_FAILED = 412

Description

The HTTP response code that means the precondition in the request has failed.

HTTP_PROXY_AUTH

public final static int HTTP_PROXY_AUTH = 407

Description

The HTTP response code that means the client needs to authenticate itself with the proxy.

HTTP_REQ_TOO_LONG

public final static int HTTP_REQ_TOO_LONG = 414

Description

The HTTP response code that means the client request is too long.

HTTP_RESET

public final static int HTTP_RESET = 205

Description

The HTTP response code that means the request has been fulfilled, and the client should reset its view.

HTTP_SEE_OTHER

public final static int HTTP_SEE_OTHER = 303

Description

The HTTP response code that means the requested resource is available at another URL.

HTTP_SERVER_ERROR

public final static int HTTP_SERVER_ERROR = 500

Description

The HTTP response code that means the server encountered a problem and could not fulfill the request.

HTTP_UNAUTHORIZED

public final static int HTTP_UNAUTHORIZED = 401

Description

The HTTP response code that means the client is not authenticated for the requested resource.

HTTP_UNAVAILABLE

public final static int HTTP_UNAVAILABLE = 503

Description

The HTTP response code that means the server is temporarily unable to fulfill the request.

HTTP_UNSUPPORTED_TYPE

public final static int HTTP_UNSUPPORTED_TYPE = 415

Description

The HTTP response code that means the server cannot process the type of the request.

HTTP_USE_PROXY

public final static int HTTP_USE_PROXY = 305

Description

The HTTP response code that means a proxy must be used to access the requested resource.

HTTP_VERSION

public final static int HTTP_VERSION = 505

Description

The HTTP response code that means the server does not support the HTTP version used in the request.

Variables

method

protected String method = "GET"

Description

The method of this request. Valid values are: `"DELETE"`, `"GET"`, `"HEAD"`, `"OPTIONS"`, `"POST"`, `"PUT"`, and `"TRACE"`.

responseCode

protected int responseCode = -1

Description

The response code from the server, which may be one of the `HTTP_` constants.

responseMessage

protected String responseMessage = null

Description

The response message from the server that corresponds to `responseCode`.

Constructors

HttpURLConnection

protected HttpURLConnection(URL u)

Parameters

`u`

A `URL` object that represents a resource.

Description

This constructor creates an `HttpURLConnection` for the given `URL` object.

Class Methods

getFollowRedirects

public static boolean getFollowRedirects()

Returns

A `boolean` value that indicates whether or not HTTP redirect codes are automatically followed.

Description

This method indicates whether or not this `HttpURLConnection` follows HTTP redirects. The default value is `false`.

setFollowRedirects

public static void setFollowRedirects(boolean set)

Parameters

set

A boolean value that specifies whether or not HTTP redirects should be followed.

Throws

SecurityException

If there is a SecurityManager installed and its checkSetFactory() method throws a SecurityException.

Description

This method specifies whether or not this HttpURLConnection follows HTTP redirects.

Instance Methods

disconnect

public abstract void disconnect()

Description

This method closes the connection to the server.

getRequestMethod

public String getRequestMethod()

Returns

The method of this request.

Description

This method returns the method of this request.

getResponseCode

public int getResponseCode() throws IOException

Returns

The response code from the server.

Throws

IOException

If any kind of I/O error occurs.

Description

This method returns the code the server sent in response to this request. For example, suppose the server response is:

```
HTTP/1.0 404 Not Found
```

In this case, the method returns integer value `404`.

getResponseMessage

public int getResponseMessage() throws IOException

Returns

The response message from the server.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns the message the server sent in response to this request. For example, suppose the server response is:

```
HTTP/1.0 404 Not Found
```

In this case, the method returns the string `"Not Found"`.

setRequestMethod

`public void setRequestMethod(String method) throws ProtocolException`

Parameters

`method`

The new method for this request.

Throws

`ProtocolException`

If the connection has already been made or if `method` is invalid.

Description

This method sets the method of this request. Valid values are: `"DELETE"`, `"GET"`, `"HEAD"`, `"OPTIONS"`, `"POST"`, `"PUT"`, and `"TRACE"`.

usingProxy

public abstract boolean usingProxy()

Returns

A `boolean` value that indicates whether or not this `HttpURLConnection` is using a proxy.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns a flag that indicates if this connection is going through a proxy or not.

FileNameMap BOOK INDEX InetAddress

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

InetAddress

Name

InetAddress

Synopsis

Class Name:

`java.net.InetAddress`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `InetAddress` class encapsulates an Internet Protocol (IP) address. `InetAddress` objects are used by the various classes that are responsible for specifying the destination addresses of outbound network packets, such as `DatagramSocket`, `MulticastSocket`, and `Socket`. `InetAddress` does not provide any `public` constructors. Instead, you must use the `static` methods `getAllByName()`, `getByName()`, and `getLocalHost()` to create `InetAddress` objects.

Class Summary

```
public final class java.net.InetAddress extends java.lang.Object
                   implements java.io.Serializable {
  // Class Methods
  public static InetAddress[] getAllByName(String host);
  public static InetAddress getByName(String host);
  public static InetAddress getLocalHost();
  // Instance Methods
  public boolean equals(Object obj);
  public byte[] getAddress();
  public String getHostAddress();                // New in 1.1
  public String getHostName();
  public int hashCode();
  public boolean isMulticastAddress();           // New in 1.1
  public String toString();
}
```

Class Methods

getAllByName

`public static InetAddress[] getAllByName(String host) throws UnknownHostException`

Parameters

`host`

A `String` that contains a hostname.

Returns

An array of `InetAddress` objects that corresponds to the given name.

Throws

`SecurityException`

If the application is not allowed to connect to `host`.

`UnknownHostException`

If `host` cannot be resolved.

Description

This method finds all of the IP addresses that correspond to the given hostname. The hostname can be a machine name, such as `"almond.nuts.com"`, or a string representation of an IP address, such as `"208.25.146.1"`.

getByName

```
public static InetAddress getByName(String host) throws UnknownHostException
```

Parameters

`host`

A `String` that contains a host name.

Returns

An `InetAddress` that corresponds to the given name.

Throws

`SecurityException`

If the application is not allowed to connect to `host`.

`UnknownHostException`

If `host` cannot be resolved.

Description

This method returns the primary IP address that correspond to the given hostname. The hostname can be a machine name, such as `"almond.nuts.com"`, or a string representation of an IP address, such as `"208.25.146.1"`.

getLocalHost

```
public static InetAddress getLocalHost() throws UnknownHostException
```

Returns

An `InetAddress` that corresponds to the name of the local machine.

Throws

`SecurityException`

If the application is not allowed to connect to `host`.

`UnknownHostException`

If `host` cannot be resolved.

Description

This method finds the IP address of the local machine.

Instance Methods

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equivalent; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `InetAddress` that specifies the same IP address as the object this method is associated with.

getAddress

public byte[] getAddress()

Returns

A byte array with elements that correspond to the bytes of the IP address that this object represents.

Description

This method returns the IP address associated with this object as an array of bytes in network order. That means that the first element of the array contains the highest order byte, and the last element of the array contains the lowest order byte.

getHostAddress

public String getHostAddress()

Availability

New as of JDK 1.1

Returns

A `String` that contains the IP address of this object.

Description

This method returns a string representation of the IP address associated with this object. For example: `"206.175.64.78"`.

getHostName

public String getHostName()

Returns

The hostname associated with this object.

Description

In most cases, this method returns the hostname that corresponds to the IP address associated with this object. However, there are a few special cases:

- If the address associated with this object is address of the local machine, the method may return `null`.
- If the method cannot determine a home name to go with the address associated with this object, the method returns a string representation of the address.
- If the application is not allowed to know the hostname, the method returns a string representation of the address.

hashCode

public int hashCode()

Returns

The hashcode based on the IP address of the object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this object, based on the IP address associated with this object.

isMulticastAddress

public boolean isMulticastAddress()

Availability

New as of JDK 1.1

Returns

`true` if this object represents a multicast address; `false` otherwise.

Description

This method returns a flag that indicates if this object represents an IP multicast address. A multicast address is a Class D address, which means that its four highest-order bits are set to 1110. In other words, multicast addresses are in the range 224.0.0.1 through 239.255.255.255 inclusive.

toString

public String toString()

Returns

The string representation of this `InetAddress`.

Overrides

`Object.toString()`

Description

This method returns a `String` that contains both the hostname and IP address of this object.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`

`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

HttpURLConnection BOOK INDEX MalformedURLException

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

MalformedURLException

Name

MalformedURLException

Synopsis

Class Name:

```
java.net.MalformedURLException
```

Superclass:

```
java.io.IOException
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `MalformedURLException` is thrown when a malformed URL is encountered, which can occur if a URL does not contain a valid protocol or if the string is unparsable.

Class Summary

```
public class java.net.MalformedURLException extends java.io.IOException {
  // Constructors
  public MalformedURLException();
  public MalformedURLException(String msg);
}
```

Constructors

MalformedURLException

public MalformedURLException()

Description

This constructor `create`s a `MalformedURLException` with no associated detail message.

public MalformedURLException(String msg)

Parameters

`msg`

The detail message.

Description

This constructor creates a `MalformedURLException` with the specified detail message.

Inherited Methods

MulticastSocket

Name

MulticastSocket

Synopsis

Class Name:

`java.net.MulticastSocket`

Superclass:

`java.net.DatagramSocket`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `MulticastSocket` class implements packet-oriented, connectionless, multicast data communication. In Internet parlance, this is the User Datagram Protocol (UDP) with additional functionality for joining and leaving groups of other multicast hosts on the Internet. A multicast group is specified by a Class D address, which means that the four highest-order bits are set to 1110. In other words, multicast addresses are in the range 224.0.0.1 through 239.255.255.255 inclusive.

`MulticastSocket` inherits most of its functionality from `DatagramSocket`; it adds the ability to join and leave multicast groups. When a `MulticastSocket` joins a group, it receives all of the packets destined for the group. Any `DatagramSocket` or `MulticastSocket` can send packets to a multicast group.

Class Summary

```
public final class java.net.MulticastSocket
                   extends java.net.DatagramSocket {
  // Constructors
  public MulticastSocket();
  public MulticastSocket(int port);
  // Instance Methods
  public InetAddress getInterface();
  public byte getTTL();
  public void joinGroup(InetAddress mcastaddr);
  public void leaveGroup(InetAddress mcastaddr)
  public synchronized void send(DatagramPacket p, byte ttl);
  public void setInterface(InetAddress inf);
  public void setTTL(byte ttl);
}
```

Constructors

MulticastSocket

public MulticastSocket() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to listen on the port.

Description

This constructor creates a `MulticastSocket` that is bound to any available port on the local host machine.

public MulticastSocket(int port) throws IOException

Parameters

`port`

A port number.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to listen on the given port.

Description

This constructor creates a `MulticastSocket` that is bound to the given port on the local host machine.

Instance Methods

getInterface

public InetAddress getInterface() throws SocketException

Returns

The address of the network interface used for outgoing multicast packets.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method returns the IP address that this `MulticastSocket` uses to send out packets to multicast destinations.

getTTL

public byte getTTL() throws IOException

Returns

> The time-to-live (TTL) value for this socket.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

> This method returns the TTL value for this socket. This value is the number of hops an outgoing packet can traverse before it is discarded.

joinGroup

public void joinGroup(InetAddress mcastaddr) throws IOException

Parameters

> `mcastaddr`
>
> > The IP address of the group to join.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.
>
> `SecurityException`
>
> > If the application is not allowed to access the given multicast address.

Description

> This method is used to join a multicast group. An exception is thrown if the given address is not a multicast address. While the socket is part of a group, it receives all the packets that are sent to the group.

leaveGroup

public void leaveGroup(InetAddress mcastaddr) throws IOException

Parameters

`mcastaddr`

The IP address of the group to leave.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to access the given multicast address.

Description

This method is used to leave a multicast group. An exception is thrown if the given address is not a multicast address.

send

```
public synchronized void send(DatagramPacket p, byte ttl) throws IOException
```

Parameters

`p`

The `DatagramPacket` to be sent.

`ttl`

The time-to-live (TTL) value for this packet.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to send data to the packet's destination.

Description

This method sends a packet from this socket using the given TTL value. The packet data, packet length, destination address, and destination port number are specified by the given `DatagramPacket`.

Generally, it is easier to use `setTTL()` to set the TTL value for the socket, then use `send(DatagramPacket)` to send data. This method is provided for special cases.

setInterface

public void setInterface(InetAddress inf) throws SocketException

Parameters

`inf`

The new address of the network interface for multicast packets.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method is used to set the address that is used for outgoing multicast packets.

setTTL

public void setTTL(byte ttl) throws IOException

Parameters

`ttl`

The new time-to-live (TTL) value for this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method is used to set the TTL value of the socket. The TTL value is the number of hops an outgoing packet can traverse before it is discarded.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`DatagramSocket`
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`getLocalAddress()`	`DatagramSocket`
`getLocalPort()`	`DatagramSocket`	`getSoTimeout()`	`DatagramSocket`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`receive(DatagramPacket)`	`DatagramSocket`
`send(DatagramPacket)`	`DatagramSocket`	`setSoTimeout(int)`	`DatagramSocket`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

NoRouteToHostException

Name

NoRouteToHostException

Synopsis

Class Name:

    `java.net.NoRouteToHostException`

Superclass:

    `java.net.SocketException`

Immediate Subclasses:

    None

Interfaces Implemented:

    None

Availability:

    New as of JDK 1.1

Description

A `NoRouteToHostException` is thrown when a socket connection cannot be established with a remote host.

This type of exception usually indicates that a firewall is blocking access to the host, or that an intermediate router is down.

Class Summary

```
public class java.net.NoRouteToHostException
             extends java.net.SocketException {
  // Constructors
  public NoRouteToHostException();
  public NoRouteToHostException(String msg);
}
```

Constructors

NoRouteToHostException

public NoRouteToHostException()

Description

This constructor `create`s a `NoRouteToHostException` with no associated detail message.

public NoRouteToHostException(String msg)

Parameters

`msg`

The detail message.

Description

This constructor creates a `NoRouteToHostException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`fillInStackTrace()`	`Throwable`	`finalize()`	`Object`

`getClass()`	`Object`	`getLocalizedMessage()`	`Throwable`

ProtocolException

Synopsis

Class Name:

`java.net.ProtocolException`

Superclass:

`java.io.IOException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `ProtocolException` is thrown to indicate that there has been an error in an underlying protocol, such as an HTTP or TCP protocol error.

Class Summary

```
public class java.net.ProtocolException extends java.io.IOException {
  // Constructors
  public ProtocolException();
  public ProtocolException(String host);
}
```

Constructors

ProtocolException

public ProtocolException()

Description

> This constructor `create`s a `ProtocolException` with no associated detail message.

public ProtocolException(String host)

Parameters

> `host`
>
> > The detail message.

Description

> This constructor creates a `ProtocolException` with the specified detail message, which should be the host that caused the underlying protocol error.

Inherited Methods

NoRouteToHostException | BOOK INDEX | ServerSocket

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

ServerSocket

Name

ServerSocket

Synopsis

Class Name:

`java.net.ServerSocket`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `ServerSocket` class represents a socket that listens for connection requests from clients on a specified port. When a connection is requested, a `Socket` object is created to handle the communication.

The low-level network access in `ServerSocket` is provided by a subclass of the `abstract` class `SocketImpl`. An application can change the server socket factory that creates the `SocketImpl` subclass by supplying a `SocketImplFactory` using the `setSocketFactory()` method. This feature allows an application to create sockets that are appropriate for the local network configuration and accommodate such things as firewalls.

Class Summary

```
public class java.net.ServerSocket extends java.lang.Object {
  // Constructors
  public ServerSocket(int port);
  public ServerSocket(int port, int backlog);
  public ServerSocket(int port, int backlog,
                      InetAddress bindAddr);              // New in 1.1
  // Class Methods
  public static synchronized void setSocketFactory(SocketImplFactory fac);
  // Instance Methods
  public Socket accept();
  public void close();
  public InetAddress getInetAddress();
  public int getLocalPort();
  public synchronized int getSoTimeout()                  // New in 1.1
  public synchronized void setSoTimeout(int timeout);     // New in 1.1
  public String toString();
  // Protected Instance Methods
  protected final void implAccept(Socket s);              // New in 1.1
}
```

Constructors

ServerSocket

public ServerSocket(int port) throws IOException

Parameters

`port`

A port number, or 0 for any available port.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to listen on the given port.

Description

This method creates a server socket that listens for a connection on the given port. A default of 50 pending connections can be queued by the `ServerSocket`. Calling `accept()` removes a pending connections from the queue. If the queue is full, additional connection requests are refused.

If an application has specified a server socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

public ServerSocket(int port, int backlog) throws IOException

Parameters

`port`

A port number, or 0 for any available port.

`backlog`

The maximum length of the pending connections queue.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to listen on the given port.

Description

This method creates a server socket that listens for a connection on the given port. The `backlog` parameter specifies how many pending connections can be queued by the `ServerSocket`. Calling `accept()` removes a pending connection from the queue. If the queue is full, additional connection requests are refused.

If an application has specified a server socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

`public ServerSocket(int port, int backlog, InetAddress bindAddr) throws IOException`

Availability

New as of JDK 1.1

Parameters

`port`

A port number, or 0 for any available port.

`backlog`

The maximum length of the pending connections queue.

`bindAddr`

A local address.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to listen on the given port.

Description

This method creates a server socket that listens for a connection on the given port of `bindAddr`. On machines with multiple addresses, `bindAddr` specifies the address on which this `ServerSocket` listens. The `backlog` parameter specifies how many pending connections can be queued by the `ServerSocket`. Calling `accept()` removes pending connections from the queue. If the queue is full, additional connection requests are refused.

If an application has specified a server socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

Class Methods

setSocketFactory

`public static synchronized void setSocketFactory( SocketImplFactory fac) throws IOException`

Parameters

`fac`

An object that implements `SocketImplFactory`.

Throws

`IOException`

If the factory has already been defined.

`SecurityException`

If the application does not have permission to set the factory.

Description

This method is used to set the `SocketImplFactory`. This factory object produces instances of subclasses of `SocketImpl` that do the low-level work of server sockets. When a `ServerSocket` constructor is called, the `createSocketImpl()` method of the factory is called to create the server socket implementation.

Instance Methods

accept

public Socket accept() throws IOException

Returns

A `Socket` object for the connection.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to accept the connection.

Description

This method accepts a connection and returns a `Socket` object to handle communication. If there are pending connections, the method accepts a pending connection from the queue and returns immediately. Otherwise, the method may block until a connection is requested. If a time-out value has been specified using the `setSoTimeout()` method, `accept()` may time out and throw an `InterruptedIOException` if no connection is requested in the time-out period.

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

> This method closes this server socket, releasing any system resources it holds.

getInetAddress

public InetAddress getInetAddress()

Returns

> The IP address to which this `ServerSocket` is listening.

Description

> Generally, this method returns the address of the local host. However, a `ServerSocket` can be constructed with an alternate address using `ServerSocket(int, int, InetAddress)`. The method returns `null` if the socket is not yet connected.

getLocalPort

public int getLocalPort()

Returns

> The port number to which this `ServerSocket` is listening.

Description

> This method returns the port number to which this object is connected.

getSoTimeout

public synchronized int getSoTimeout() throws IOException

Availability

> New as of JDK 1.1

Returns

> The receive timeout value for the socket.

Throws

> `IOException`
>
> > If any kind of I/O error occurs.

Description

This method returns the receive time-out value for this socket. A value of zero indicates that `accept()` waits indefinitely for an incoming packet, while a non-zero value indicates the number of milliseconds it waits.

setSoTimeout

`public synchronized void setSoTimeout(int timeout) throws SocketException`

Availability

New as of JDK 1.1

Parameters

`timeout`

The new time-out value, in milliseconds, for this socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method is used to set the time-out value that is used for `accept()`. A nonzero value is the length of time, in milliseconds, the `ServerSocket` should wait for a connection. A value of zero indicates that the `ServerSocket` should wait indefinitely. If a time-out value is needed, this method must be called before `accept()`.

toString

public String toString()

Returns

The string representation of this `ServerSocket`.

Overrides

`Object.toString()`

Description

This method returns a `String` that contains the address and port of this `ServerSocket`.

Protected Instance Methods

implAccept

protected final void implAccept(Socket s) throws IOException

Availability

New as of JDK 1.1

Parameters

`s`

The `Socket` object to be connected.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to accept the connection.

Description

This method is a helper method for `accept()`. It can be overridden in subclasses of `ServerSocket` to support new subclasses of `Socket`.

Inherited Methods

Method	Inherited From	Method	Inherited From

Socket

Name

Socket

Synopsis

Class Name:

`java.net.Socket`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Socket` class implements stream-based, connection-oriented, reliable data communication. Although `Socket` objects are often used with the Transmission Control Protocol, commonly known as TCP, they are independent of the actual protocol being used. The `Socket` class encapsulates client logic that is common to connection-oriented protocols. Sockets are two-way data pipes that are connected on either end to an address and port number. As of JDK 1.1, new constructors allow you to specify the local address and port as well as the remote address and port.

A `Socket` object uses an object that belongs to a subclass of the `abstract` class `SocketImpl` to access protocol-specific logic. A program can specify the subclass of `SocketImpl` that is used by passing an appropriate `SocketImplFactory` object to the `setSocketImplFactory()` method before any `Socket` objects are created. This feature allows a program to create sockets that are able to accommodate such things as firewalls or even work with different protocols.

Class Summary

```
public class java.net.Socket extends java.lang.Object {
  // Constructors
  public Socket(String host, int port);
  public Socket(InetAddress address, int port);
  public Socket(String host, int port,
                InetAddress localAddr, int localPort);     // New in 1.1
  public Socket(InetAddress address, int port,
                InetAddress localAddr, int localPort);     // New in 1.1
  public Socket(String host, int port,
                boolean stream);                     // Deprecated in 1.1
  public Socket(InetAddress host, int port,
                boolean stream);                     // Deprecated in 1.1
  protected Socket();                                      // New in 1.1
  protected Socket(SocketImpl impl);                       // New in 1.1
  // Class Methods
  public static synchronized void setSocketImplFactory(
                                  SocketImplFactory fac);
  // Instance Methods
  public synchronized void close();
  public InetAddress getInetAddress();
  public InputStream getInputStream();
  public InetAddress getLocalAddress();                    // New in 1.1
  public int getLocalPort();
  public OutputStream getOutputStream();
  public int getPort();
  public int getSoLinger();                                // New in 1.1
  public synchronized int getSoTimeout();                  // New in 1.1
  public boolean getTcpNoDelay();                          // New in 1.1
  public void setSoLinger(boolean on, int val);            // New in 1.1
  public synchronized void setSoTimeout(int timeout);      // New in 1.1
  public void setTcpNoDelay(boolean on);                   // New in 1.1
  public String toString();
}
```

Constructors

Socket

`public Socket(String host, int port) throws IOException, UnknownHostException`

Parameters

`host`

The name of a remote machine.

`port`

A port on a remote machine.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to connect to the given host and port.

`UnknownHostException`

If the IP address of the given hostname cannot be determined.

Description

This constructor creates a `Socket` and connects it to the specified port on the given host.

If a program has specified a socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

public Socket(InetAddress address, int port) throws IOException

Parameters

`address`

The IP address of a remote machine.

`port`

A port on a remote machine.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to connect to the given address and port.

Description

This constructor creates a `Socket` and connects it to the specified port on the host at the given address.

If a program has specified a socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

`public Socket(String host, int port, InetAddress localAddr, int localPort) throws IOException`

Availability

New as of JDK 1.1

Parameters

`host`

The name of a remote machine.

`port`

A port on a remote machine.

`localAddr`

An IP address on the local host.

`localPort`

A port on the local host.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to connect to the given host and port.

Description

This constructor creates a `Socket` and connects it to the specified port on the given host. The constructor also binds the `Socket` to the specified local address and port.

If a program has specified a socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

`public Socket(InetAddress address, int port, InetAddress localAddr, int localPort) throws IOException`

Availability

New as of JDK 1.1

Parameters

`address`

The IP address of a remote machine.

`port`

A port on a remote machine.

`localAddr`

An IP address on the local host.

`localPort`

A port on the local host.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to connect to the given address and port.

Description

This constructor creates a `Socket` and connects it to the specified port on the host at the given address. The constructor also binds the `Socket` to the specified local address and port.

If a program has specified a socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

`public Socket(String host, int port, boolean stream) throws IOException`

Availability

Deprecated as of JDK 1.1

Parameters

`host`

The name of a remote machine.

`port`

A port on a remote machine.

`stream`

A `boolean` value that indicates if this socket is a stream socket.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to connect to the given host and port.

Description

This constructor creates a `Socket` and connects it to the specified port on the given host.

If the `stream` argument is `true`, a stream socket is created. Otherwise, a datagram socket is created. This constructor is deprecated as of JDK 1.1; use `DatagramSocket` for datagrams.

If a program has specified a socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

`public Socket(InetAddress address, int port, boolean stream) throws IOException`

Availability

Deprecated as of JDK 1.1

Parameters

`address`

The IP address of a remote machine.

`port`

A port on a remote machine.

`stream`

A `boolean` value that indicates if this socket is a stream socket.

Throws

`IOException`

If any kind of I/O error occurs.

`SecurityException`

If the application is not allowed to connect to the given host and port.

Description

This constructor creates a `Socket` and connects it to the specified port on the host at the given address.

If the `stream` argument is `true`, a stream socket is created. Otherwise, a datagram socket is created. This constructor is deprecated as of JDK 1.1; use `DatagramSocket` for datagrams.

If a program has specified a socket factory, the `createSocketImpl()` method of that factory is called to create the actual socket implementation. Otherwise, the constructor creates a plain socket.

protectedSocket()

Availability

New as of JDK 1.1

Description

This constructor creates a `Socket` that uses an instance of the system default `SocketImpl` subclass for its low-level network access.

protectedSocket(SocketImpl impl) throws SocketException

Availability

New as of JDK 1.1

Parameters

`impl`

The socket implementation to use.

Throws

`SocketException`

This exception is never thrown by this constructor.

Description

This constructor creates a `Socket` that uses the given object for its low-level network access.

Class Methods

setSocketImplFactory

`public static synchronized void setSocketImplFactory( SocketImplFactory fac) throws IOException`

Parameters

`fac`

An object that implements `SocketImplFactory`.

Throws

`IOException`

If the factory has already been defined.

`SecurityException`

If the application does not have permission to set the factory.

Description

This method sets the `SocketImplFactory`. This factory produces instances of subclasses of `SocketImpl` that do the low-level work of sockets. When a `Socket` constructor is called, the `createSocketImpl()` method of the factory is called to create the socket implementation.

Instance Methods

close

public synchronized void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes this socket, releasing any system resources it holds.

getInetAddress

public InetAddress getInetAddress()

Returns

The remote IP address to which this `Socket` is connected.

Description

This method returns the IP address of the remote host to which this socket is connected.

getInputStream

public InputStream getInputStream() throws IOException

Returns

An `InputStream` that wraps this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns an `InputStream` that reads data from the socket.

getLocalAddress

public InetAddress getLocalAddress()

Availability

New as of JDK 1.1

Returns

The local IP address from which this `Socket` originates.

Description

This method returns the local address that is the origin of the socket.

getLocalPort

public int getLocalPort()

Returns

The local port number from which this `Socket` originates.

Description

This method returns the local port number that is the origin of the socket.

getOutputStream

public OutputStream getOutputStream() throws IOException

Returns

An `OutputStream` that wraps this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns an `OutputStream` that sends data through the socket.

getPort

public int getPort()

Returns

The remote port number to which this `Socket` is connected.

Description

This method returns the port number of the remote host to which this socket is connected.

getSoLinger

public int getSoLinger() throws SocketException

Availability

New as of JDK 1.1

Returns

The close time-out value for the socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method returns the close time-out value for this socket. A value of `-1` or `0` indicates that `close()`closes the socket immediately. A value greater than `0` indicates the amount of time, in seconds, that `close()` blocks, waiting for unsent data to be sent.

getSoTimeout

public synchronized int getSoTimeout() throws SocketException

Availability

New as of JDK 1.1

Returns

The read time-out value for the socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method returns the read time-out value for this socket. A value of zero indicates that the `read()` method of the associated `InputStream` waits indefinitely for an incoming packet, while a non-zero value indicates the number of milliseconds it waits before throwing an `InterruptedIOException`.

getTcpNoDelay

public boolean getTcpNoDelay() throws SocketException

Availability

New as of JDK 1.1

Returns

`true` if Nagle's algorithm is disabled for this connection; `false` otherwise.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method indicates whether Nagle's algorithm is disabled for this socket or not. Said another way, it indicates whether the `TCPNODELAY` option is enabled or not.

In essence, Nagle's algorithm takes small outgoing packets that are closely spaced in time and combines them into larger packets. This improves overall efficiency, since each packet has a certain amount of overhead; however, it does so at the expense of immediacy.

setSoLinger

`public void setSoLinger(boolean on, int val) throws SocketException`

Availability

New as of JDK 1.1

Parameters

`on`

A `boolean` value that specifies whether or not `close()` blocks

`val`

The new close time-out value, in seconds, for this socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method sets the close timeout value for this socket. If `val` is `-1` or `0`, or if `on` is `false`, `close()` closes the socket immediately. If `on` is `true` and `val` is greater than 0, `val` indicates the amount of time, in seconds, that `close()` blocks, waiting for unsent data to be sent.

setSoTimeout

`public synchronized void setSoTimeout(int timeout) throws SocketException`

Availability

New as of JDK 1.1

Parameters

`timeout`

The new read time-out value, in milliseconds, for the socket.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method is used to set the time-out value that is used for the `read()` method of the corresponding `InputStream`. A non-zero value is the length of time, in milliseconds, that the `Socket` should wait for data before throwing an `InterruptedIOException`. A value of zero indicates that the `Socket` should wait indefinitely. If a timeout value is needed, this method must be called before `read()`.

setTcpNoDelay

public void setTcpNoDelay(boolean on) throws SocketException

Availability

New as of JDK 1.1

Parameters

`on`

A `boolean` value that specifies whether or not to disable Nagle's algorithm.

Throws

`SocketException`

If any kind of socket error occurs.

Description

This method specifies whether Nagle's algorithm is disabled for this socket or not. Said another way, it determines whether the `TCPNODELAY` option is enabled or not.

In essence, Nagle's algorithm takes small outgoing packets that are closely spaced in time and combines them into larger packets. This improves overall efficiency, since each packet has a certain amount of overhead; however, it does so at the expense of immediacy.

toString

public String toString()

Returns

The string representation of this `Socket`.

Overrides

`Object.toString()`

Description

This method returns a `String` that contains the address and port of this `Socket`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

SocketException

Name

SocketException

Synopsis

Class Name:

`java.net.SocketException`

Superclass:

`java.io.IOException`

Immediate Subclasses:

`java.net.BindException`,

`java.net.ConnectException`,

`java.net.NoRouteToHostException`

Interfaces Implemented:

None

Availability:

JDK 1.0 and later

Description

A `SocketException` is thrown when an error occurs while a socket is being used. As of JDK 1.1, there are some more specific subclasses of `SocketException`, namely `BindException`, `ConnectException`, and `NoRouteToHostException`.

Class Summary

```
public class java.net.SocketException extends java.io.IOException {
  // Constructors
  public SocketException();
  public SocketException(String msg);
}
```

Constructors

SocketException

public SocketException()

Description

> This constructor `create`s a `SocketException` with no associated detail message.

public SocketException(String msg)

Parameters

> `msg`
>
> > The detail message.

Description

> This constructor creates a `SocketException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

fillInStackTrace()	Throwable	finalize()	Object
getClass()	Object	getLocalizedMessage()	Throwable

Socket BOOK INDEX SocketImpl

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

SocketImpl

Name

SocketImpl

Synopsis

Class Name:

`java.net.SocketImpl`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `SocketImpl` class is an `abstract` class that defines the bulk of the methods that make the `Socket` and `ServerSocket` classes work. Thus, `SocketImpl` is used to create both client and server sockets. Non-`public` subclasses of `SocketImpl` provide platform-specific implementations of stream-based socket communication. A plain socket implements the methods in `SocketImpl` as described; other implementations could provide socket communication through a proxy or firewall.

Class Summary

```
public abstract class java.net.SocketImpl extends java.lang.Object {
  // Variables
  protected InetAddress address;
  protected FileDescriptor fd;
  protected int localport;
  protected int port;
  // Instance Methods
  public String toString();
  // Protected Instance Methods
  protected abstract void accept(SocketImpl s);
  protected abstract int available();
  protected abstract void bind(InetAddress host, int port);
  protected abstract void close();
  protected abstract void connect(String host, int port);
  protected abstract void connect(InetAddress address, int port);
  protected abstract void create(boolean stream);
  protected FileDescriptor getFileDescriptor();
  protected InetAddress getInetAddress();
  protected abstract InputStream getInputStream();
  protected int getLocalPort();
  protected abstract OutputStream getOutputStream();
  protected int getPort();
  protected abstract void listen(int backlog);
}
```

Variables

address

protected InetAddress address

Description

> The remote IP address to which this socket is connected.

fd

protected FileDescriptor fd

Description

> The file descriptor that represents this socket.

localPort

protected int localPort

Description

The local port number of this socket.

port

protected int port

Description

The remote port number of this socket.

Instance Methods

toString

public String toString()

Returns

The string representation of this `SocketImpl`.

Overrides

`Object.toString()`

Description

This method returns a `String` that contains a representation of this object.

Protected Instance Methods

accept

protected abstract void accept(SocketImpl s) throws IOException

Parameters

`s`

A `SocketImpl` to connect.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method accepts a connection. The method connects the given socket `s` to a remote host in response to the remote host's connection request on this `SocketImpl`.

available

protected abstract int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns the number of bytes that can be read from the socket without waiting for more data to arrive.

bind

```
protected abstract void bind(InetAddress host, int port) throws IOException
```

Parameters

`host`

An IP address.

`port`

A port number.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method binds the socket to the given address and port. If the address or the port is unavailable, an exception is thrown.

close

protected abstract void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the socket, releasing any system resources it holds.

connect

`protected abstract void connect(String host, int port) throws IOException`

Parameters

`host`

A remote hostname.

`port`

A port number on the remote host.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method connects this socket to the specified port on the given host.

`protected abstract void connect(InetAddress address, int port) throws IOException`

Parameters

`address`

A remote IP address.

`port`

A port number on the remote host.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method connects this socket to the specified port on the host at the given address.

create

protected abstract void create(boolean stream) throws IOException

Parameters

`stream`

A `boolean` value that indicates if this socket is a stream socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method creates a socket that is not bound and not connected. If the `stream` argument is `true`, a stream socket is created. Otherwise, a datagram socket is created.

getFileDescriptor

protected final FileDescriptor getFileDescriptor

Returns

The file descriptor for this socket.

Description

This method returns the file descriptor associated with this `SocketImpl`.

getInetAddress

protected InetAddress getInetAddress()

Returns

The remote IP address to which this `SocketImpl` is connected.

Description

This method returns the IP address of the remote host to which this `SocketImpl` is connected.

getInputStream

protected abstract InputStream getInputStream() throws IOException

Returns

An `InputStream` that wraps this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns an `InputStream` that reads data from the socket.

getLocalPort

protected int getLocalPort()

Returns

The local port number from which this `SocketImpl` originates.

Description

This method returns the local port number that is the origin of the socket.

getOutputStream

`protected abstract OutputStream getOutputStream() throws IOException`

Returns

An `OutputStream` that wraps this socket.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method returns an `OutputStream` that sends data through the socket.

getPort

protected int getPort()

Returns

The remote port number to which this `SocketImpl` is connected.

Description

This method returns the port number of the remote host to which this socket is connected.

listen

protected abstract void listen(int backlog) throws IOException

Parameters

`backlog`

The maximum length of pending connections queue.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This object can directly accept a connection if its `accept()` method has been called and is waiting for a connection. Otherwise, the local system rejects connections to this socket unless `listen()` has been called.

This method requests that the local system listen for connections and accept them on behalf of this object. The accepted connections are placed in a queue of the specified length. When there are connections in the queue, a call to this object's `accept()` method removes a connection from the queue and immediately returns. If the queue is full, additional connection requests are refused.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

SocketImplFactory

Name

SocketImplFactory

Synopsis

Interface Name:

```
java.net.SocketImplFactory
```

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented By:

None

Availability:

JDK 1.0 or later

Description

The SocketImplFactory interface defines a method that creates a SocketImpl object. The interface is implemented by classes that select SocketImpl subclasses to support the Socket and ServerSocket classes.

Interface Declaration

```
public abstract interface java.net.SocketImplFactory {
  // Methods
  public abstract SocketImpl createSocketImpl();
}
```

Methods

createSocketImpl

public abstract SocketImpl createSocketImpl()

Returns

> A SocketImpl object.

Description

> This method creates an instance of a subclass of SocketImpl that is appropriate for the environment.

URL

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

URL

Name

URL

Synopsis

Class Name:

```
java.net.URL
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

```
java.io.Serializable
```

Availability:

JDK 1.0 or later

Description

The `URL` class represents a Uniform Resource Locator, or URL. The class provides methods for retrieving the various parts of a URL and also access to the resource itself.

An absolute URL consists of a protocol, a hostname, a port number, a filename, and an optional reference, or anchor. For example, consider the following URL:

```
http://www.woolf.net:81/books/Orlando/chapter4.html#p6
```

This URL consists of the following parts:

Part	Value
Protocol	`http`
Hostname	`www.woolf.net`
Port number	`81`
Filename	`/books/Orlando/chapter4.html`
Reference	`p6`

A relative URL specifies only enough information to locate the resource relative to another URL. The filename component is the only part that must be specified for a relative URL. If the protocol, hostname, or port number is not specified, the value is taken from a fully specified URL. For example, the following is a relative URL based on the absolute URL above:

```
chapter6.html
```

This relative URL is equivalent to the following absolute URL:

```
http://www.woolf.net:81/books/Orlando/chapter6.html
```

The `URL` class also provides access to the resource itself, through the `getContent()`, `openConnection()`, and `openStream()` methods. However, these are all convenience functions: other classes do the actual work of accessing the resource.

A protocol handler is an object that knows how to deal with a specific protocol. For example, an `http` protocol handler opens a connection to an `http` host. In `java.net`, subclasses of `URLStreamHandler` deal with different protocols. A `URLStreamHandlerFactory` selects a subclass of `URLStreamHandler` based on a MIME type. Once the `URLStreamHandler` has established a connection with a host using a specific protocol, a subclass of `ContentHandler` retrieves resource data from the host and creates an object from it.

Class Summary

```
public final class java.net.URL extends java.lang.Object
                                implements java.io.Serializable {
  // Constructors
  public URL(String spec);
  public URL(URL context, String spec);
  public URL(String protocol, String host, String file);
  public URL(String protocol, String host, int port, String file);
  // Class Methods
  public static synchronized void setURLStreamHandlerFactory(
                                  URLStreamHandlerFactory fac);
  // Instance Methods
  public boolean equals(Object obj);
  public final Object getContent();
  public String getFile();
  public String getHost();
  public int getPort();
  public String getProtocol();
  public String getRef();
  public int hashCode();
  public URLConnection openConnection();
  public final InputStream openStream();
  public boolean sameFile(URL other);
  public String toExternalForm();
  public String toString();
  // Protected Instance Methods
  protected void set(String protocol, String host, int port,
                     String file, String ref);
}
```

Constructors

URL

public URL(String spec) throws MalformedURLException

Parameters

`spec`

A `String` that represents a URL.

Throws

`MalformedURLException`

If the string is incorrectly constructed or specifies an unknown protocol.

Description

This constructor creates a `URL` by parsing the given string. The string should specify an absolute URL. Calling this constructor is equivalent to calling `URL(null,_3C/tt_3E spec).`

public URL(URL context, String spec) throws MalformedURLException

`Parameters`

`context`

`A base URL that provides the context for parsing spec.`

`spec`

`A String that represents a URL.`

Throws

MalformedURLException

If the string is incorrectly constructed or specifies an unknown protocol.

Description

This constructor creates a URL relative to the base URL specified by context. If context is not null, and spec specifies a partial URL, the missing parts of spec are inherited from context.

The given string is first parsed to see if it specifies a protocol. If the string contains a colon (:) before the first occurrence of a slash (/), the characters before the colon comprise the protocol.

If spec does not specify a protocol, and context is not null, the protocol is inherited from context, as are the hostname, port number, and filename. If context is null in this situation, the constructor throws a MalformedURLException.

If spec does specify a protocol, and context is null or specifies a different protocol, the context argument is ignored and spec should specify an absolute URL. If context specifies the same protocol as spec, the hostname, port number, and filename from context are inherited.

Once the constructor has created a fully specified URL object, it searches for an appropriate protocol handler of type URLStreamHandler, as described for URL(String,_3C/tt_3E String, int, String). Then the parseURL(default.htm) method of the URLStreamHandleris called to parse the remainder of the URL so that the fields in spec can override any values inherited from context.

public URL(String protocol, String host, String file) throws MalformedURLException

Parameters

protocol

A protocol.

host

A hostname.

file

A filename.

Throws

MalformedURLException

If an unknown protocol is specified.

Description

This constructor creates a URL with the given protocol, hostname, and filename. The port number is set to the default port for the given protocol. Calling this constructor is equivalent to calling URL(protocol,_3C/tt_3E host, -1, file).

public URL(String protocol, String host, int port, String file) throws MalformedURLException

Parameters

protocol

A protocol.

host

A hostname.

port

A port number or -1 to use the default port for the protocol.

file

A filename.

Throws

MalformedURLException

If an unknown protocol is specified.

Description

This constructor creates a URL with the given protocol, hostname, port number, and filename.

If this is the first URL object being created with the specified protocol, a protocol handler of type URLStreamHandler is created for the protocol. Here are the steps that are taken to create a protocol handler:

1. If an application has set up a URLStreamHandlerFactory by calling setURLStreamHandlerFactory(), the constructor calls the createURLStreamHandler() method of that object to create the protocol

handler. The protocol is passed as a String argument to that method.

2. If no URLStreamHandlerFactory has been established, or the createURLStreamHandler() method returns null, the constructor retrieves the value of the system property java.protocol.handler.pkgs. If this value is not null, it is interpreted as a list of packages separated by vertical bar (|) characters. The constructor then tries to load the class named *package*.*protocol*.Handler, where *package* is the name of the first package in the list and *protocol* is the name of the protocol. If the class exists, and is a subclass of URLStreamHandler, it is used as the URLStreamHandler for the protocol. If the class does not exist, or if it exists but is not a subclass of URLStreamHandler, the constructor tries the next package in the list.

3. If the previous step fails to find an appropriate protocol handler, the constructor tries to load the class named sun.net.www.protocol.*protocol*.Handler, where *protocol* is the name of the protocol. If the class exists and is a subclass of URLStreamHandler, it is used as the URLStreamHandler for the protocol. If the class does not exist, or if it exists but is not a subclass of URLStreamHandler, a MalformedURLException is thrown.

Class Methods

setURLStreamHandlerFactory

public static synchronized void setURLStreamHandlerFactory(URLStreamHandlerFactory fac)

Parameters

fac

An object that implements URLStreamHandlerFactory.

Throws

Error

If the factory has already been defined.

SecurityException

If the application does not have permission to set the factory.

Description

This method tells the URL class to use the given URLStreamHandlerFactory object for handling all URL objects. The purpose of this mechanism is to allow a program that hosts applets, such as a web browser, control over the creation of URLStreamHandler objects.

Instance Methods

equals

public boolean equals(Object obj)

Parameters

obj

The object to be compared with this object.

Returns

true

if the objects are equivalent;

false

if they are not.

Overrides

Object.equals()

Description

This method returns true if obj is an instance of URL with the same protocol, hostname, port number, and filename as this URL. The reference is only compared if it is not null in this URL.

getContent

public Object getContent() throws IOException

Returns

The Object created from the resource represented by this URL.

Throws

IOException

If any kind of I/O error occurs.

Description

This method returns the content of the URL, encapsulated in an object that is appropriate for the type of the content. The method is shorthand for calling openConnection().getContent(), which uses a ContentHandler object to retrieve the content.

getFile

public String getFile()

Returns

The filename of the URL.

Description

This method returns the name of the file of this URL. Note that the file can be misleading; although the resource represented by this URL may be a file, it can also be generated on the fly by the server.

getHost

public String getHost()

Returns

The hostname of the URL.

Description

This method returns the hostname from this URL.

getPort

public int getPort()

Returns

The port number of the URL.

Description

This method returns the port number of this URL. If a port number is not specified for this URL, meaning it uses the default port for the protocol, -1 is returned.

getProtocol

public String getProtocol()

Returns

The protocol of the URL.

Description

This method returns the protocol of this URL. Some examples of protocols are: http, ftp, and mailto.

getRef

public String getRef()

Returns

The reference of the URL.

Description

This method returns the reference, or anchor, of this URL.

hashCode

public int hashCode()

Returns

The hashcode of the URL.

Overrides

Object.hashCode()

Description

This method returns a hashcode for this object.

openConnection

public URLConnection openConnection() throws IOException

Returns

A URLConnection object for the URL.

Throws

IOException

If any kind of I/O error occurs.

Description

This method returns a URLConnection than manages a connection to the resource represented by this URL. If there is not already an open connection, the method opens a connection by calling the openConnection() method of the URLStreamHandler for this URL. A URLStreamHandler for the protocol of the URL is created by the constructor of the URL.

openStream

public final InputStream openStream() throws IOException

Returns

A InputStream that reads from this URL.

Throws

IOException

If any kind of I/O error occurs.

Description

This method returns an InputStream object that reads the content of the given URL. The method is shorthand for calling openConnection().getInputStream().

sameFile

public boolean sameFile(URL other)

Parameters

other

The URL to compare.

Returns

A boolean value that indicates if this URL is equivalent to other with the exception of references.

Description

This method returns true if this object and the given URL object specify the same protocol, specify hosts that have the same IP address, specify the same port number, and specify the same filename. The filename comparison is case-sensitive. References specified by the URLs are not considered by this method. This method is a helper method for equals().

toExternalForm

public String toExternalForm)

Returns

A string representation of the URL.

Description

This method returns a string representation of this URL. The string representation is determined by the protocol of the URL. The method calls the toExternalForm() method of the URLStreamHandler for this URL. A URLStreamHandler for the protocol of the URL is created by the constructor of the URL.

toString

public String toString()

Returns

A string representation of the URL.

Overrides

Object.toString()

Description

This method returns a string representation of this URL by calling toExternalForm().

Protected Instance Methods

set

protected void set(String protocol, String host, int port, String file, String ref)

Parameters

protocol

A protocol.

host

A hostname.

port

A port number.

file

A filename.

ref

A reference.

Description

This method sets the protocol, hostname, port number, filename, and reference of this URL. The method is called by a URLStreamHandler to set the parts of the URL. A URLStreamHandler for the protocol of the URL is created by the constructor of the URL. It is this URLStreamHandler that parses the URL string. This method is used after parsing to set the values of the URL.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	finalize()	Object
getClass()	Object	notify()	Object
notifyAll()	Object	wait()	Object
wait(long)	Object	wait(long, int)	Object

URLConnection

Name

URLConnection

Synopsis

Class Name:

`java.net.URLConnection`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.net.HttpURLConnection`

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `URLConnection` class is an `abstract` class that represents a connection to a `URL`. A subclass of `URLConnection` supports a protocol-specific connection. A `URLConnection` can both read from and write to a `URL`.

A `URLConnection` object is created when the `openConnection()` method is called for a `URL` object. At this point, the actual connection has not yet been made, so setup parameters and general request properties can be modified for the specific connection. The various `set` methods control the setup parameters and request properties. Then the actual connection is made by calling the `connect()` method. Finally, the remote object becomes available, and the header fields and the content are accessed using various `get` methods.

The `URLConnection` class defines quite a few methods for setting parameters and retrieving information. Fortunately, for simple connections, all of the setup parameters and request properties can be left alone, as they all have reasonable default values. In most cases, you'll only be interested in the `getInputStream()` and `getContent()` methods. `getInputStream()` provides an `InputStream` that reads from the `URL`, while `getContent()` uses a `ContentHandler` to return an `Object` that represents the content of the resource. These methods are mirrored by the `openStream()` and `getContent()` convenience methods in the `URL` class.

Class Summary

```
public abstract class java.net.URLConnection extends java.lang.Object {
  // Variables
  protected boolean allowUserInteraction;
  protected boolean connected;
  protected boolean doInput;
  protected boolean doOutput;
  public static FileNameMap fileNameMap;            // New in 1.1
  protected long ifModifiedSince;
  protected URL url;
  protected boolean useCaches;
  // Constructors
  protected URLConnection(URL url);
  // Class Methods
  public static boolean getDefaultAllowUserInteraction();
  public static String getDefaultRequestProperty(String key);
  protected static String guessContentTypeFromName(String fname);
  public static String guessContentTypeFromStream(InputStream is);
  public static synchronized void setContentHandlerFactory(
                                  ContentHandlerFactory fac);
  public static void setDefaultAllowUserInteraction(
                     boolean defaultallowuserinteraction);
  public static void setDefaultRequestProperty(String key,
                     String value);
  // Instance Methods
  public abstract void connect();
  public boolean getAllowUserInteraction();
  public Object getContent()
  public String getContentEncoding();
  public int getContentLength();
  public String getContentType();
  public long getDate();
  public boolean getDefaultUseCaches();
  public boolean getDoInput();
  public boolean getDoOutput();
  public long getExpiration();
  public String getHeaderField(int n);
  public String getHeaderField(String name);
  public long getHeaderFieldDate(String name, long default);
  public int getHeaderFieldInt(String name, int default);
  public String getHeaderFieldKey(int n);
  public long getIfModifiedSince();
  public InputStream getInputStream();
  public long getLastModified();
  public OutputStream getOutputStream();
  public String getRequestProperty(String key);
  public URL getURL(default.htm);
  public boolean getUseCaches();
  public void setAllowUserInteraction(boolean allowuserinteraction);
  public void setDefaultUseCaches(boolean defaultusecaches);
  public void setDoInput(boolean doinput);
  public void setDoOutput(boolean dooutput);
  public void setIfModifiedSince(long ifmodifiedsince);
  public void setRequestProperty(String key, String value);
  public void setUseCaches(boolean usecaches);
  public String toString();
}
```

Variables

allowUserInteraction

protected boolean allowUserInteraction

Description

> A flag that indicates whether or not user interaction is enabled for this connection. If this variable is `true`, it is possible to allow user interactions such as popping up dialog boxes. If it is `false`, no user interaction is allowed. The variable can be set by `setAllowUserInteraction()` and retrieved by `getAllowUserInteraction()`. The default value is `false`, unless the `setDefaultAllowUserInteraction()` method has been called, in which case that method call controls the default value.

connected

protected boolean connected

Description

> A flag that indicates whether or not this object has established a connection to a remote host.

doInput

protected boolean doInput

Description

> A flag that indicates whether or not this connection is enabled for input. Setting this variable to `true` indicates that the connection is going to read data. The variable can be set by `setDoInput()` and retrieved by `getDoInput()`. The default value is `true`.

doOutput

protected boolean doOutput

Description

> A flag that indicates whether or not this connection is enabled for output. Setting this variable to `true` indicates that the connection is going to write data. The variable can be set by `setDoOutput()` and retrieved by `getDoOutput()`. The default value is `false`.

fileNameMap

public static FileNameMap fileNameMap

Availability

> New as of JDK 1.1

Description

> A reference to the object that maps filename extensions to MIME type strings. This variable is used in `guessContentTypeFromName()`.

ifModifiedSince

protected long ifModifiedSince

Description

> A time value, specified as the number of seconds since January 1, 1970, that controls whether or not a resource is fetched based on its last modification time. Some protocols do not bother to retrieve a resource if there is a current local cached copy. However, if the resource has been modified more recently than `ifModifiedSince`, it is retrieved. If `ifModifiedSince` is 0, the resource is always retrieved. The variable can be set by `setIfModifiedSince()` and retrieved by `getIfModifiedSince()`. The default value is 0, which means that the resource must always be retrieved.

url

protected URL url

Description

> The resource to which this `URLConnection` connects. This variable is set to the value of the `URL` argument in the `URLConnection` constructor. It can be retrieved by `getURL(default.htm)`.

useCaches

protected boolean useCaches

Description

A flag that indicates whether or not locally cached resources are used. Some protocols cache documents. If this variable is `true`, the protocol is allowed to use caching whenever possible. If it is `false`, the protocol must always try to retrieve the resource. The variable can be set by `setUseCaches()` and retrieved by `getUseCaches()`. The default value is `true`, unless the `setDefaultUseCaches()` method has been called, in which case that method call controls the default value.

Constructors

URLConnection

protected URLConnection(URL url)

Parameters

`url`

The `URL` to access.

Description

This constructor creates a `URLConnection` object to manage a connection to the destination specified by the given `URL`. The actual connection is not created, however.

Class Methods

getDefaultAllowUserInteraction

public static boolean getDefaultAllowUserInteraction()

Returns

`true` if user interaction is allowed by default; `false` otherwise.

Description

This method returns the default value of the `allowUserInteraction` variable for all instances of `URLConnection`. The default value is `false`, unless the `setDefaultAllowUserInteraction()` method has been called, in which case that method call controls the default value.

getDefaultRequestProperty

public static String getDefaultRequestProperty(String key)

Parameters

`key`

The name of a request property.

Returns

The default value of the named request property.

Description

This method returns the default value for the request property named by the `key` parameter.

guessContentTypeFromName

protected static String guessContentTypeFromName(String fname)

Parameters

`fname`

A `String` that contains the name of a file.

Returns

A guess at the MIME type of the given file, or `null` if a guess cannot be made.

Description

This method uses the `FileNameMap` specified by the variable `fileNameMap` to return a MIME content type for the given filename.

guessContentTypeFromStream

```
 protected static String guessContentTypeFromStream(InputStream is) throws
IOException
```

Parameters

`is`

The input stream to inspect

Returns

A guess at the MIME type of the given input stream, or `null` if a guess cannot be made.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method looks at the first few bytes of an `InputStream` and returns a guess of the MIME content type. Note that the `InputStream` must support marks, which usually means that there is a `BufferedInputStream` at some level. Here are some strings that are recognized and the inferred content type:

String	MIME Type Guess
`#def`	`image/x-bitmap`
`<!`	`text/html`
`<body`	`text/html`
`<head>`	`text/html`
`<html>`	`text/html`
`! XPM2`	`image/x-pixmap`
`GIF8`	`image/gif`

setContentHandlerFactory

```
public static synchronized void setContentHandlerFactory(ContentHandlerFactory fac)
```

Parameters

`fac`

An object that implements `ContentHandlerFactory`.

Throws

`Error`

If the factory has already been defined.

`SecurityException`

If the application does not have permission to set the factory.

Description

This method tells the `URLConnection` class to use the given `ContentHandlerFactory` object for all `URLConnection` objects. The purpose of this mechanism is to allow a program that hosts applets, such as a web browser, control over the creation of `ContentHandler` objects.

setDefaultAllowUserInteraction

```
 public static void setDefaultAllowUserInteraction( boolean
defaultallowuserinteraction)
```

Parameters

`defaultallowuserinteraction`

The new default value.

Description

This method sets the default value of the `allowUserInteraction` variable for all new instances of `URLConnection`.

setDefaultRequestProperty

```
 public static void setDefaultRequestProperty(String key, String value)
```

Parameters

`key`

The name of a request property.

`value`

The new default value.

Description

This method sets the default value of the request property named by the `key` parameter.

Instance Methods

connect

public abstract void connect() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

When a `URLConnection` object is created, it is not immediately connected to the resource specified by its associated `URL` object. This method actually establishes the connection. If this method is called after the connection has been established, it does nothing.

Before the connection is established, various parameters can be set with the `set` methods. After the connection has been established, it is an error to try to set these parameters.

As they retrieve information about the resource specified by the `URL` object, many of the `get` methods require that the connection be established. If the connection has not been established when one of these methods is called, the connection is established implicitly.

getAllowUserInteraction

public boolean getAllowUserInteraction()

Returns

`true` if user interaction is allowed for this connection; `false` otherwise.

Description

This method returns the value of the `allowUserInteraction` variable for this `URLConnection`.

getContent

```
public Object getContent() throws IOException, UnknownServiceException
```

Returns

An `Object` created from this `URLConnection`.

Throws

`IOException`

If any kind of I/O error occurs.

`UnknownServiceException`

If the protocol cannot support the content type.

Description

This method retrieves the content of the resource specified by the `URL` object associated with this `URLConnection`. If the connection for this object has not been established, the method implicitly establishes it.

The method returns an object that encapsulates the content of the connection. For example, for a connection that has content type `image/jpeg`, the method might return a object that belongs to subclass of `Image,` or for content type text/plain, it might return a String. The instanceof operator should determine the specific type of object that is returned.

The method first determines the content type of the connection by calling getContentType(). If this is the first time the content type has been seen, a content handler of type ContentHandler is created for the content type. Here are the steps that are taken to create a content handler:

1. If an application has set up a ContentHandlerFactory by calling setContentHandlerFactory(), the method calls the createContentHandler() method of that object to create the content handler. The content type is passed as a String argument to that method.

2. If no ContentHandlerFactory has been established, or the createContentHandler() method returns null, the method retrieves the value of the system property java.content.handler.pkgs. If this value is not null, it is interpreted as a list of packages separated by vertical bar (|) characters. The method then tries to load the class named *package*.*contentType*, where *package* is the name of the first package in the list and *contentType* is formed by taking the content-type string and replacing every slash (/) character with a period (.) and every other nonalphanumeric character with an underscore (_). If the class exists and is a subclass of ContentHandler, it is used as the ContentHandler for the content type. If the class does not exist, or if it exists but is not a subclass of ContentHandler, the method tries the next package in the list.

3. If the previous step fails to find an appropriate content handler, the method tries to load the class named sun.net.www.content.*contentType*, where *contentType* is formed by taking the content-type string and replacing every slash (/) character with a period (.) and every other nonalphanumeric character with an underscore (_). If the class exists and is a subclass of ContentHandler, it is used as the ContentHandler for the content type. If the class does not exist, or if it exists but is not a subclass of ContentHandler, a UnknownServiceException is thrown.

getContentEncoding

public String getContentEncoding()

Returns

The content encoding, or null if it is not known.

Description

This method retrieves the content encoding of the resource specified by the URL object associated with this URLConnection. In other words, the method returns the value of the content-encoding header field. If the connection for this object has not been established, the method implicitly establishes it.

getContentLength

public int getContentLength()

Returns

The content length or -1 if it is not known.

Description

> This method retrieves the content length of the resource specified by the `URL` object associated with this `URLConnection`. In other words, the method returns the value of the `content-length` header field. If the connection for this object has not been established, the method implicitly establishes it.

getContentType

public String getContentType()

Returns

> The content type, or `null` if it is not known.

Description

> This method retrieves the content type of the resource specified by the `URL` object associated with this `URLConnection`. In other words, the method returns the value of the `content-type` header field. This string is generally be a MIME type, such as `image/jpeg` or `text/html`. If the connection for this object has not been established, the method implicitly establishes it.

getDate

public long getDate()

Returns

> The content date, or 0 if it is not known.

Description

> This method retrieves the date of the resource specified by the `URL` object associated with this `URLConnection`. In other words, the method returns the value of the `date` header field. The date is returned as the number of seconds since January 1, 1970. If the connection for this object has not been established, the method implicitly establishes it.

getDefaultUseCaches

public boolean getDefaultUseCaches()

Returns

> `true` if the use of caches is allowed by default; `false` otherwise.

Description

> This method returns the default value of the `useCaches` variable for all instances of `URLConnection`. The default value is `true`, unless the `setDefaultUseCaches()` method has been called, in which case that method call controls the default value.

getDoInput

public boolean getDoInput()

Returns

> `true` if this `URLConnection` is to be used for input; `false` otherwise.

Description

> This method returns the value of the `doInput` variable for this `URLConnection`.

getDoOutput

public boolean getDoOutput()

Returns

> `true` if this `URLConnection` is to be used for output; `false` otherwise.

Description

> This method returns the value of the `doOutput` variable for this `URLConnection`.

getExpiration

public long getExpiration()

Returns

> The content expiration date, or if it is not known.

Description

> This method retrieves the expiration date of the resource specified by the `URL` object associated with this `URLConnection`. In other words, the method returns the value of the `expires` header field. The date is returned as the number of seconds since January 1, 1970. If the connection for this object has not been established, the method implicitly establishes it.

getHeaderField

public String getHeaderField(int n)

Parameters

> `n`

A header field index.

Returns

The value of the header field with the given index, or `null` if `n` is greater than the number of fields in the header.

Description

This method retrieves the value of the header field at index `n` of the resource specified by the `URL` object associated with this `URLConnection`. If the connection for this object has not been established, the method implicitly establishes it.

public String getHeaderField(String name)

Parameters

`name`

A header field name.

Returns

The value of the named header field, or `null` if the header field is not known or its value cannot be determined.

Description

This method retrieves the value of the named header field of the resource specified by the `URL` object associated with this `URLConnection`. This method is a helper for methods like `getContentEncoding()` and `getContentType()`. If the connection for this object has not been established, the method implicitly establishes it.

getHeaderFieldDate

public long getHeaderFieldDate(String name, long default)

Parameters

`name`

A header field name.

`default`

A default date value.

Returns

The value of the named header field parsed as a date value, or `default` if the field is missing or cannot be parsed.

Description

This method retrieves the value of the named header field of the resource specified by the `URL` object associated with this `URLConnection` and parses it as a date value. The date is returned as the number of seconds since January 1, 1970. If the value of the header field cannot be determined or it is not a properly formed date, the given default value is returned. If the connection for this object has not been established, the method implicitly establishes it.

getHeaderFieldInt

public int getHeaderFieldInt(String name, int default)

Parameters

`name`

A header field name.

`default`

A default value.

Returns

The value of the named header field parsed as a number, or `default` if the field is missing or cannot be parsed.

Description

This method retrieves the value of the named header field of the resource specified by the `URL` object associated with this `URLConnection` and parses it as a number. If the value of the header field cannot be determined or it is not a properly formed integer, the given default value is returned. If the connection for this object has not been established, the method implicitly establishes it.

getHeaderFieldKey

public String getHeaderFieldKey(int n)

Parameters

`n`

A header field index.

Returns

The name of the header field at the given index, or `null` if `n` is greater than the number of fields in the header.

Description

This method retrieves the name of the header field at index `n` of the resource specified by the `URL` object associated with this `URLConnection`. If the connection for this object has not been established, the method implicitly establishes it.

getIfModifiedSince

public long getIfModifiedSince()

Returns

The value of the `ifModifiedSince` variable.

Description

This method returns the value of the `ifModifiedSince` variable for this `URLConnection`.

getInputStream

`public InputStream getInputStream() throws IOException, UnknownServiceException`

Returns

An `InputStream` that reads data from this connection.

Throws

`IOException`

If any kind of I/O error occurs.

`UnknownServiceException`

If this protocol does not support input.

Description

This method returns an `InputStream` that reads the contents of the resource specified by the `URL` object associated with this `URLConnection`.

getLastModified

public long getLastModified()

Returns

The content last-modified date, or if it is not known.

Description

This method retrieves the last-modified date of the resource specified by the `URL` object associated with this

`URLConnection`. In other words, the method returns the value of the `last-modified` header field. The date is returned as the number of seconds since January 1, 1970. If the connection for this object has not been established, the method implicitly establishes it.

getOutputStream

`public OutputStream getOutputStream() throws IOException, UnknownServiceException`

Returns

An `OutputStream` that writes data to this connection.

Throws

`IOException`

If any kind of I/O error occurs.

`UnknownServiceException`

If this protocol does not support output.

Description

This method returns an `OutputStream` that writes to the resource specified by the `URL` object associated with this `URLConnection`.

getRequestProperty

public String getRequestProperty(String key)

Parameters

`key`

The name of a request property.

Returns

The value of the named request property.

Description

This method returns the value of the request property named by the `key` parameter.

getURL

public URL getURL(default.htm)

Returns

The `URL` that this connection accesses.

Description

This method returns a reference to the `URL` associated with this object. This is the value of the `url` variable for this `URLConnection`.

getUseCaches

public boolean getUseCaches()

Returns

`true` if this `URLConnection` uses caches; `false` otherwise.

Description

This method returns the value of the `useCaches` variable for this `URLConnection`.

setAllowUserInteraction

public void setAllowUserInteraction(boolean allowuserinteraction)

Parameters

`allowuserinteraction`

A `boolean` value that indicates whether user interaction is allowed or not.

Throws

`IllegalAccessError`

If this method is called after the connection has been established.

Description

This method sets the value of the `allowUserInteraction` variable for this `URLConnection`. This method must be called before this object establishes a connection.

setDefaultUseCaches

public void setDefaultUseCaches(boolean defaultusecaches)

Parameters

`defaultusecaches`

The new default value.

Description

This method sets the default value of the `useCaches` variable for all new instances of `URLConnection`.

setDoInput

public void setDoInput(boolean doinput)

Parameters

`doinput`

A `boolean` value that indicates if this connection is to be used for input.

Throws

`IllegalAccessError`

If this method is called after the connection has been established.

Description

This method sets the value of the `doInput` variable for this `URLConnection`. This method must be called before this object establishes a connection.

setDoOutput

public void setDoOutput(boolean dooutput)

Parameters

`dooutput`

A `boolean` value that indicates if this connection is to be used for output.

Throws

`IllegalAccessError`

If this method is called after the connection has been established.

Description

This method sets the value of the `doOutput` variable for this `URLConnection`. This method must be called before this object establishes a connection.

setIfModifiedSince

public void setIfModifiedSince(long ifmodifiedsince)

Parameters

`ifmodifiedsince`

A time value, specified as the number of seconds since January 1, 1970.

Throws

`IllegalAccessError`

If this method is called after the connection has been established.

Description

This method sets the value of the `ifModifiedSince` variable for this `URLConnection`. This method must be called before this object establishes a connection.

setRequestProperty

public void setRequestProperty(String key, String value)

Parameters

`key`

The name of a request property.

`value`

The new value.

Throws

`IllegalAccessError`

If this method is called after the connection has been established.

Description

This method sets the value of the request property named by the `key` parameter.

setUseCaches

public void setUseCaches(boolean defaultusecaches)

Parameters

`defaultusecaches`

A `boolean` value that indicates if this connection uses caches.

Throws

`IllegalAccessError`

If this method is called after the connection has been established.

Description

This method sets the value of the `useCaches` variable for this `URLConnection`. This method must be called before this object establishes a connection.

toString

public String toString()

Returns

A string representation of the `URLConnection`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `URLConnection`.

Inherited Methods

URLEncoder

Name

URLEncoder

Synopsis

Class Name:

```
java.net.URLEncoder
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `URLEncoder` class defines a single `static` method that converts a `String` to its URL-encoded form. More precisely, the `String` is converted to a MIME type called `x-www-form-urlencoded`.

This is the format used when posting forms on the Web. The algorithm leaves letters, numbers, and the dash (`-`), underscore (`_`), period (`.`), and asterisk (`*`) characters unchanged. Space characters are converted to plus signs (`+`). All other characters are encoded with a percent sign (`%`) followed by the character code represented as a two-digit hexadecimal number. For example, consider the following string:

```
Jean-Louis Gassée
```

This string gets encoded as:

```
Jean-Louis+Gas%8ee
```

The point of the `URLEncoder` class is to provide a way to canonicalize a string into an extremely portable subset of ASCII that can be handled properly by computers around the world.

Class Summary

```
public class java.net.URLEncoder extends java.lang.Object {
  // Class Methods
  public static String encode(String s);
}
```

Class Methods

encode

public static String encode(String s)

Parameters

`s`

The string to encode.

Returns

A URL-encoded string.

Description

This method returns the contents of the `String` in the `x-www-form-urlencoded` format.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long timeout, int nanos)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

URLStreamHandler

Name

URLStreamHandler

Synopsis

Class Name:

`java.net.URLStreamHandler`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `URLStreamHandler` class is an `abstract` class that defines methods that encapsulate protocol-specific behavior. A stream handler protocol knows how to establish a connection for a particular protocol and how to parse the protocol-specific portion of a URL. An application does not normally create a `URLStreamHandler` directly; the appropriate subclass of `URLStreamHandler` is created by a `URLStreamHandlerFactory`.

The main purpose of a subclass of `URLStreamHandler` is to create a `URLConnection` object for a given `URL`. The `URLStreamHandler` object creates an object of the appropriate subclass of `URLConnection` for the protocol type specified by the URL. In order for a `URL` object to handle a protocol type such as `http`, `ftp`, or `nntp`, it needs an object of the appropriate subclass of `URLStreamHandler` to handle the protocol-specific details.

Class Summary

```
public abstract class java.net.URLStreamHandler extends java.lang.Object {
  // Protected Instance Methods
  protected abstract URLConnection openConnection(URL u)
  protected void parseURL(URL u, String spec, int start, int limit);
  protected void setURL(URL u, String protocol, String host,
                        int port, String file, String ref);
  protected String toExternalForm(URL u);
}
```

Protected Instance Methods

openConnection

`protected abstract URLConnection openConnection(URL u) throws IOException`

Parameters

`u`

The `URL` being connected to.

Returns

The `URLConnection` object for the given `URL`.

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method handles the protocol-specific details of establishing a connection to a remote resource specified by the `URL`. The connection should be handled just up to the point where the resource data can be downloaded. A `ContentHandler` then takes care of downloading the data and creating an appropriate object.

A subclass of `URLStreamHandler` must implement this method.

parseURL

protected void parseURL(URL u, String spec, int start, int limit)

Parameters

`u`

A reference to a `URL` object that receives the results of parsing.

`spec`

The string representation of a URL to be parsed.

`start`

The offset at which to begin parsing the protocol-specific portion of the URL.

`limit`

The offset of the last character that is to be parsed.

Description

This method parses the string representation of a URL into a `URL` object.

Some parts of the `URL` object may already be specified if `spec` specifies a relative URL. However, values for those parts in `spec` can override the inherited context.

The method only parses the protocol-specific portion of the URL. In other words, `start` should specify the character immediately after the first colon (:), which marks the termination of the protocol type, and `limit` should either be the last character in the string or the first pound sign (#), which marks the beginning of a protocol-independent anchor. Rather than return a result, the method calls the `set()` method of the specified `URL` object to set its fields to the appropriate values.

The implementation of the `parseURL(default.htm)` method in `URLStreamHandler` parses the string representation as if it were an `http` specification. A subclass that implements a protocol stream handler for a different protocol must override this method to properly parse the URL.

setURL

protected void setURL(URL u, String protocol, String host, int port, String file, String ref)

Parameters

`u`

A reference to a URL object to be modified.

protocol

A protocol.

host

A hostname.

port

A port number.

file

A filename.

ref

A reference.

Description

This method sets the protocol, hostname, port number, filename, and reference of the given URL to the specified values by calling the set() method of the URL. Only subclasses of URLStreamHandler are allowed to call the set() method of a URL object.

toExternalForm

protected String toExternalForm(URL u)

Parameters

u

The URL object to convert to a string representation.

Returns

A string representation of the given URL.

Description

This method unparses a URL object and returns a string representation of the URL.

The implementation of the toExternalForm() method in URLStreamHandler returns a string representation that is appropriate for an `http` specification. A subclass that implements a protocol stream handler for a different protocol must override this method to create a correct string representation.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`

URLStreamHandlerFactory

Name

URLStreamHandlerFactory

Synopsis

Interface Name:

`java.net.StreamHandlerFactory`

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented By:

None

Availability:

JDK 1.0 or later

Description

The `URLStreamHandlerFactory` interface defines a method that creates a `URLStreamHandler` object for a specific protocol. The interface is implemented by classes that select `URLStreamHandler` subclasses to process particular protocol types.

The `URL` class uses a `URLStreamHandlerFactory` to create `URLStreamHandler` objects. The protocol type is determined by the portion of the URL up to the first colon. For example, given the following URL:

```
http://www.tolstoi.org/ilych.html
```

the protocol type is `http`. A `URLStreamHandlerFactory` that recognizes `http` returns a `URLStreamHandler` that can process the URL.

Interface Declaration

```
public abstract interface java.net.URLStreamHandlerFactory {
  // Methods
  public abstract URLStreamHandler createURLStreamHandler(String protocol);
}
```

Methods

createURLStreamHandler

public abstract URLStreamHandler createURLStreamHandler (String protocol)

Parameters

> `protocol`
>
> > A `String` that represents a protocol.

Description

> This method creates an object of the appropriate subclass of `URLStreamHandler` that can process a URL using the named protocol.

See Also

`URL`, `URLStreamHandler`

UnknownHostException

Name

UnknownHostException

Synopsis

Class Name:

    `java.net.UnknownHostException`

Superclass:

    `java.io.IOException`

Immediate Subclasses:

    None

Interfaces Implemented:

    None

Availability:

    JDK 1.0 or later

Description

A `UnknownHostException` is thrown when a hostname cannot be resolved to an IP address.

Class Summary

```
public class java.net.UnknownHostException extends java.io.IOException {
  // Constructors
  public UnknownHostException();
  public UnknownHostException(String host);
}
```

Constructors

UnknownHostException

public UnknownHostException()

Description

> This constructor `create`s an `UnknownHostException` with no associated detail message.

public UnknownHostException(String host)

Parameters

> `host`
>
> > The detail message.

Description

> This constructor creates an `UnknownHostException` with the specified detail message, which should be the hostname that cannot be resolved.

Superclass:

    java.io.IOException

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `UnknownServiceException` is thrown when an unrecognized service is requested, which can occur when the MIME type returned by a `URLConnection` does not match any recognized types.

Class Summary

```
public class java.net.UnknownServiceException
             extends java.io.IOException {
  // Constructors
  public UnknownServiceException();
  public UnknownServiceException(String msg);
}
```

Constructors

UnknownServiceException

public UnknownServiceException()

Description

This constructor `create`s an `UnknownServiceException` with no associated detail message.

public UnknownServiceException(String msg)

Parameters

`msg`

The detail message.

Description

This constructor creates an `UnknownServiceException` with the specified detail message.

Inherited Methods

UnknownHostException | BOOK INDEX | BreakIterator

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

CharacterIterator

Name

CharacterIterator

Synopsis

Interface Name:

```
java.text.CharacterIterator
```

Super-interface:

```
java.lang.Cloneable
```

Immediate Sub-interfaces:

None

Implemented By:

```
java.text.StringCharacterIterator
```

Availability:

New as of JDK 1.1

Description

The `CharacterIterator` interface defines methods that support bidirectional movement through a sequence of text. The interface is implemented by classes that maintain a current position in a sequence of characters. The interface provides methods for moving to the first, last, next, and previous characters in the sequence. The `BreakIterator` classes uses this interface to locate boundaries in textual sequences.

Class Summary

```
public abstract interface java.text.CharacterIterator
                          extends java.lang.Cloneable {
  // Constants
  public static final char DONE;
  // Methods
  public abstract Object clone();
  public abstract char current();
  public abstract char first();
  public abstract int getBeginIndex();
  public abstract int getEndIndex();
  public abstract int getIndex();
  public abstract char last();
  public abstract char next();
  public abstract char previous();
  public abstract char setIndex(int position);
}
```

Constants

DONE

public final static char DONE

Description

> A constant that indicates that the beginning or end of the text has been reached. It can be returned by `next()` or `previous()`.

Methods

clone

public abstract Object clone()

Returns

> A copy of this `CharacterIterator`.

Overrides

> `Object.clone()`

Description

> This method creates a copy of this `CharacterIterator` and returns it.

current

public abstract char current()

Returns

> The character at the current position of this `CharacterIterator` or `DONE` if the current position is not within the text sequence.

Description

> This method returns the character at the current position of this `CharacterIterator`. The current position is returned by `getIndex()`.

first

public abstract char first()

Returns

> The first character in this `CharacterIterator`.

Description

This method returns the character at the first position in this `CharacterIterator`. The first position is returned by `getBeginIndex()`. The current position of the iterator is set to this position.

getBeginIndex

public abstract int getBeginIndex()

Returns

The index of the first character in this `CharacterIterator`.

Description

This method returns the index of the beginning of the text for this `CharacterIterator`.

getEndIndex

public abstract int getEndIndex()

Returns

The index after the last character in this `CharacterIterator`.

Description

This method returns the index of the character following the end of the text for this `CharacterIterator`.

getIndex

public abstract int getIndex()

Returns

The index of the current character in this `CharacterIterator`.

Description

This method returns the current position, or index, of this `CharacterIterator`.

last

public abstract char last()

Returns

The last character in this `CharacterIterator`.

Description

This method returns the character at the ending position of this `CharacterIterator`. The last position is the value of `getEndIndex()-1`. The current position of the iterator is set to this position.

next

public abstract char next()

Returns

The next character in this `CharacterIterator` or `DONE` if the current position is already at the end of the text.

Description

This method increments the current position of this `CharacterIterator` by one and returns the character at the new position. If the current position is already at `getEndIndex()`, the position is not changed, and `DONE` is returned.

previous

public abstract char previous()

Returns

The previous character in this `CharacterIterator` or `DONE` if the current position is already at the beginning of the text.

Description

This method decrements the current position of this `CharacterIterator` by one and returns the character at the new position. If the current position is already at `getBeginIndex()`, the position is not changed, and `DONE` is returned.

setIndex

public abstract char setIndex(int position)

Parameters

`position`

The new position.

Returns

The character at the specified position in this `CharacterIterator`.

Throws

`IllegalArgumentException`

If the given position is not between `getBeginIndex()` and `getEndIndex()-1`.

Description

This method sets the current position, or index, of this `CharacterIterator` to the given position.

See Also

`BreakIterator`, `StringCharacterIterator`

ChoiceFormat

Name

ChoiceFormat

Synopsis

Class Name:

`java.text.ChoiceFormat`

Superclass:

`java.text.NumberFormat`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `ChoiceFormat` class is a concrete subclass of `NumberFormat` that maps numerical ranges to strings, or formats. `ChoiceFormat` objects are used most often by `MessageFormat` objects to handle plurals, verb agreement, and other such issues.

The ranges in a `ChoiceFormat` are specified as an ascending array of `double` values, where each number is the bottom end of a range. A value is mapped to a format when it falls within the range for that format. If the value does not fall in any of the ranges, it is mapped to the first or the last format, depending on whether the value is too low or too high. For example, consider the following code:

```
double[] limits = {1, 10, 100};
String[] labels = {"small", "medium", "large"}
ChoiceFormat cf = new ChoiceFormat(limits, labels);
```

Any number greater than or equal to one and less than 10 is mapped to the format `"small"`. Any number greater than or equal to 10 and less than 100 is mapped to `"medium"`. Numbers greater than or equal to 100 are mapped to `"large"`. Furthermore, numbers less than one are also mapped to `"small"`.

The `nextDouble()` and `previousDouble()` methods can generate `double` values that are higher or lower than other `double` values. These methods provide another way to specify the limits used by a `ChoiceFormat` object.

As shown above, you can create a `ChoiceFormat` object by specifying the limits and formats in two separate arrays. You can also create a `ChoiceFormat` object using a pattern string that specifies the limits and formats. The string is of the form:

```
[limit1]#[format1]|[limit2]#[format2]|...
```

A `<` character can be used in place of the # to indicate that the next higher number, as determined by `nextDouble()`, should be used as the limit. The `toPattern()` method can be used to generate the pattern string for an existing `ChoiceFormat` object.

Note that you create `ChoiceFormat` objects directly, rather than through factory methods. This is because `ChoiceFormat` does not implement any locale-specific behavior. To produce properly internationalized output, the formats for a `ChoiceFormat` should come from a `ResourceBundle` instead of being embedded in the code.

Class Summary

```
public class java.text.ChoiceFormat extends java.text.NumberFormat {
  // Constructors
  public ChoiceFormat(String newPattern);
  public ChoiceFormat(double[] limits, String[] formats);
  // Class Methods
  public static final double nextDouble(double d);
  public static double nextDouble(double d, boolean positive);
  public static final double previousDouble(double d);
  // Instance Methods
  public void applyPattern(String newPattern);
  public Object clone();
  public boolean equals(Object obj);
  public StringBuffer format(double number,
                     StringBuffer toAppendTo, FieldPosition status);
  public StringBuffer format(long number,
                     StringBuffer toAppendTo, FieldPosition status);
  public Object[] getFormats();
  public double[] getLimits();
  public int hashCode();
  public Number parse(String text, ParsePosition status);
  public void setChoices(double[] limits, String[] formats);
  public String toPattern();
}
```

Constructors

ChoiceFormat

public ChoiceFormat(String newPattern)

Parameters

`newPattern`

The pattern string.

Description

This constructor creates a `ChoiceFormat` that uses the limits and formats represented by the given pattern string.

public ChoiceFormat(double[] limits, String[] formats)

Parameters

`limits`

An array of limits. Each element is the lower end of a range that runs up through, but not including, the next element.

`formats`

An array of format strings that correspond to the limit ranges.

Description

This constructor creates a `ChoiceFormat` that uses the given limits and format strings

Class Methods

nextDouble

public static final double nextDouble(double d)

Parameters

`d`

A `double` value.

Returns

The least `double` that is greater than `d`.

Description

This method returns the least `double` greater than `d`. Calling this method is equivalent to `nextDouble(d, true)`.

public static double nextDouble(double d, boolean positive)

Parameters

`d`

A `double` value.

`positive`

A `boolean` value that specifies whether to return the next higher or next lower value.

Returns

If `positive` is `true`, the least `double` that is greater than `d`. If `positive` is `false`, the greatest `double` that is less than `d`.

Description

This method finds the next higher or next lower `double` value from `d`, depending on the value of `positive`. If `positive` is `true`, the method returns the least `double` greater than `d`. Otherwise, the method returns the greatest `double` less than `d`.

previousDouble

public static final double previousDouble(double d)

Parameters

`d`

A `double` value.

Returns

The greatest `double` that is less than `d`.

Description

This method returns the greatest `double` less than `d`. Calling this method is equivalent to `nextDouble(d, false)`.

Instance Methods

applyPattern

public void applyPattern(String newPattern)

Parameters

`newPattern`

The pattern string.

Description

This method tells this `ChoiceFormat` to use the limits and formats represented by the given formatting pattern string. Pattern strings for `ChoiceFormat` objects are described above in the class description.

clone

public Object clone()

Returns

A copy of this `ChoiceFormat`.

Overrides

`NumberFormat.clone()`

Description

This method creates a copy of this `ChoiceFormat` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Format.equals()`

Description

This method returns `true` if `obj` is an instance of `ChoiceFormat` and is equivalent to this `ChoiceFormat`.

format

`public StringBuffer format(double number, StringBuffer toAppendTo, FieldPosition status)`

Parameters

`number`

The `double` value to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`status`

Ignored.

Returns

The given `StringBuffer` with the `String` corresponding to the given number appended to it.

Overrides

`NumberFormat.format(double, StringBuffer, FieldPosition)`

Description

This method formats the given number and appends the result to the given `StringBuffer`.

`public StringBuffer format(long number, StringBuffer toAppendTo, FieldPosition status)`

Parameters

`number`

The `long` value to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`status`

Ignored.

Returns

The given `StringBuffer` with the `String` corresponding to the given number appended to it.

Overrides

`NumberFormat.format(long, StringBuffer, FieldPosition)`

Description

This method formats the given number and appends the result to the given `StringBuffer`.

getFormats

public Object[] getFormats()

Returns

An array that contains the format strings.

Description

This method returns an array containing the current set of format strings.

getLimits

public double[] getLimits()

Returns

An array that contains the limit values.

Description

This method returns an array that contains the current set of limits.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`NumberFormat.hashCode()`

Description

This method returns a hashcode for this `ChoiceFormat`.

parse

public Number parse(String text, ParsePosition status)

Parameters

`text`

The string to be parsed.

`status`

A `ParsePosition` object that can specify a position in the string.

Returns

A `Number` object that encapsulates the value that corresponds to the longest format string that matches the text that starts at the given position. If there is no matching format string, the value `Double.NaN` is returned.

Overrides

`NumberFormat.parse(String, ParsePosition)`

Description

This method parses a number from the given string, starting from the given position. The method returns a `Number` object that encapsulates the value that corresponds to the longest format string that matches the text starting at the given position. If there is no matching format string, the method returns the value `Double.NaN`.

If there is a matching format string, the index value of the given `ParsePosition` object is incremented by the length of that format string.

setChoices

public void setChoices(double[] limits, String[] formats)

Parameters

`limits`

An array of limits. Each element is the lower end of a range that runs up through, but not including, the next element.

`formats`

An array of format strings that correspond to the limit ranges.

Description

This method sets the limits and format strings that this `ChoiceFormat` uses.

toPattern

public String toPattern()

Returns

The pattern string of this `ChoiceFormat`.

Description

This method returns a string that represents the limits and format strings of this `ChoiceFormat`. Pattern strings for `ChoiceFormat` objects are described above in the class description.

Fundamental Classes Reference

CollationElementIterator

Name

CollationElementIterator

Synopsis

Class Name:

`java.text.CollationElementIterator`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `RuleBasedCollator` object creates an instance of the `CollationElementIterator` class to iterate through the characters of a string and determine their relative collation sequence. A `CollationElementIterator` object performs callbacks to the `RuleBasedCollator` that created it to get the information it needs to recognize groups of characters that are treated as single collation characters. For example, a `RuleBasedCollator` for a Spanish language locale would be set up to treat `ch' as a single letter. A `CollationElementIterator` object also gets information from its `RuleBasedCollator` that is used to determine the collation ordering priority for characters.

A collation-ordering priority of a character is a composite integer value that determines how the character is collated. This priority is comprised of:

- A primary order that distinguishes between different letters. Characters that are considered to be different letters, such as `e' and `f', have different primary orders. Different forms of the same letter, such as `e' and `E', or an accented form of `e', have the same primary order. Primary orders are short values.

- A secondary order that distinguishes between accented forms of the same letter. An unaccented `e' has a different secondary order than forms of `e' that have different accents. `E' and `e' have the same secondary order, as do upper- and lowercase forms of `e' that have the same accent. Secondary orders are byte values.

- A tertiary order that distinguishes between case differences. `E' and `e' have different tertiary orders. Tertiary orders are byte values.

The `next()` method returns the collation-ordering priority of the next logical character. Primary, secondary, and tertiary orders are extracted from an ordering priority with the `primaryOrder()`, `secondaryOrder()`, and `tertiaryOrder()` methods.

Class Summary

```
public final class java.text.CollationElementIterator
                   extends java.lang.Object {
   // Constants
   public static final int NULLORDER;

  // Class Methods
   public static final int primaryOrder(int order);
   public static final short secondaryOrder(int order);
   public static final short tertiaryOrder(int order);
  // Instance Methods
   public int next();
   public void reset();
}
```

Constants

NULLORDER

public final static int NULLORDER

Description

A constant that is returned by `next()` if the end of the string has been reached.

Class Methods

primaryOrder

public static final int primaryOrder(int order)

Returns

The primary order component of the given order key.

Description

This method extracts the primary order value from the given order key.

secondaryOrder

public static final short secondaryOrder(int order)

Returns

The secondary order component of the given order key.

Description

This method extracts the secondary order value from the given order key.

tertiaryOrder

public static final short tertiaryOrder(int order)

Returns

The tertiary order component of the given order key.

Description

This method extracts the tertiary order value from the given order key.

Instance Methods

next

public int next()

Returns

The order value of the next character in the string.

Description

This method returns the order key for the next character in the string. The returned value can be broken apart using the `primaryOrder()`, `secondaryOrder()`, and `tertiaryOrder()` methods.

reset

public void reset()

Description

This method resets the position of this `CollationElementIterator` to the beginning of the string.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

CollationKey

Name

CollationKey

Synopsis

Class Name:

`java.text.CollationKey`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `CollationKey` class optimizes the sorting of many strings. The easiest way to compare strings is using `Collator.compare()`, but this can be inefficient, especially if the same strings are compared many times. Instead, you can create a `CollationKey` for each of your strings and compare the `CollationKey` objects to each other using the `compareTo()` method. A `CollationKey` is essentially a bit representation of a `String` object. Two `CollationKey` objects can be compared bitwise, which allows for a fast comparison.

You cannot create `CollationKey` objects directly; you must create them through a specific `Collator` object using `Collator.getCollationKey()`. You can only compare `CollationKey` objects that have been generated from the same `Collator`.

Class Summary

```
public final class java.text.CollationKey extends java.lang.Object {
  // Instance Methods
  public int compareTo(CollationKey target);
  public boolean equals(Object target);
  public String getSourceString();
  public int hashCode();
  public byte[] toByteArray();
}
```

Instance Methods

compareTo

public int compareTo(CollationKey target)

Parameters

`target`

The key to compare with this `CollationKey`.

Returns

`-1` if this `CollationKey` is less than `target`, `0` if this `CollationKey` is equal to `target`, or `1` if this `CollationKey` is greater than `target`.

Description

This method returns an integer that indicates the ordering of this `CollationKey` and the given `CollationKey`. Only `CollationKey` objects generated by the same `Collator` should be compared.

equals

public boolean equals(Object target)

Parameters

`target`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `CollationKey` and is equivalent to this `CollationKey`.

getSourceString

public String getSourceString()

Returns

The string that generated this `CollationKey`.

Description

This method returns the string that was passed to `Collator.getCollationKey()` to create this `CollationKey`.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `CollationKey`.

toByteArray

public byte[] toByteArray()

Returns

A byte array that represents this `CollationKey`.

Description

This method returns a byte array that represents the value of this `CollationKey`, with the most significant byte first.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`

`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Collator

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Collator

Name

Collator

Synopsis

Class Name:

`java.text.Collator`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.text.RuleBasedCollator`

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The Collator class compares strings in a manner that is appropriate for a particular locale. Although Collator is an abstract class, the getInstance() factory methods can be used to get a usable instance of a Collator subclass that implements a particular collation strategy. One subclass, RuleBasedCollator, is provided as part of the JDK.

A Collator object has a *strength* property that controls the level of difference that is considered significant for comparison purposes. The Collator class provides four strength values: PRIMARY, SECONDARY, TERTIARY, and IDENTICAL. Although the interpretation of these strengths is locale-dependent, they generally have the following meanings:

PRIMARY

> The comparison considers letter differences, but ignores case and diacriticals.

SECONDARY

> The comparison considers letter differences and diacriticals, but ignores case.

TERTIARY

> The comparison considers letter differences, case, and diacriticals.

IDENTICAL

> The comparison considers all differences.

The default comparison strength is TERTIARY.

If you only need to compare two String objects once, the compare() method of the Collator class provides the best performance. However, if you need to compare the same String objects multiple times, such as when you are sorting, you should use CollationKey objects instead. A CollationKey object contains a String that has been converted into a series of bits that can be compared in a bitwise fashion against other CollationKey objects. You use a Collator object to create a CollationKey for a given String.

Class Summary

```
public abstract class java.text.Collator extends java.lang.Object
                      implements java.io.Serializable,
                                 java.lang.Cloneable {
  // Constants
  public static final int CANONICAL_DECOMPOSITION;
  public static final int FULL_DECOMPOSITION;
  public static final int IDENTICAL;
  public static final int NO_DECOMPOSITION;
  public static final int PRIMARY;
  public static final int SECONDARY;
  public static final int TERTIARY;
  // Constructors
  protected Collator();
  // Class Methods
  public static synchronized Locale[] getAvailableLocales();
  public static synchronized Collator getInstance();
  public static synchronized Collator getInstance(Locale desiredLocale);
  // Instance Methods
  public Object clone();
  public abstract int compare(String source, String target);
  public boolean equals(Object that);
  public boolean equals(String source, String target);
  public abstract CollationKey getCollationKey(String source);
  public synchronized int getDecomposition();
  public synchronized int getStrength();
  public abstract synchronized int hashCode();
  public synchronized void setDecomposition(int decompositionMode);
  public synchronized void setStrength(int newStrength);
}
```

Constants

CANONICAL_DECOMPOSITION

public final static int CANONICAL_DECOMPOSITION

Description

> A decomposition constant that specifies that Unicode 2.0 characters which are canonical variants are decomposed for collation. This is the default decomposition setting.

FULL_DECOMPOSITION

public final static int FULL_DECOMPOSITION

Description

A decomposition constant that specifies that Unicode 2.0 canonical variants and compatibility variants are decomposed for collation. This is the most complete decomposition setting, and thus the slowest setting.

IDENTICAL

public final static int IDENTICAL

Description

A strength constant that specifies that all differences are considered significant for comparison purposes.

NO_DECOMPOSITION

public final static int NO_DECOMPOSITION

Description

A decomposition setting that specifies that no Unicode characters are decomposed for collation. This is the least complete decomposition setting, and thus the fastest setting. It only works correctly for languages that do not use diacriticals.

PRIMARY

public final static int PRIMARY

Description

A strength constant that specifies that only primary differences are considered significant for comparison purposes. Primary differences are typically letter differences.

SECONDARY

public final static int SECONDARY

Description

A strength constant that specifies that only secondary differences and above are considered significant for comparison purposes. Secondary differences are typically differences in diacriticals, or accents.

TERTIARY

public final static int TERTIARY

Description

> A strength constant that specifies that only tertiary differences and above are considered significant for comparison purposes. Tertiary differences are typically differences in case. This is the default strength setting.

Constructors

Collator

protected Collator()

Description

> This constructor creates a `Collator` with the default strength of `TERTIARY` and default decomposition mode of `CANONICAL_DECOMPOSITION`.

Class Methods

getAvailableLocales

public static synchronized Locale[] getAvailableLocales()

Returns

> An array of `Locale` objects.

Description

> This method returns an array of the `Locale` objects for which this class can create `Collator` objects.

getInstance

public static synchronized Collator getInstance()

Returns

A `Collator` appropriate for the default `Locale`.

Description

This method creates a `Collator` that compares strings in the default `Locale`.

`public static synchronized Collator getInstance( Locale desiredLocale)`

Parameters

`desiredLocale`

The `Locale` to use.

Returns

A `Collator` appropriate for the given `Locale`.

Description

This method creates a `Collator` that compares strings in the given `Locale`.

Instance Methods

clone

public Object clone()

Returns

A copy of this `Collator`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `Collator` and returns it.

compare

public abstract int compare(String source, String target)

Parameters

`source`

The source string.

`target`

The target string.

Returns

`-1` if `source` is less than `target`, `0` if the strings are equal, or `1` if `source` is greater than `target`.

Description

This method compares the given strings according to the collation rules for this `Collator` and returns a value that indicates their relationship. If either of the strings are compared more than once, a `CollationKey` should be used instead.

equals

public boolean equals(Object that)

Parameters

`that`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Collator` and is equivalent to this `Collator`.

public boolean equals(String source, Source target)

Parameters

`source`

The source string.

`target`

The target string.

Returns

`true` if the given strings are equal; `false` otherwise.

Description

This method compares the given strings for equality using the collation rules for this `Collator`. Note that this method applies locale-specific rules and is thus not the same as `String.equals()`.

getCollationKey

public abstract CollationKey getCollationKey(String source)

Parameters

`source`

The string to use when generating the `CollationKey`.

Returns

A `CollationKey` for the given string.

Description

This method generates a `CollationKey` for the given string. The returned object can be compared with other `CollationKey` objects using `CollationKey.compareTo()`. This comparison is faster than using `Collator.compare()`, so if the same string is used for many comparisons, you should use `CollationKey` objects.

getDecomposition

public synchronized int getDecomposition()

Returns

The decomposition mode for this `Collator`.

Description

This method returns the current decomposition mode for this `Collator`. The decomposition mode specifies how composed Unicode characters are handled during collation. You can adjust the decomposition mode to choose between faster and more complete collation. The returned value is one of the following values: `NO_DECOMPOSITION`, `CANONICAL_DECOMPOSITION`, or `FULL_DECOMPOSITION`.

getStrength

public synchronized int getStrength()

Returns

The strength setting for this `Collator`.

Description

This method returns the current strength setting for this `Collator`. The strength specifies the minimum level of difference that is considered significant during collation. The returned value is one of the following values: `PRIMARY`, `SECONDARY`, `TERTIARY`, or `IDENTICAL`.

hashCode

public abstract synchronized int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `Collator`.

setDecomposition

public synchronized void setDecomposition(int decompositionMode)

Parameters

`decompositionMode`

The decomposition mode: `NO_DECOMPOSITION`, `CANONICAL_DECOMPOSITION`, or `FULL_DECOMPOSITION`.

Description

This method sets the decomposition mode for this `Collator`. The decomposition mode specifies how composed Unicode characters are handled during collation. You can adjust the decomposition mode to choose between faster and more complete collation.

setStrength

public synchronized void setStrength(int newStrength)

Parameters

`newStrength`

The new strength setting: `PRIMARY`, `SECONDARY`, `TERTIARY`, or `IDENTICAL`.

Description

This method sets the strength of this `Collator`. The strength specifies the minimum level of difference that is considered significant during collation.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

DateFormat

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

DateFormat

Name

DateFormat

Synopsis

Class Name:

`java.text.DateFormat`

Superclass:

`java.text.Format`

Immediate Subclasses:

`java.text.SimpleDateFormat`

Interfaces Implemented:

`java.lang.Cloneable`

Availability:

New as of JDK 1.1

Description

The `DateFormat` class formats and parses dates and times in a locale-specific manner. `DateFormat` is an `abstract` class, but it provides factory methods that return useful instances of `DateFormat` subclasses. These factory methods come in three groups:

- The `getDateInstance()` methods return objects that format and parse only dates.

- The `getDateTimeInstance()` methods return objects that format and parse date and time combinations.
- The `getTimeInstance()` methods return objects that format only times.

Certain of these factory methods allow you to specify the style, or length, of the resulting date and time strings. The interpretation of the style parameter is locale-specific. For the locale `Locale.US`, the styles and their results are as follows:

`FULL`

```
Tuesday, March 04, 1997 12:00:00 o'clock AM EST
```

`LONG`

```
March 04, 1997 12:00:00 AM EST
```

`MEDIUM`

```
04-Mar-97 12:00:00 AM
```

`SHORT`

```
3/4/97 12:00 AM
```

There is also a `DEFAULT` style, which is equivalent to `MEDIUM`.

The `DateFormat` class defines a number of field constants that represent the various fields in formatted date and time strings. These field constants can create `FieldPosition` objects.

Class Summary

```
public abstract class java.text.DateFormat extends java.text.Format
                      implements java.lang.Cloneable {
  // Constants
  public static final int AM_PM_FIELD;
  public static final int DATE_FIELD;
  public static final int DAY_OF_WEEK_FIELD;
  public static final int DAY_OF_WEEK_IN_MONTH_FIELD;
  public static final int DAY_OF_YEAR_FIELD;
  public static final int DEFAULT;
  public static final int ERA_FIELD;
  public static final int FULL;
  public static final int HOUR0_FIELD;
  public static final int HOUR1_FIELD;
  public static final int HOUR_OF_DAY0_FIELD;
  public static final int HOUR_OF_DAY1_FIELD;
  public static final int LONG;
  public static final int MEDIUM;
  public static final int MILLISECOND_FIELD;
  public static final int MINUTE_FIELD;
  public static final int MONTH_FIELD;
  public static final int SECOND_FIELD;
  public static final int SHORT;
  public static final int TIMEZONE_FIELD;
  public static final int WEEK_OF_MONTH_FIELD;
  public static final int WEEK_OF_YEAR_FIELD;
  public static final int YEAR_FIELD;
  // Variables
  protected Calendar calendar;
  protected NumberFormat numberFormat;
  // Constructors
  protected DateFormat();
  // Class Methods
  public static Locale[] getAvailableLocales();
  public static final DateFormat getDateInstance();
  public static final DateFormat getDateInstance(int style);
  public static final DateFormat getDateInstance(int style, Locale aLocale);
  public static final DateFormat getDateTimeInstance();
  public static final DateFormat getDateTimeInstance(int dateStyle,
                                 int timeStyle);
  public static final DateFormat getDateTimeInstance(int dateStyle,
                                 int timeStyle, Locale aLocale);
  public static final DateFormat getInstance();
  public static final DateFormat getTimeInstance();
  public static final DateFormat getTimeInstance(int style);
  public static final DateFormat getTimeInstance(int style, Locale aLocale);
  // Instance Methods
  public Object clone();
  public boolean equals(Object obj);
  public final String format(Date date);
  public final StringBuffer format(Object obj, StringBuffer toAppendTo,
                          FieldPosition fieldPosition);
  public abstract StringBuffer format(Date date, StringBuffer toAppendTo,
                             FieldPosition fieldPosition);
  public Calendar getCalendar();
  public NumberFormat getNumberFormat();
  public TimeZone getTimeZone();

  public abstract Date parse(String text, ParsePosition pos);
  public Object parseObject(String source, ParsePosition pos);
  public void setCalendar(Calendar newCalendar);
  public void setLenient(boolean lenient);
  public void setNumberFormat(NumberFormat newNumberFormat);
  public void setTimeZone(TimeZone zone);
}
```

Constants

AM_PM_FIELD

public final static int AM_PM_FIELD

Description

A field constant that represents the A.M./P.M. field.

DATE_FIELD

public final static int DATE_FIELD

Description

A field constant that represents the date (day of month) field.

DAY_OF_WEEK_FIELD

public final static int DAY_OF_WEEK_FIELD

Description

A field constant that represents the day-of-the-week field.

DAY_OF_WEEK_IN_MONTH_FIELD

public final static int DAY_OF_WEEK_IN_MONTH_FIELD

Description

A field constant that represents the day of the week in the current month field.

DAY_OF_YEAR_FIELD

public final static int DAY_OF_YEAR_FIELD

Description

A field constant that represents the day-of-the-year field.

DEFAULT

public final static int DEFAULT

Description

A constant that specifies the default style.

ERA_FIELD

public final static int ERA_FIELD

Description

A field constant that represents the era field.

FULL

public final static int FULL

Description

A constant that specifies the most complete style.

HOUR0_FIELD

public final static int HOUR0_FIELD

Description

A field constant that represents the zero-based hour field.

HOUR1_FIELD

public final static int HOUR1_FIELD

Description

A field constant that represents the one-based hour field.

HOUR_OF_DAY0_FIELD

public final static int HOUR_OF_DAY0_FIELD

Description

A field constant that represents the zero-based hour of the day field.

HOUR_OF_DAY1_FIELD

public final static int HOUR_OF_DAY1_FIELD

Description

A field constant that represents the one-based hour of the day field.

LONG

public final static int LONG

Description

A constant that specifies the long style.

MEDIUM

public final static int MEDIUM

Description

A constant that specifies the medium style.

MILLISECOND_FIELD

public final static int MILLISECOND_FIELD

Description

A field constant that represents the millisecond field.

MINUTE_FIELD

public final static int MINUTE_FIELD

Description

A field constant that represents the minute field.

MONTH_FIELD

public final static int MONTH_FIELD

Description

A field constant that represents the month field.

SECOND_FIELD

public final static int SECOND_FIELD

Description

A field constant that represents the second field.

SHORT

public final static int SHORT

Description

A constant that specifies the short style.

TIMEZONE_FIELD

public final static int TIMEZONE_FIELD

Description

A field constant that represents the time-zone field.

WEEK_OF_MONTH_FIELD

public final static int WEEK_OF_MONTH_FIELD

Description

A field constant that represents the week-of-the-month field.

WEEK_OF_YEAR_FIELD

public final static int WEEK_OF_YEAR_FIELD

Description

A field constant that represents the week-of-the-year field.

YEAR_FIELD

public final static int YEAR_FIELD

Description

A field constant that represents the year field.

Variables

calendar

protected Calendar calendar

Description

> A `Calendar` object that internally generates the field values for formatting dates and times.

numberFormat

protected NumberFormat numberFormat

Description

> A `NumberFormat` object that internally formats the numbers in dates and times.

Constructors

DateFormat

protected DateFormat()

Description

> This constructor creates a `DateFormat`.

Class Methods

getAvailableLocales

public static Locale[] getAvailableLocales()

Returns

> An array of `Locale` objects.

Description

> This method returns an array of the `Locale` objects for which this class can create `DateFormat` objects.

getDateInstance

public static final DateFormat getDateInstance()

Returns

> A `DateFormat` appropriate for the default `Locale` that uses the default style.

Description

This method creates a `DateFormat` that formats and parses dates in the default locale with the default style.

public static final DateFormat getDateInstance(int style)

Parameters

`style`

A style constant.

Returns

A `DateFormat` appropriate for the default `Locale` that uses the given style.

Description

This method creates a `DateFormat` that formats and parses dates in the default locale with the given style.

`public static final DateFormat getDateInstance(int style, Locale aLocale)`

Parameters

`style`

A style constant.

`aLocale`

The `Locale` to use.

Returns

A `DateFormat` appropriate for the given `Locale` that uses the given style.

Description

This method creates a `DateFormat` that formats and parses dates in the given locale with the given style.

getDateTimeInstance

public static final DateFormat getDateTimeInstance()

Returns

A `DateFormat` appropriate for the default `Locale` that uses the default date and time styles.

Description

This method creates a `DateFormat` that formats and parses dates and times in the default locale with the default date and time styles.

`public static final DateFormat getDateTimeInstance(int dateStyle, int timeStyle)`

Parameters

`dateStyle`

A style constant.

`timeStyle`

A style constant.

Returns

A `DateFormat` appropriate for the default `Locale` that uses the given data and time styles.

Description

This method creates a `DateFormat` that formats and parses dates and times in the default locale with the given date and time styles.

`public static final DateFormat getDateTimeInstance(int dateStyle, int timeStyle, Locale aLocale)`

Parameters

`dateStyle`

A style constant.

`timeStyle`

A style constant.

`aLocale`

The `Locale` to use.

Returns

A `DateFormat` appropriate for the given `Locale` that uses the given date and time styles.

Description

This method creates a `DateFormat` that formats and parses dates and times in the given locale with the given date and time styles.

getInstance

public static final DateFormat getInstance()

Returns

A `DateFormat` appropriate for the default `Locale`.

Description

This method creates a general purpose `DateFormat` by calling `getDateTimeInstance(DateFormat.SHORT, DateFormat.SHORT)`.

getTimeInstance

public static final DateFormat getTimeInstance()

Returns

A `DateFormat` appropriate for the default `Locale` that uses the default style.

Description

This method creates a `DateFormat` that formats and parses times in the default locale with the default style.

public static final DateFormat getTimeInstance(int style)

Parameters

`style`

A style constant.

Returns

A `DateFormat` appropriate for the default `Locale` that uses the given style.

Description

This method creates a `DateFormat` that formats and parses times in the default locale with the given style.

`public static final DateFormat getTimeInstance(int style, Locale aLocale)`

Parameters

`style`

A style constant.

`aLocale`

The `Locale` to use.

Returns

A `DateFormat` appropriate for the given `Locale` that uses the given style.

Description

This method creates a `DateFormat` that formats and parses times in the given locale with the given style.

Instance Methods

clone

public Object clone()

Returns

A copy of this `DateFormat`.

Overrides

`Format.clone()`

Description

This method creates a copy of this `DateFormat` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `DateFormat` and is equivalent to this `DateFormat`.

format

public final String format(Date date)

Parameters

`date`

The `Date` object to be formatted.

Returns

A string that contains a formatted representation of the date.

Description

This method formats the given date and returns the result as a string.

public final StringBuffer format(Object obj, StringBuffer toAppendTo, FieldPosition fieldPosition)

Parameters

`obj`

The object to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`fieldPosition`

A date or time field.

Returns

The given buffer `toAppendTo` with the formatted representation of the object appended to it.

Overrides

`Format.format(Object, StringBuffer, FieldPosition)`

Description

This method formats the given object and appends the result to the given `StringBuffer`. If `fieldPosition` refers to one of the time or date fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

`public abstract StringBuffer format(Date date, StringBuffer toAppendTo, FieldPosition fieldPosition)`

Parameters

`date`

The `Date` object to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`fieldPosition`

A date or time field.

Returns

The given buffer `toAppendTo` with the formatted representation of the date appended to it.

Description

This method formats the given date and appends the result to the given `StringBuffer`. If `fieldPosition` refers to one of the time or date fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

getCalendar

public Calendar getCalendar()

Returns

The internal `Calendar` object of this `DateFormat`.

Description

This method returns the `Calendar` object that this `DateFormat` uses internally.

getNumberFormat

public NumberFormat getNumberFormat()

Returns

> The internal `NumberFormat` object of this `DateFormat`.

Description

> This method returns the `NumberFormat` object that this `DateFormat` uses internally.

getTimeZone

public TimeZone getTimeZone()

Returns

> The internal `TimeZone` object of this `DateFormat`.

Description

> This method returns the `TimeZone` object that this `DateFormat` uses internally.

hashCode

public int hashCode()

Returns

> A hashcode for this object.

Overrides

> `Object.hashCode()`

Description

> This method returns a hashcode for this `DateFormat`.

isLenient

public boolean isLenient()

Returns

> A `boolean` value that indicates the leniency of this `DateFormat`.

Description

This method returns the current leniency of this `DateFormat`. A value of `false` indicates that the `DateFormat` throws exceptions when it tries to parse questionable data, while a value of `true` indicates that the `DateFormat` makes its best guess to interpret questionable data. For example, if the `DateFormat` is being lenient, a date such as March 135, 1997 is interpreted as the 135th day after March 1, 1997.

parse

public Date parse(String text) throws ParseException

Parameters

`text`

The string to be parsed.

Returns

The `Date` object represented by the given string.

Throws

`ParseException`

If the text cannot be parsed as a date.

Description

This method parses a date from the given string, starting from the beginning of the string.

public abstract Date parse(String text, ParsePosition pos)

Parameters

`text`

The string to be parsed.

`pos`

A `ParsePosition` object that can specify a position in the string.

Returns

The `Date` object represented by the text starting at the given position.

Description

This method parses a date from the given string, starting from the given position. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

parseObject

public Object parseObject(String source, ParsePosition pos)

Parameters

`source`

The string to be parsed.

`pos`

A `ParsePosition` object that can specify a position in the string.

Returns

The object represented by the text starting at the given position.

Overrides

`Format.parseObject(String, ParsePosition)`

Description

This method parses a date from the given string, starting from the given position. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

setCalendar

public void setCalendar(Calendar newCalendar)

Parameters

`newCalendar`

The new `Calendar` to use.

Description

This method sets the `Calendar` that this `DateFormat` uses internally.

setLenient

public void setLenient(boolean lenient)

Parameters

`lenient`

A `boolean` value that specifies the leniency of this `DateFormat`.

Description

This method sets the leniency of this `DateFormat`. A value of `false` specifies that the `DateFormat` throws exceptions when it tries to parse questionable data, while a value of `true` indicates that the `DateFormat` makes its best guess to interpret questionable data. For example, if the `Calendar` is being lenient, a date such as March 135, 1997 is interpreted as the 135th day after March 1, 1997.

setNumberFormat

public void setNumberFormat(NumberFormat newNumberFormat)

Parameters

`newNumberFormat`

The new `NumberFormat` to use.

Description

This method sets the `NumberFormat` that this `DateFormat` uses internally.

setTimeZone

public void setTimeZone(TimeZone zone)

Parameters

`zone`

The new `TimeZone` to use.

Description

This method sets the `TimeZone` that this `DateFormat` uses internally.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`format(Object)`	`Format`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`parseObject(String)`	`Format`
`toString()`	`Object`	`wait()`	`Object`

`wait(long)`	`Object`	`wait(long, int)`	`Object`

DateFormatSymbols

Name

DateFormatSymbols

Synopsis

Class Name:

`java.text.DateFormatSymbols`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The `DateFormatSymbols` class encapsulates date and time formatting data that is locale-specific, like the names of the days of the week and the names of the months. Typically, you do not need to instantiate `DateFormatSymbols` yourself. Instead, an instance is automatically created for you, behind the scenes, when you use one of the factory methods in `DateFormat` to create a `DateFormat` object. You can retrieve a `DateFormatSymbols` object by calling the `getDateFormatSymbols()` method of `SimpleDateFormat`. Once you have a `DateFormatSymbols` object, you can modify the strings it uses if you want to change them.

Class Summary

```
public class java.text.DateFormatSymbols extends java.lang.Object
             implements java.io.Serializable, java.lang.Cloneable {
  // Constructors
  public DateFormatSymbols();
  public DateFormatSymbols(Locale locale);
  // Instance Methods
  public Object clone();
  public boolean equals(Object obj);
  public String[] getAmPmStrings();
  public String[] getEras();
  public String getLocalPatternChars();
  public String[] getMonths();
  public String[] getShortMonths();
  public String[] getShortWeekdays();
  public String[] getWeekdays();
  public String[][] getZoneStrings();
  public int hashCode();
  public void setAmPmStrings(String[] newAmpms);
  public void setEras(String[] newEras);
  public void setLocalPatternChars(String newLocalPatternChars);
  public void setMonths(String[] newMonths);
  public void setShortMonths(String[] newShortMonths);
  public void setShortWeekdays(String[] newShortWeekdays);
  public void setWeekdays(String[] newWeekdays);
  public void setZoneStrings(String[][] newZoneStrings);
}
```

Constructors

DateFormatSymbols

public DateFormatSymbols()

Throws

`MissingResourceException`

If the resources for the default locale cannot be found or loaded.

Description

This constructor creates a `DateFormatSymbols` object for the default locale.

public DateFormatSymbols(Locale locale)

Parameters

`locale`

The `Locale` to use.

Throws

`MissingResourceException`

If the resources for the given locale cannot be found or loaded.

Description

This constructor creates a `DateFormatSymbols` object for the given locale.

Instance Methods

clone

public Object clone()

Returns

A copy of this `DateFormatSymbols`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `DateFormatSymbols` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `DecimalFormatSymbols` and is equivalent to this `DateFormatSymbols`.

getAmPmStrings

public String[] getAmPmStrings()

Returns

An array of strings used for the A.M./P.M. field for this `DateFormatSymbols`.

Description

This method returns the strings that are used for the A.M./P.M. field (e.g., "AM", "PM").

getEras

public String[] getEras()

Returns

An array of strings used for the era field for this `DateFormatSymbols`.

Description

This method returns the strings that are used for the era field (e.g., "BC", "AD").

getLocalPatternChars

public String getLocalPatternChars()

Returns

A string that contains the data-time pattern characters for this `DateFormatSymbols`.

Description

This method returns the data-time pattern characters for the locale of this object.

getMonths

public String[] getMonths()

Returns

An array of strings used for the month field for this `DateFormatSymbols`.

Description

This method returns the strings that are used for the month field (e.g., "January", "February").

getShortMonths

public String[] getShortMonths()

Returns

An array of strings used for the short month field for this `DateFormatSymbols`.

Description

This method returns the strings that are used for the short (i.e., three-character) month field (e.g., "Jan", "Feb").

getShortWeekdays

public String[] getShortWeekdays()

Returns

An array ofstrings used for the short weekday field for this `DateFormatSymbols`.

Description

This method returns the strings that are used for the short (i.e., three-character) weekday field (e.g., "Mon", "Tue").

getWeekdays

public String[] getWeekdays()

Returns

An array ofstrings used for the weekday field for this `DateFormatSymbols`.

Description

This method returns the strings that are used for the weekday field (e.g., "Monday", "Tuesday").

getZoneStrings

public String[][] getZoneStrings()

Returns

> An array of arrays of strings used for the time zones for this `DateFormatSymbols`.

Description

> This method returns the time-zone strings. Each subarray is an array of six strings that specify a time-zone ID, its long name, its short name, its daylight-savings-time name, its short daylight-savings-time name, and a major city in the time zone. For example, an entry for Mountain Standard Time is:

```
{"MST", "Mountain Standard Time", "MST",
 "Mountain Daylight Time", "MDT", "Denver"}
```

hashCode

public int hashCode()

Returns

> A hashcode for this object.

Overrides

> `Object.hashCode()`

Description

> This method returns a hashcode for this `DateFormatSymbols` object.

setAmPmStrings

public void setAmPmStrings(String[] newAmpms)

Parameters

`newAmpms`

The new strings.

Description

This method sets the strings that are used for the A.M./P.M. field for this `DateFormatSymbols`.

setEras

public void setEras(String[] newEras)

Parameters

`newEras`

The new strings.

Description

This method sets the strings that are used for the era field for this `DateFormatSymbols`.

setLocalPatternChars

public void setLocalPatternChars(String newLocalPatternChars)

Parameters

`newLocalPatternChars`

The new date-time pattern characters.

Description

This method sets the date-time pattern characters of this `DateFormatSymbols` object.

setMonths

public void setMonths(String[] newMonths)

Parameters

`newMonths`

The new strings.

Description

This method sets the strings that are used for the month field for this `DateFormatSymbols`.

setShortMonths

public void setShortMonths(String[] newShortMonths)

Parameters

`newShortMonths`

The new strings.

Description

This method sets the strings that are used for the short (i.e., three-character) month field for this `DateFormatSymbols`.

setShortWeekdays

public void setShortWeekdays(String[] newShortWeekdays)

Parameters

`newShortWeekdays`

The new strings.

Description

This method sets the strings that are used for the short (i.e., three-character) weekday field for this `DateFormatSymbols`.

setWeekdays

public void setWeekdays(String[] newWeekdays)

Parameters

`newWeekdays`

The new strings.

Description

This method sets the strings that are used for the weekday field for this `DateFormatSymbols`.

setZones

public void setZones(String[][] newZoneStrings)

Parameters

`newZoneStrings`

The new strings.

Description

This method sets the strings that are used for the time-zone field for this `DateFormatSymbols`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

`Calendar`, `DateFormat`, `Locale`, `SimpleDateFormat`, `TimeZone`

DecimalFormat

Name

DecimalFormat

Synopsis

Class Name:

> `java.text.DecimalFormat`

Superclass:

> `java.text.NumberFormat`

Immediate Subclasses:

> None

Interfaces Implemented:

> None

Availability:

> New as of JDK 1.1

Description

The `DecimalFormat` class is a concrete subclass of `NumberFormat` that formats and parses numbers using a formatting pattern. Typically, you do not need to instantiate `DecimalFormat` yourself. Instead, the factory methods of `NumberFormat` return instances of `DecimalFormat` that are appropriate for particular locales.

However, if you need a specialized number format, you can instantiate your own `DecimalFormat` using a pattern string. You can also modify the formatting pattern of an existing `DecimalFormat` object using the `applyPattern()` method.

A pattern string has the following form:

```
positive-pattern[;negative-pattern]
```

If the negative pattern is omitted, negative numbers are formatted using the positive pattern with a `-` character prepended to the result. Each pattern has the following form:

```
[prefix]integer[.fraction][suffix]
```

The following symbols are significant in the pattern string.

Symbol	Description
`0`	A digit
`#`	A digit where 0 is not shown
`.`	A placeholder for a decimal separator
`,`	A placeholder for a grouping separator
`;`	The format separator
`-`	The default negative prefix
`%`	Divides value by 100 and shows as a percentage

Any characters other than these special characters can appear in the prefix or the suffix. A single quote can be used to escape a special character, if you need to use one of these symbols in a prefix or a suffix.

For example, the pattern string for U.S. currency values is:

```
$#,##0.00;($#,##0.00)
```

This indicates that a `$` character is prepended to all formatted values. The grouping separator character `,` is inserted every three digits. Exactly two digits after the decimal place are always shown. Negative values are shown in parentheses. Thus, the value `-1234.56` produces output like:

```
($1,234.56)
```

Internally, the `DecimalFormat` class uses a `DecimalFormatSymbols` object to get the numerical strings that are appropriate for a particular locale. If you want to modify these strings, you can get the `DecimalFormatSymbols` object by calling `getDecimalFormatSymbols()`.

Class Summary

```
public class java.text.DecimalFormat extends java.text.NumberFormat {
  // Constructors
  public DecimalFormat();
  public DecimalFormat(String pattern);
  public DecimalFormat(String pattern, DecimalFormatSymbols symbols);
  // Instance Methods
  public void applyLocalizedPattern(String pattern);
  public void applyPattern(String pattern);
  public Object clone();
  public boolean equals(Object obj);
  public StringBuffer format(double number, StringBuffer result,
                      FieldPosition fieldPosition);
  public StringBuffer format(long number, StringBuffer result,
                      FieldPosition fieldPosition);
  public DecimalFormatSymbols getDecimalFormatSymbols();
  public int getGroupingSize();
  public int getMultiplier();
  public String getNegativePrefix();
  public String getNegativeSuffix();
  public String getPositivePrefix();
  public String getPositiveSuffix();
  public int hashCode();
  public boolean isDecimalSeparatorAlwaysShown();
  public Number parse(String text, ParsePosition status);
  public void setDecimalFormatSymbols(DecimalFormatSymbols newSymbols);
  public void setDecimalSeparatorAlwaysShown(boolean newValue);
  public void setGroupingSize(int newValue);
  public void setMultiplier(int newValue);
  public void setNegativePrefix(String newValue);
  public void setNegativeSuffix(String newValue);
  public void setPositivePrefix(String newValue);
  public void setPositiveSuffix(String newValue);
  public String toLocalizedPattern();
  public String toPattern();
}
```

Constructors

DecimalFormat

public DecimalFormat()

Description

> This constructor creates a `DecimalFormat` that uses the default formatting pattern and `DecimalFormatSymbols` that are appropriate for the default locale.

public DecimalFormat(String pattern)

Parameters

> `pattern`
>
> > The pattern string.

Description

This constructor creates a `DecimalFormat` that uses the given formatting pattern and a `DecimalFormatSymbols` that is appropriate for the default locale.

public DecimalFormat(String pattern, DecimalFormatSymbols symbols)

Parameters

`pattern`

The pattern string.

`symbols`

The `DecimalFormatSymbols` to use.

Description

This constructor creates a `DecimalFormat` that uses the given formatting pattern and `DecimalFormatSymbols` object.

Instance Methods

applyLocalizedPattern

public void applyLocalizedPattern(String pattern)

Parameters

`pattern`

The pattern string.

Description

This method tells this `DecimalFormat` to use the given formatting pattern to format and parse numbers. The pattern string is assumed to have been localized to the `DecimalFormatSymbols` object this `DecimalFormat` uses.

applyPattern

public void applyPattern(String pattern)

Parameters

`pattern`

The pattern string.

Description

This method tells this `DecimalFormat` to use the given formatting pattern to format and parse numbers. The pattern string is localized to the `DecimalFormatSymbols` object this `DecimalFormat` uses.

clone

public Object clone()

Returns

A copy of this `DecimalFormat`.

Overrides

`NumberFormat.clone()`

Description

This method creates a copy of this `DecimalFormat` and then returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`NumberFormat.equals()`

Description

This method returns `true` if `obj` is an instance of `DecimalFormat` and is equivalent to this `DecimalFormat`.

format

`public StringBuffer format(double number, StringBuffer result, FieldPosition fieldPosition)`

Parameters

`number`

The `double` value to be formatted.

`result`

A `StringBuffer` on which to append the formatted information.

`fieldPosition`

A number field.

Returns

The given buffer `result` with the formatted representation of the number appended to it.

Overrides

`NumberFormat.format(double, StringBuffer, FieldPosition)`

Description

This method formats the given number and appends the result to the given `StringBuffer`. If `fieldPosition` refers to one of the number fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

`public StringBuffer format(long number, StringBuffer result, FieldPosition fieldPosition)`

Parameters

`number`

The `long` value to be formatted.

`result`

A `StringBuffer` on which to append the formatted information.

`fieldPosition`

A number field.

Returns

The given buffer `result` with the formatted representation of the number appended to it.

Overrides

`NumberFormat.format(double, StringBuffer, FieldPosition)`

Description

This method formats the given number and appends the result to the given `StringBuffer`. If `fieldPosition` refers to one of the number fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

getDecimalFormatSymbols

public DecimalFormatSymbols getDecimalFormatSymbols()

Returns

The `DecimalFormatSymbols` object used by this `DecimalFormat`.

Description

This method returns the `DecimalFormatSymbols` object that this `DecimalFormat` uses internally.

getGroupingSize

public int getGroupingSize()

Returns

The grouping size of this `DecimalFormat`.

Description

This method returns the grouping size of this `DecimalFormat`. The grouping size is the number of digits between grouping separators in the integer portion of a number. For example, in the number `1,234.56`, the grouping size is `3` (and the grouping symbol is ",").

getMultiplier

public int getMultiplier()

Returns

The multiplier of this `DecimalFormat`.

Description

This method returns the multiplier of this `DecimalFormat`. The multiplier is used to adjust a number before it is formatted or after it is parsed. For example, a percent format has a multiplier of 100 and a suffix of `` `%' ``. Thus, a value of `.42` could be formatted as `42%`.

getNegativePrefix

public String getNegativePrefix()

Returns

The string that is prepended to negative values.

Description

This method returns the prefix string for negative numbers.

getNegativeSuffix

public String getNegativeSuffix()

Returns

The string that is appended to negative values.

Description

This method returns the suffix string for negative numbers.

getPositivePrefix

public String getPositivePrefix()

Returns

The string that is prepended to positive values.

Description

This method returns the prefix string for positive numbers.

getPositiveSuffix

public String getPositiveSuffix()

Returns

The string that is appended to positive values.

Description

This method returns the suffix string for positive numbers.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`NumberFormat.hashCode()`

Description

This method returns a hashcode for this `DecimalFormat`.

isDecimalSeparatorAlwaysShown

public boolean isDecimalSeparatorAlwaysShown()

Returns

A `boolean` value that indicates whether or not the decimal separator symbol is always shown.

Description

This method returns `true` if this `DecimalFormat` always shows the decimal separator. The method returns `false` if the decimal separator is only shown if there is a fractional portion of the number being formatted.

parse

public Number parse(String text, ParsePosition status)

Parameters

`text`

The string to be parsed.

`status`

A `ParsePosition` object that specifies a position in the string.

Returns

The `Number` object represented by the text starting at the given position.

Overrides

`NumberFormat.parse(String, ParsePosition)`

Description

This method parses a number from the given string, starting from the given position. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

setDecimalFormatSymbols

`public void setDecimalFormatSymbols( DecimalFormatSymbols newSymbols)`

Parameters

`newSymbols`

The new `DecimalFormatSymbols` object to use.

Description

This method sets the `DecimalFormatSymbols` object that this `DecimalFormat` uses internally.

setDecimalSeparatorAlwaysShown

public void setDecimalSeparatorAlwaysShown(boolean newValue)

Parameters

`newValue`

The new decimal separator value.

Description

This method specifies whether or not the decimal separator symbol is always shown in formatted numbers. If `newValue` is `false`, the separator is only shown for numbers that have a fractional part. Otherwise, the separator is always shown.

setGroupingSize

public void setGroupingSize(int newValue)

Parameters

`newValue`

The new grouping size.

Description

This method sets the grouping size of this `DecimalFormat`. The grouping size is the number of digits between grouping separators in the integer portion of a number. For example, in the number `1,234.56`, the grouping size is `3` (and the grouping symbol is ",").

setMultiplier

public void setMultiplier(int newValue)

Parameters

`newValue`

The new multiplier.

Description

This method sets the multiplier of this `DecimalFormat`. The multiplier is used to adjust a number before it is formatted or after it is parsed. For example, a percent format has a multiplier of 100 and a suffix of `%`. Thus, a value of `.42` could be formatted as `42%`.

setNegativePrefix

public void setNegativePrefix(String newValue)

Parameters

`newValue`

The new prefix.

Description

This method sets the prefix string for negative values.

setNegativeSuffix

public void setNegativeSuffix(String newValue)

Parameters

`newValue`

The new suffix.

Description

This method sets the suffix string for negative values.

setPositivePrefix

public void setPositivePrefix(String newValue)

Parameters

`newValue`

The new prefix.

Description

This method sets the prefix string for positive values.

setPositiveSuffix

public void setPositiveSuffix(String newValue)

Parameters

`newValue`

The new suffix.

Description

This method sets the suffix string for positive values.

toLocalizedPattern

public String toLocalizedPattern()

Returns

The pattern string of this `DecimalFormat`.

Description

This method returns the pattern string of this `DecimalFormat`, localized with the `DecimalFormatSymbols` object of this `DecimalFormat`.

toPattern

public String toPattern()

Returns

The pattern string of this `DecimalFormat`.

Description

This method returns the pattern string of this `DecimalFormat`.

DecimalFormatSymbols

Name

DecimalFormatSymbols

Synopsis

Class Name:

`java.text.DecimalFormatSymbols`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The `DecimalFormatSymbols` class encapsulates number-formatting data that is locale-specific, like grouping separators and decimal separators. Typically, you do not need to instantiate `DecimalFormatSymbols` yourself. Instead, an instance is automatically created for you, behind the scenes, when you use one of the factory methods in `NumberFormat` to create a `DecimalFormat` object. You can retrieve a `DecimalFormatSymbols` object by calling the `getDecimalFormatSymbols()` method of `DecimalFormat`. Once you have a `DecimalFormatSymbols` object, you can modify the strings it uses if you want to change them.

Class Summary

```
public final class java.text.DecimalFormatSymbols extends java.lang.Object
                   implements java.io.Serializable, java.lang.Cloneable {
  // Constructors
  public DecimalFormatSymbols();
  public DecimalFormatSymbols(Locale locale);
  // Instance Methods
  public Object clone();
  public boolean equals(Object obj);
  public char getDecimalSeparator();
  public char getDigit();
  public char getGroupingSeparator();
  public String getInfinity();
  public char getMinusSign();
  public String getNaN();
  public char getPatternSeparator();
  public char getPerMill();
  public char getPercent();
  public char getZeroDigit();
  public int hashCode();
  public void setDecimalSeparator(char decimalSeparator);
  public void setDigit(char digit);
  public void setGroupingSeparator(char groupingSeparator);
  public void setInfinity(String infinity);
  public void setMinusSign(char minusSign);
  public void setNaN(String NaN);
  public void setPatternSeparator(char patternSeparator);
  public void setPerMill(char perMill);
  public void setPercent(char percent);
  public void setZeroDigit(char zeroDigit);
}
```

Constructors

DecimalFormatSymbols

public DecimalFormatSymbols()

Description

This constructor creates a `DecimalFormatSymbols` object for the default locale.

public DecimalFormatSymbols(Locale locale)

Parameters

`locale`

The `Locale` to use.

Description

This constructor creates a `DecimalFormatSymbols` object for the given locale.

Instance Methods

clone

public Object clone()

Returns

A copy of this `DecimalFormatSymbols`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `DecimalFormatSymbols` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `DateFormatSymbols` and is equivalent to this `DecimalFormatSymbols`.

getDecimalSeparator

public char getDecimalSeparator()

Returns

The character used to separate the integer and fractional parts of a number for this `DecimalFormatSymbols`.

Description

This method returns the decimal separator character (e.g., ".", ",").

getDigit

public char getDigit()

Returns

The character used to represent a digit in a pattern string for this `DecimalFormatSymbols`.

Description

This method returns the digit pattern character, which represents a digit that is not shown if it is zero.

getGroupingSeparator

public char getGroupingSeparator()

Returns

The character used to separate long numbers for this `DecimalFormatSymbols`.

Description

This method returns the grouping separator character (e.g., ",", ".").

getInfinity

public String getInfinity()

Returns

The string used to represent infinity for this `DecimalFormatSymbols`.

Description

This method returns the string that represents infinity.

getMinusSign

public char getMinusSign()

Returns

The character used to signify negative numbers for this `DecimalFormatSymbols`.

Description

This method returns the character that signifies negative numbers.

getNaN

public String getNaN()

Returns

The string used to represent the value not-a-number for this `DecimalFormatSymbols`.

Description

This method returns the string that represents not-a-number.

getPatternSeparator

public char getPatternSeparator()

Returns

The pattern separator character for this `DecimalFormatSymbols`.

Description

This method returns the character used in pattern strings to separate the positive subpattern and negative subpattern.

getPerMill

public char getPerMill()

Returns

The character used to represent the per mille sign for this `DecimalFormatSymbols`.

Description

This method returns the character that represents a per mille value.

getPercent

public char getPercent()

Returns

The character used to represent the percent sign for this `DecimalFormatSymbols`.

Description

This method returns the character that represents a percent value (e.g., %).

getZeroDigit

public char getZeroDigit()

Returns

The character used to represent a digit in a pattern string for this `DecimalFormatSymbols`.

Description

This method returns the zero-digit pattern character, which represents a digit that is shown even if it is zero.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `DecimalFormatSymbols` object.

setDecimalSeparator

public void setDecimalSeparator(char decimalSeparator)

Parameters

`decimalSeparator`

The new decimal separator.

Description

This method sets the decimal separator character for this `DecimalFormatSymbols`.

setDigit

public void setDigit(char digit)

Parameters

`digit`

The new digit pattern character.

Description

This method sets the digit pattern character, which represents a digit that is not shown if it is zero, for this `DecimalFormatSymbols`.

setGroupingSeparator

public void setGroupingSeparator(char groupingSeparator)

Parameters

`groupingSeparator`

The new grouping separator.

Description

This method sets the grouping separator character for this `DecimalFormatSymbols`.

setInfinity

public Void setInfinity(String infinity)

Parameters

`infinity`

The new infinity string.

Description

This method sets the string that represents infinity for this `DecimalFormatSymbols`.

setMinusSign

public void setMinusSign(char minusSign)

Parameters

`minusSign`

The new minus sign.

Description

This method sets the character that signifies negative numbers for this `DecimalFormatSymbols`.

setNaN

public Void setNaN(String NaN)

Parameters

`NaN`

The new non-a-number string.

Description

This method sets the string that represents not-a-number for this `DecimalFormatSymbols`.

setPatternSeparator

public void setPatternSeparator(char patternSeparator)

Parameters

`patternSeparator`

The new pattern separator.

Description

This method sets the character that is used in pattern strings to separate the positive subpattern and negative subpattern for this `DecimalFormatSymbols`.

setPerMill

public void setPerMill(char perMill)

Parameters

`perMill`

The new per mille sign.

Description

This method sets the character that represents the per mille sign for this `DecimalFormatSymbols`.

setPercent

public void setPercent(char percent)

Parameters

`percent`

The new percent sign.

Description

This method sets the character that represents the percent sign for this `DecimalFormatSymbols`.

setZeroDigit

public void setZeroDigit(char zeroDigit)

Parameters

`zeroDigit`

The new zero-digit pattern character.

Description

This method sets the zero-digit pattern character, which represents a digit that is shown even if it is zero, for this `DecimalFormatSymbols`.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Format

Name

Format

Synopsis

Class Name:

`java.text.Format`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.text.DateFormat`, `java.text.MessageFormat`,

`java.text.NumberFormat`

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The `Format` class is an `abstract` class that is the superclass of all classes that handle locale-sensitive parsing and formatting of dates, numbers, and messages. The two `format()` methods take the information in a supplied object and convert it to a string. The two `parseObject()` methods do the reverse; they take the information from a string and construct an appropriate object.

Class Summary

```
public abstract class java.text.Format extends java.lang.Object
                      implements java.io.Serializable, java.lang.Cloneable {
  // Instance Methods
  public Object clone();
  public final String format(Object obj);
  public abstract StringBuffer format(Object obj, StringBuffer toAppendTo,
                                       FieldPosition pos);
  public Object parseObject(String source);
  public abstract Object parseObject(String source, ParsePosition status);
}
```

Instance Methods

clone

public Object clone()

Returns

> A copy of this `Format`.

Overrides

> `Object.clone()`

Description

> This method creates a copy of this `Format` and returns it.

format

public final String format(Object obj)

Parameters

`obj`

The object to be formatted.

Returns

A string that contains a formatted representation of the object.

Throws

`IllegalArgumentException`

If the given object cannot be formatted.

Description

This method formats the given object by calling `format(Object, StringBuffer, FieldPosition)` with an empty `StringBuffer` and a `FieldPosition` that has a value of 0.

`public abstract StringBuffer format(Object obj, StringBuffer toAppendTo, FieldPosition pos)`

Parameters

`obj`

The object to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`pos`

A field.

Returns

The given buffer `toAppendTo` with the formatted representation of the object appended to it.

Throws

`IllegalArgumentException`

If the given object cannot be formatted.

Description

This method formats the given object and appends the result to the given `StringBuffer`. After the object has been formatted, the beginning and ending indices of the given `FieldPosition` are updated to reflect the field's position in the formatted output.

A subclass of `Format` must implement this method.

parseObject

public Object parseObject(String source) throws ParseException

Parameters

`source`

The string to be parsed.

Returns

The object represented by the given string.

Throws

`ParseException`

If the text cannot be parsed by this `Format`.

Description

This method parses the given text and returns an appropriate object. It does this by calling `parseObject(String, ParsePosition)` with a `ParsePosition` that has an index of 0.

`public abstract Object parseObject(String source, ParsePosition status)`

Parameters

`source`

The string to be parsed.

`status`

A `ParsePosition` object that specifies a position in the string.

Returns

The object represented by the text starting at the given position.

Description

This method parses the given text, starting at the specified position, and returns an object created from the data. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

A subclass of `Format` must implement this method.

Inherited Methods

Method	Inherited From	Method	Inherited From
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

MessageFormat

Name

MessageFormat

Synopsis

Class Name:

    java.text.MessageFormat

Superclass:

    java.text.Format

Immediate Subclasses:

    None

Interfaces Implemented:

    None

Availability:

    New as of JDK 1.1

Description

The `MessageFormat` class constructs textual messages using a formatting pattern string. Conceptually, the class functions much like `printf()` in C. Syntactically, however, it is quite different. A `MessageFormat` object uses a pattern string; formatted arguments are placed into the pattern string to produce a resulting string. Arguments are delimited by matching sets of curly braces and may include additional information about how that data should be formatted. For example, consider the following code:

```
String message =
  "Boot of server {0}began at {1, time}on {1, date, full}.";
MessageFormat boot = new MessageFormat(message);
Date now = new Date();
Object[] arguments = {"luna3", now};
System.out.println(boot.format(arguments));
```

This code produces the following output:

```
Boot of server luna3 began at 11:13:22 AM on Monday, March 03, 1997.
```

Each of the arguments is numbered and includes an optional type and an optional style. In the example above, `{1, date, full}` indicates that the argument at index `1` in the argument array should be formatted using a `DateFormat` object with the `FULL` style. The allowed types and styles are:

Type	Object	Styles
`choice`	`ChoiceFormat`	*pattern*
`date`	`DateFormat`	`short`, `medium`, `long`, `full`, *pattern*
`number`	`NumberFormat`	`integer`, `percent`, `currency`, *pattern*
`time`	`DateFormat`	`short`, `medium`, `long`, `full`, *pattern*

For the `date` and `time` types, the styles correspond to the styles, or lengths, of the resulting date and time strings. You can also specify a date or time pattern string as you would for creating a `SimpleDateFormat` object. For the `number` type, the styles correspond to formatting normal numbers, percentage values, and currency values. You can also specify a number pattern string as you would for creating a `DecimalFormat` object. For the `choice` type, you can specify a choice pattern as you would for creating a `ChoiceFormat` object. If no type is specified, the argument should be a string.

The following example shows how to use a `choice` format pattern with a `MessageFormat`:

```
Object[] arguments = {new Integer(1)};
String grammar = "At last count, {0}server{0, choice, 0#s|1#|1<s}
 {0, choice, 0#were|1#was|1<were}booted.";
MessageFormat booted = new MessageFormat(grammar);
System.out.println(booted.format(arguments));
arguments[0] = new Integer(2);
System.out.println(booted.format(arguments));
```

This example produces the following output:

```
At last count, 1 server was booted.
At last count, 2 servers were booted.
```

As an alternative to specifying all of the formatting in the pattern string, you can use an array of `Format` objects to format the arguments. You can specify this array using `setFormats()`.

Note that you create `MessageFormat` objects directly, rather than through factory methods. This is because `MessageFormat` does not implement any locale-specific behavior. To produce properly internationalized output, the pattern string that is used to construct a `MessageFormat` should come from a `ResourceBundle` instead of being embedded in the code.

Class Summary

```
public class java.text.MessageFormat extends java.text.Format {
  // Constructors
  public MessageFormat(String pattern);
  // Class Methods
  public static String format(String pattern, Object[] arguments);
  // Instance Methods
  public void applyPattern(String newPattern);
  public Object clone();
  public boolean equals(Object obj);
  public final StringBuffer format(Object source, StringBuffer result,
                             FieldPosition ignore);
  public final StringBuffer format(Object[] source, StringBuffer result,
                             FieldPosition ignore);
  public Format[] getFormats();
  public Locale getLocale();
  public int hashCode();
  public Object[] parse(String source);
  public Object[] parse(String source, ParsePosition status);
  public Object parseObject(String text, ParsePosition status);
  public void setFormat(int variable, Format newFormat);
  public void setFormats(Format[] newFormats);
  public void setLocale(Locale theLocale);
  public String toPattern();
}
```

Constructors

MessageFormat

public MessageFormat(String pattern)

Parameters

`pattern`

The pattern string.

Description

This constructor creates a `MessageFormat` with the given formatting pattern string.

Class Methods

format

public static String format(String pattern, Object[] arguments)

Parameters

`pattern`

The pattern string.

`arguments`

An array of arguments.

Description

Calling this `static` method is equivalent to constructing a `MessageFormat` using the given formatting pattern string and asking it to format the given arguments with the `format()` method.

Instance Methods

applyPattern

public void applyPattern(String pattern)

Parameters

`pattern`

The pattern string.

Description

This method tells this `MessageFormat` to use the given formatting pattern to format and parse arguments.

clone

public Object clone()

Returns

A copy of this `MessageFormat`.

Overrides

`Format.clone()`

Description

This method creates a copy of this `MessageFormat` and then returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Format.equals()`

Description

This method returns `true` if `obj` is an instance of `MessageFormat` and is equivalent to this `MessageFormat`.

format

`public StringBuffer format(Object source, StringBuffer result, FieldPosition ignore)`

Parameters

`source`

The object to be formatted.

`result`

A `StringBuffer` on which to append the formatted information.

`ignore`

Ignored.

Returns

The given buffer `result` with the formatted representation of the object appended to it.

Overrides

`Format.format(Object, StringBuffer, FieldPosition)`

Description

This method formats the given object and appends the result to the given `StringBuffer`. The method assumes that the given object is an array of arguments.

`public StringBuffer format(Object[] source, StringBuffer result, FieldPosition ignore)`

Parameters

`source`

The object array to be formatted.

`result`

A `StringBuffer` on which to append the formatted information.

`ignore`

Ignored.

Returns

The given buffer `result` with the formatted representation of the object array appended to it.

Description

This method formats the given arguments in the object array and appends the result to the given `StringBuffer`.

getFormats

public Format[] getFormats()

Returns

An array of the formats used by this `MessageFormat`.

Description

This method returns the format objects that this `MessageFormat` uses. Note that formats are numbered according to the order in which they appear in the formatting pattern string, not according to their specified argument numbers.

getLocale

public Locale getLocale()

Returns

`The Locale` of this `MessageFormat`.

Description

This method returns the locate for this `MessageFormat`. This locale is used to get default date, time, and number formatters.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `MessageFormat`.

parse

public Object[] parse(String source) throws ParseException

Parameters

`source`

The string to be parsed.

Returns

An array of objects represented by the given string.

Throws

`ParseException`

If the text cannot be parsed.

Description

This method parses arguments from the given string, which should be in the format given by the formatting pattern string of this `MessageFormat`. If the string is not correctly formatted, an exception is thrown.

public Object[] parse(String source, ParsePosition status)

Parameters

`source`

The string to be parsed.

`status`

A `ParsePosition` object that specifies a position in the string.

Returns

An array of objects represented by the test starting at the given position.

Description

This method parses arguments from the given string, starting at the specified position. The string should be in the format given by the formatting pattern string of this `MessageFormat`.

parseObject

public Object parseObject(String text, ParsePosition status)

Parameters

`text`

The string to be parsed.

`status`

A `ParsePosition` object that specifies a position in the string.

Returns

The object represented by the test starting at the given position.

Overrides

`Format.parseObject(String, ParsePosition)`

Description

This method parses arguments from the given string, starting at the specified position. The string should be in the format given by the formatting pattern string of this `MessageFormat`.

setFormat

public void setFormat(int variable, Format newFormat)

Parameters

`variable`

The index of an argument in the pattern string.

`newFormat`

The format object to use.

Description

This method sets the `Format` object that is used for the given argument in the formatting pattern string.

setFormats

public void setFormats(Format[] newFormats)

Parameters

`newFormats`

The format objects to use.

Description

This method sets the `Format` objects that format the arguments of this `MessageFormat`. Note that formats are numbered according to the order in which they appear in the formatting pattern string, not according to their specified argument numbers.

setLocale

public void setLocale(Locale theLocale)

Parameters

`theLocale`

The new locale.

Description

This method sets the `Locale` object that generates the default date, time, and number format objects.

toPattern

public String toPattern()

Returns

> The pattern string of this `MessageFormat`.

Description

> This method returns the pattern string of this `MessageFormat`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`format(Object)`	`Format`
`getClass()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`parseObject(String)`	`Format`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

NumberFormat

Name

NumberFormat

Synopsis

Class Name:

`java.text.NumberFormat`

Superclass:

`java.text.Format`

Immediate Subclasses:

`java.text.ChoiceFormat`, `java.text.DecimalFormat`

Interfaces Implemented:

`java.lang.Cloneable`

Availability:

New as of JDK 1.1

Description

The `NumberFormat` class formats and parses numbers in a locale-specific manner. NumberFormat is an abstract class, but it provides factory methods that return useful instances of NumberFormat subclasses. These factory methods come in three groups:

- The `getCurrencyInstance()` methods return objects that format and parse currency values.
- The `getNumberInstance()` methods return objects that format and parse normal numbers.
- The `getPercentInstance()` methods return objects that format percentage values.

For example, to format a number as an Italian currency value, you can use this code:

```
double salary = 1234.56;
System.out.println
  (NumberFormat.getCurrencyInstance(Locale.ITALY).format(salary));
```

This produces the following output:

```
L 1.234,56
```

The `NumberFormat` class defines two field constants that represent the integer and fractional fields in a formatted number. These field constants create `FieldPosition` objects.

Class Summary

```
public abstract class java.text.NumberFormat extends java.text.Format
                      implements java.lang.Cloneable {
  // Constants
  public static final int FRACTION_FIELD;
  public static final int INTEGER_FIELD;
  // Class Methods
  public static Locale[] getAvailableLocales();
  public static final NumberFormat getCurrencyInstance();
  public static NumberFormat getCurrencyInstance(Locale inLocale);
  public static final NumberFormat getInstance();
  public static NumberFormat getInstance(Locale inLocale);
  public static final NumberFormat getNumberInstance();
  public static NumberFormat getNumberInstance(Locale inLocale);
  public static final NumberFormat getPercentInstance();
  public static NumberFormat getPercentInstance(Locale inLocale);
  // Instance Methods
  public Object clone();
  public boolean equals(Object obj);
  public final String format(double number);
  public final String format(long number);
  public final StringBuffer format(Object number, StringBuffer toAppendTo,
                              FieldPosition pos);
  public abstract StringBuffer format(double number,
                                 StringBuffer toAppendTo, FieldPosition pos);
  public abstract StringBuffer format(long number, StringBuffer toAppendTo,
                                 FieldPosition pos);
  public int getMaximumFractionDigits();
  public int getMaximumIntegerDigits();
  public int getMinimumFractionDigits();
  public int getMinimumIntegerDigits();
  public int hashCode();
  public boolean isGroupingUsed();
  public boolean isParseIntegerOnly();
  public Number parse(String text);
  public abstract Number parse(String text, ParsePosition parsePosition);
  public final Object parseObject(String source,
                        ParsePosition parsePosition);
  public void setGroupingUsed(boolean newValue);
  public void setMaximumFractionDigits(int newValue);
  public void setMaximumIntegerDigits(int newValue);
  public void setMinimumFractionDigits(int newValue);
  public void setMinimumIntegerDigits(int newValue);
  public void setParseIntegerOnly(boolean value);
}
```

Constants

FRACTION_FIELD

public final static int FRACTION_FIELD

Description

A field constant that represents the fractional part of the number.

INTEGER_FIELD

public final static int INTEGER_FIELD

Description

A field constant that represents the integer part of the number.

Class Methods

getAvailableLocales

public static Locale[] getAvailableLocales()

Returns

> An array of `Locale` objects.

Description

> This method returns an array of the `Locale` objects for which this class can create `NumberFormat` objects.

getCurrencyInstance

public static final NumberFormat getCurrencyInstance()

Returns

> A `NumberFormat` appropriate for the default `Locale` that formats currency values.

Description

> This method creates a `NumberFormat` that formats and parses currency values in the default locale.

public static NumberFormat getCurrencyInstance(Locale inLocale)

Parameters

> `inLocale`
>
> > The `Locale` to use.

Returns

> A `NumberFormat` appropriate for the given `Locale` that formats currency values.

Description

> This method creates a `NumberFormat` that formats and parses currency values in the given locale.

getInstance

public static final NumberFormat getInstance()

Returns

A default `NumberFormat` appropriate for the default `Locale`.

Description

This method creates a default `NumberFormat` that formats and parses values in the default locale.

public static NumberFormat getInstance(Locale inLocale)

Parameters

`inLocale`

The `Locale` to use.

Returns

A default `NumberFormat` appropriate for the given `Locale`.

Description

This method creates a `NumberFormat` that formats and parses values in the given locale.

getNumberInstance

public static final NumberFormat getNumberInstance()

Returns

A `NumberFormat` appropriate for the default `Locale` that formats normal numbers.

Description

This method creates a `NumberFormat` that formats and parses number values in the default locale.

public static NumberFormat getNumberInstance(Locale inLocale)

Parameters

`inLocale`

The `Locale` to use.

Returns

A `NumberFormat` appropriate for the given `Locale` that formats normal numbers.

Description

This method creates a `NumberFormat` that formats and parses number values in the given locale.

getPercentInstance

public static final NumberFormat getPercentInstance()

Returns

A `NumberFormat` appropriate for the default `Locale` that formats percentage values.

Description

This method creates a `NumberFormat` that formats and parses percent values in the default locale.

public static NumberFormat getPercentInstance(Locale inLocale)

Parameters

`inLocale`

The `Locale` to use.

Returns

A `NumberFormat` appropriate for the given `Locale` that formats percentage values.

Description

This method creates a `NumberFormat` that formats and parses percent values in the given locale.

Instance Methods

clone

public Object clone()

Returns

A copy of this `NumberFormat`.

Overrides

`Format.clone()`

Description

This method creates a copy of this `NumberFormat` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `NumberFormat` and is equivalent to this `NumberFormat`.

format

public final String format(double number)

Parameters

`number`

The `double` value to be formatted.

Returns

A string that contains a formatted representation of the value.

Description

This method formats the given number and returns the result as a string.

public final String format(long number)

Parameters

`number`

The `long` value to be formatted.

Returns

A string that contains a formatted representation of the value.

Description

This method formats the given number and returns the result as a string.

`public final StringBuffer format(Object number, StringBuffer toAppendTo, FieldPosition pos)`

Parameters

`number`

The object to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`pos`

A number field.

Returns

The given buffer `toAppendTo` with the formatted representation of the object appended to it.

Overrides

`Format.format(Object, StringBuffer, FieldPosition)`

Description

This method formats the given object and appends the result to the given `StringBuffer`. If `pos` refers to one of the number fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

`public abstract StringBuffer format(double number, StringBuffer toAppendTo, FieldPosition pos)`

Parameters

`number`

The `double` value to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`pos`

A number field.

Returns

The given buffer `toAppendTo` with the formatted representation of the object appended to it.

Description

This method formats the given number and appends the result to the given `StringBuffer`. If `pos` refers to one of the number fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

`public abstract StringBuffer format(long number, StringBuffer toAppendTo, FieldPosition pos)`

Parameters

`number`

The `long` value to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`pos`

A number field.

Returns

The given buffer `toAppendTo` with the formatted representation of the object appended to it.

Description

This method formats the given number and appends the result to the given `StringBuffer`. If `pos` refers to one of the number fields, its beginning and ending indices are filled with the beginning and ending positions of the given field in the resulting formatted string.

getMaximumFractionDigits

public int getMaximumFractionDigits()

Returns

The maximum number of digits allowed in the fraction portion.

Description

This method returns the maximum number of digits that can be in the fraction part of the number.

getMaximumIntegerDigits

public int getMaximumIntegerDigits()

Returns

The maximum number of digits allowed in the integer portion.

Description

This method returns the maximum number of digits that can be in the integer part of the number.

getMinimumFractionDigits

public int getMinimumFractionDigits()

Returns

The minimum number of digits allowed in the fraction portion.

Description

This method returns the minimum number of digits that can be in the fraction part of the number.

getMinimumIntegerDigits

public int getMinimumIntegerDigits()

Returns

The minimum number of digits allowed in the integer portion.

Description

This method returns the minimum number of digits that can be in the integer part of the number.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `NumberFormat`.

isGroupingUsed

public boolean isGroupingUsed()

Returns

A `boolean` value that indicates whether or not this `NumberFormat` uses a grouping character to break up long sequences of digits in the integer part of a number.

Description

This method returns `true` if this `NumberFormat` uses a grouping character. For example, it is common in the United States to use a comma as a grouping character: `1,234.56`.

isParseIntegerOnly

public boolean isParseIntegerOnly()

Returns

A `boolean` value that indicates whether or not this `NumberFormat` parses only integers.

Description

This method returns `true` if this `NumberFormat` parses only integers.

parse

public Number parse(String text) throws ParseException

Parameters

`text`

The string to be parsed.

Returns

The `Number` object represented by the given string.

Throws

`ParseException`

If the text cannot be parsed as a number.

Description

This method parses a number from the given string, starting from the beginning of the string.

`public abstract Number parse(String text, ParsePosition parsePosition)`

Parameters

`text`

The string to be parsed.

`parsePosition`

A `ParsePosition` object that specifies a position in the string.

Returns

The `Number` object represented by the text starting at the given position.

Description

This method parses a number from the given string, starting from the given position. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

parseObject

`public final Object parseObject(String source, ParsePosition parsePosition)`

Parameters

`source`

The string to be parsed.

`parsePosition`

A `ParsePosition` object that specifies a position in the string.

Returns

The object represented by the text starting at the given position.

Overrides

`Format.parseObject(String, ParsePosition)`

Description

This method parses a number from the given string, starting from the given position. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

setGroupingUsed

public void setGroupingUsed(boolean newValue)

Parameters

`newValue`

The new grouping flag.

Description

This method sets whether or not this `NumberFormat` uses a grouping character to break up long sequences of digits in the integer part of a number. For example, it is common in the United States to use a comma as a grouping character: `1,234.56`.

setMaximumFractionDigits

public void setMaximumFractionDigits(int newValue)

Parameters

`newValue`

The new maximum number of fraction digits.

Description

This method sets the maximum number of digits that may be present in the fraction part of the number. The maximum value must be greater than the minimum number of fraction digits allowed. If the value is less than the current minimum, the minimum is also set to this value.

setMaximumIntegerDigits

public void setMaximumIntegerDigits(int newValue)

Parameters

`newValue`

The new maximum number of integer digits.

Description

This method sets the maximum number of digits that may be present in the integer part of the number. The maximum value must be greater than the minimum number of integer digits allowed. If the value is less than the current minimum, the minimum is also set to this value.

setMinimumFractionDigits

public void setMinimumFractionDigits(int newValue)

Parameters

`newValue`

The new minimum number of fraction digits.

Description

This method sets the minimum number of digits that may be present in the fraction part of the number. The minimum value must be less than the maximum number of fraction digits allowed. If the value is greater than the current maximum, the maximum is also set to this value.

setMinimumIntegerDigits

public void setMinimumIntegerDigits(int newValue)

Parameters

`newValue`

The new minimum number of integer digits.

Description

This method sets the minimum number of digits that may be present in the integer part of the number. The minimum value must be less than the maximum number of integer digits allowed. If the value is greater than the current maximum, the maximum is also set to this value.

setParseIntegerOnly

public void setParseIntegerOnly(boolean value)

Parameters

`value`

The new parsing flag.

Description

This method sets whether or not this `NumberFormat` parses only integers. If the value is `true`, this `NumberFormat` only parse integers. Otherwise it parses both the integer and fractional parts of numbers.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`format(Object)`	`Format`

RuleBasedCollator

Name

RuleBasedCollator

Synopsis

Class Name:

```
java.text.RuleBasedCollator
```

Superclass:

```
java.text.Collator
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `RuleBasedCollator` class is a concrete subclass of `Collator` that can compare strings using a table of rules. The rules for many locales already exist. To get a useful `Collator` for a given locale, use the `getInstance(Locale)` factory method of `Collator`.

If you need a special-purpose `Collator` or a `Collator` for a new locale, you can create your own `RuleBasedCollator` from a string that represents the rules. The rules are expressed in three primary forms:

```
[relation] [text]
[reset] [text]
[modifier]
```

The rules can be chained together. The only modifier is the `@` character, which specifies that all diacriticals are sorted backwards, as in French.

The valid relations are:

`>`

Greater than as a primary difference

`;`

Greater than as a secondary difference or difference in accent

`,`

Greater than as a tertiary difference or difference in case

`=`

Equal

For example `"<a<b"` is two chained rules that state that `'a'` is greater than all ignorable characters, and `'b'` is greater than `'a'`. To expand this rule to include capitals, use `"<a,A<b,B"`.

A reset, specified by the & character, is used to insert rules in an existing list of chained rules. For example, we can add a rule to sort `'e'` with an umlaut (Unicode 0308) after plain `'e'`. The existing rules might look like `"<a<b<c<d<e<f"`. We can add the following reset, `"&e;e\u0308"`, so that the complete rule table looks like `"<a<b<c<d<e<f&e;e\u0308"`.

Class Summary

```
public class java.text.RuleBasedCollator extends java.text.Collator {
  // Constructors
  public RuleBasedCollator(String rules);
  // Instance Methods
  public Object clone();
  public int compare(String source, String target);
  public boolean equals(Object obj);
  public CollationElementIterator
         getCollationElementIterator( String source);
  public CollationKey getCollationKey(String source);
  public String getRules();
  public int hashCode();
}
```

Constructors

RuleBasedCollator

public RuleBasedCollator(String rules) throws ParseException

Parameters

`rules`

A string that contains the rules.

Throws

`ParseException`

If the given rules are incorrectly formed.

Description

This constructor creates a `RuleBasedCollator` with the given rules.

Instance Methods

clone

public Object clone()

Returns

A copy of this `RuledBasedCollator`.

Overrides

`Collator.clone()`

Description

This method creates a copy of this `RuledBasedCollator` and returns it.

compare

public int compare(String source, String target)

Parameters

`source`

The source string.

`target`

The target string.

Returns

`-1` if `source` is less than `target`, `0` if the strings are equal, or `1` if `source` is greater than `target`.

Overrides

`Collator.compare()`

Description

This method compares the given strings according to the rules for this `RuleBasedCollator` and returns a value that indicates their relationship. If either of the strings are compared more than once, a `CollationKey` should be used instead.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Collator.equals()`

Description

This method returns `true` if `obj` is an instance of `RuleBasedCollator` and is equivalent to this `RuleBasedCollator`.

getCollationElementIterator

```
public CollationElementIterator getCollationElementIterator( String source)
```

Parameters

`source`

The source string.

Returns

A `CollationElementIterator` for the given string.

Description

This method generates a `CollationElementIterator` for the given string.

getCollationKey

public CollationKey getCollationKey(String source)

Parameters

`source`

The source string.

Returns

A `CollationKey` for the given string.

Overrides

`Collator.getCollationKey()`

Description

This method generates a `CollationKey` for the given string. The returned object can be compared with other `CollationKey` objects using `CollationKey.compareTo()`. This comparison is faster than using `RuleBasedCollator.compare()`, so if the same string is used for many comparisons, you should use `CollationKey` objects.

getRules

public String getRules()

Returns

The rules string for this `RuleBasedCollator`.

Description

This method returns a string that contains the rules that this `RuleBasedCollator` is using.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Collator.hashCode()`

Description

This method returns a hashcode for this `RuleBasedCollator`.

Inherited Methods

Method	Inherited From	Method	Inherited From

SimpleDateFormat

Name

SimpleDateFormat

Synopsis

Class Name:

`java.text.SimpleDateFormat`

Superclass:

`java.text.DateFormat`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `SimpleDateFormat` class is a concrete subclass of `DateFormat` that formats and parses dates and times using a formatting pattern. Typically, you do not need to instantiate `SimpleDateFormat` yourself. Instead, the factory methods of `DateFormat` return instances of `SimpleDateFormat` that are appropriate for particular locales.

However, if you need a specialized date and time format, you can instantiate your own `SimpleDateFormat` using a pattern string. You can also modify the formatting pattern of an existing `SimpleDateFormat` object using the `applyPattern()` method. The following symbols are significant in the pattern string.

Symbol	**Description**	**Example**	**Type**
`G`	Era	AD	Text
`y`	Year	1997	Numeric
`M`	Month in year	3 or March	Text or numeric
`d`	Day in month	4	Numeric
`h`	Hour in A.M./P.M. (1-12)	2	Numeric
`H`	Hour in day (0-23)	14	Numeric
`m`	Minute in hour	33	Numeric
`s`	Second in minute	21	Numeric
`S`	Milliseconds	333	Numeric
`E`	Day of week	Thursday	Text
`D`	Day in year	63	Numeric
`F`	Day of week of month	1	Numeric
`w`	Week in year	9	Numeric
`W`	Week in month	1	Numeric
`a`	A.M./P.M.	P.M.	Text
`k`	Hour in day (1-24)	14	Numeric
`K`	Hour in A.M./P.M. (0-11)	2	Numeric
`z`	Time zone	EST	Text

Symbols that are numeric can be repeated to specify a minimum number of digits. For example, `"hh"` produces an hour field that is always at least two digits, like `"02"`. Symbols that are textual can be repeated to specify whether the short form or the long form of the text string is used, if there are both short and long forms. If four or more symbols are specified, the long form is used; otherwise the short form is used. For example, `"E"` produces a short form of the day of the week, such as `"Tue"`, while `"EEEE"` produces the long form, such as `"Tuesday"`. For the month of the year, if one or two `"M"` symbols are used, the field is numeric. If three or more `"M"` symbols are used, the field is textual.

Single quotes can be used to specify literal text that should be included in the formatted output, and any unrecognized symbol is treated as literal text. For example, the following pattern:

```
hh:mm a 'in the' zzzz 'zone.'
```

produces output like:

```
02:33 PM in the Eastern Standard Time zone.
```

Internally, the `SimpleDataFormat` class uses a `DateFormatSymbols` object to get the date and time strings that are appropriate for a particular locale. If you want to modify these strings, you can get the `DateFormatSymbols` object by calling `getDateFormatSymbols()`.

Class Summary

```
public class java.text.SimpleDateFormat  extends java.text.DateFormat {
  // Constructors
  public SimpleDateFormat();
  public SimpleDateFormat(String pattern);
  public SimpleDateFormat(String pattern, Locale loc);
  public SimpleDateFormat(String pattern, DateFormatSymbols formatData);
  // Instance Methods
  public void applyLocalizedPattern(String pattern);
  public void applyPattern(String pattern);
  public Object clone();
  public boolean equals(Object obj);
  public StringBuffer format(Date date, StringBuffer toAppendTo,
                      FieldPosition pos);
  public DateFormatSymbols getDateFormatSymbols();
  public int hashCode();
  public Date parse(String text, ParsePosition pos);
  public void setDateFormatSymbols(DateFormatSymbols newFormatSymbols);
  public String toLocalizedPattern();
  public String toPattern();
}
```

Constructors

SimpleDateFormat

public SimpleDateFormat()

Description

> This constructor creates a `SimpleDateFormat` that uses a default formatting pattern and `DateFormatSymbols` that are appropriate for the default locale. It produces the same result as calling `DateFormat.getDateTimeInstance(DateFormat.SHORT, DateFormat.SHORT)`.

public SimpleDateFormat(String pattern)

Parameters

> `pattern`
>
> > The pattern string.

Description

> This constructor creates a `SimpleDateFormat` that uses the given formatting pattern and a `DateFormatSymbols` object that is appropriate for the default locale.

public SimpleDateFormat(String pattern, Locale loc)

Parameters

`pattern`

The pattern string.

`loc`

The `Locale` to use.

Description

This constructor creates a `SimpleDateFormat` that uses the given formatting pattern and a `DateFormatSymbols` object that is appropriate for the given locale.

`public SimpleDateFormat(String pattern, DateFormatSymbols formatData)`

Parameters

`pattern`

The pattern string.

`formatData`

The `DateFormatSymbols` to use.

Description

This constructor creates a `SimpleDateFormat` that uses the given formatting pattern and `DateFormatSymbols` object.

Instance Methods

applyLocalizedPattern

public void applyLocalizedPattern(String pattern)

Parameters

`pattern`

The pattern string.

Description

This method tells this `SimpleDateFormat` to use the given formating pattern to format and parse dates and times. The pattern string is assumed to have been localized to the `DateFormatSymbols` object this `SimpleDateFormat` uses.

applyPattern

public void applyPattern(String pattern)

Parameters

`pattern`

The pattern string.

Description

This method tells this `SimpleDateFormat` to use the given formatting pattern to format and parse dates and times. The pattern string is localized to the `DateFormatSymbols` object this `SimpleDateFormat` uses.

clone

public Object clone()

Returns

A copy of this `SimpleDateFormat`.

Overrides

`DateFormat.clone()`

Description

This method creates a copy of this `SimpleDateFormat` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`DateFormat.equals()`

Description

This method returns `true` if `obj` is an instance of `SimpleDateFormat` and is equivalent to this `SimpleDateFormat`.

format

```
public StringBuffer format(Date date, StringBuffer toAppendTo, FieldPosition pos)
```

Parameters

`date`

The `Date` object to be formatted.

`toAppendTo`

A `StringBuffer` on which to append the formatted information.

`pos`

A date or time field.

Returns

The given buffer `toAppendTo` with the formatted representation of the object appended to it.

Overrides

`DateFormat.format(Date, StringBuffer, FieldPosition)`

Description

This method formats the given date and appends the result to the given `StringBuffer`. If `pos` refers to one of the time or date fields, its beginning and ending indexes are filled with the beginning and ending positions of the given field in the resulting formatted string.

getDateFormatSymbols

public DateFormatSymbols getDateFormatSymbols()

Returns

The `DateFormatSymbols` object used by this `SimpleDateFormat`.

Description

This method returns the `DateFormatSymbols` object that this `SimpleDateFormat` uses internally.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`DateFormat.hashCode()`

Description

This method returns a hashcode for this `SimpleDateFormat`.

parse

public Date parse(String text, ParsePosition pos)

Parameters

`text`

The string to be parsed.

`pos`

A `ParsePosition` object that specifies a position in the string.

Returns

The `Date` object represented by the text starting at the given position.

Overrides

`DateFormat.parse(String, ParsePosition)`

Description

This method parses a date from the given string, starting from the given position. After the string has been parsed, the given `ParsePosition` object is updated so that its index is after the parsed text.

setDateFormatSymbols

```
public void setDateFormatSymbols( DateFormatSymbols newFormatSymbols)
```

Parameters

`newFormatSymbols`

The new `DateFormatSymbols` object to use.

Description

This method sets the `DateFormatSymbols` object that this `SimpleDateFormat` uses internally.

toLocalizedPattern

public String toLocalizedPattern()

Returns

The pattern string of this `SimpleDateFormat`.

Description

This method returns the pattern string of this `SimpleDateFormat`, localized with the `DateFormatSymbols` object of this `SimpleDateFormat`.

toPattern

public String toPattern()

Returns

The pattern string of this `SimpleDateFormat`.

Description

This method returns the pattern string of this `SimpleDateFormat`.

StringCharacterIterator

Name

StringCharacterIterator

Synopsis

Class Name:

```
java.text.StringCharacterIterator
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

```
java.text.CharacterIterator
```

Availability:

New as of JDK 1.1

Description

The `StringCharacterIterator` class can move bidirectionally through a character string. In other words, the class iterates through the characters in a `String`. The class implements the `CharacterIterator` interface. The class is used by `BreakIterator` to find boundaries in text strings.

Class Summary

```
public final class java.text.StringCharacterIterator
                    extends java.lang.Object
                    implements java.text.CharacterIterator {
  // Constructors
  public StringCharacterIterator(String text);
  public StringCharacterIterator(String text, int pos);
  public StringCharacterIterator(String text, int begin, int end, int pos);
  // Instance Methods
  public Object clone();
  public char current();
  public boolean equals(Object obj);
  public char first();
  public int getBeginIndex();
  public int getEndIndex();
  public int getIndex();
  public int hashCode();
  public char last();
  public char next();
  public char previous();
  public char setIndex(int p);
}
```

Constructors

StringCharacterIterator

public StringCharacterIterator(String text)

Parameters

`text`

The `String` to use.

Description

This constructor creates a `StringCharacterIterator` that uses the given string. The initial index of the iterator is at the beginning of the string, or in other words, at index `0`.

public StringCharacterIterator(String text, int pos)

Parameters

`text`

The `String` to use.

`pos`

The initial position.

Description

This constructor creates a `StringCharacterIterator` that uses the given string. The initial index of the iterator is set to the given initial position.

`public StringCharacterIterator(String text, int begin, int end, int pos)`

Parameters

`text`

The `String` to use.

`begin`

The beginning index.

`end`

The ending index.

`pos`

The initial position.

Description

This constructor creates a `StringCharacterIterator` that uses the specified range of the given string. In other words, the iterator uses the sequence of text from the specified beginning index to the specified ending index. The initial index of the iterator is set to the given initial position.

Instance Methods

clone

public Object clone()

Returns

> A copy of this `StringCharacterIterator`.

Implements

> `CharacterIterator.clone()`

Overrides

> `Object.clone()`

Description

> This method creates a copy of this `StringCharacterIterator` and returns it.

current

public char current()

Returns

> The character at the current position of this `StringCharacterIterator` or `DONE` if the current position is not within the text sequence.

Implements

> `CharacterIterator.current()`

Description

> This method returns the character at the current position of this `CharacterIterator`. The current position is returned by `getIndex()`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `StringCharacterIterator` and is equivalent to this `StringCharacterIterator`.

first

public char first()

Returns

The first character in this `StringCharacterIterator`.

Implements

`CharacterIterator.first()`

Description

This method returns the character at the first position in this `StringCharacterIterator`. The first position is returned by `getBeginIndex()`. The current position of the iterator is set to this position.

getBeginIndex

public int getBeginIndex()

Returns

The index of the first character in this `StringCharacterIterator`.

Implements

`CharacterIterator.getBeginIndex()`

Description

This method returns the index of the beginning of the text for this `StringCharacterIterator`.

getEndIndex

public int getEndIndex()

Returns

The index after the last character in this `StringCharacterIterator`.

Implements

`CharacterIterator.getEndIndex()`

Description

This method returns the index of the character following the end of the text for this `StringCharacterIterator`.

getIndex

public int getIndex()

Returns

The index of the current character in this `StringCharacterIterator`.

Description

This method returns the current position, or index, of this `StringCharacterIterator`.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `StringCharacterIterator`.

last

public char last()

Returns

The last character in this `StringCharacterIterator`.

Implements

`CharacterIterator.last()`

Description

This method returns the character at the ending position of this `StringCharacterIterator`. The last position is the value of `getEndIndex()-1`. The current position of the iterator is set to this position.

next

public char next()

Returns

The next character in this `StringCharacterIterator` or `DONE` if the current position is already at the end of the text.

Implements

`CharacterIterator.next()`

Description

This method increments the current position of this `StringCharacterIterator` by 1 and returns the character at the new position. If the current position is already at `getEndIndex()`, the position is not changed and `DONE` is returned.

previous

public char previous()

Returns

The previous character in this `StringCharacterIterator` or `DONE` if the current position is already at the beginning of the text.

Implements

`CharacterIterator.previous()`

Description

This method decrements the current position of this `StringCharacterIterator` by 1 and returns the character at the new position. If the current position is already at `getBeginIndex()`, the position is not changed and `DONE` is returned.

setIndex

public char setIndex(int p)

Parameters

`p`

The new position.

Returns

The character at the specified position in this `StringCharacterIterator`.

Throws

`IllegalArgumentException`

If the given position is not between `getBeginIndex()` and `getEndIndex()-1`.

Implements

`CharacterIterator.setIndex()`

Description

This method sets the current position, or index, of this `StringCharacterIterator` to the given position.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`finalize()`	`Object`	`getClass()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Calendar

Name

Calendar

Synopsis

Class Name:

`java.util.Calendar`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.util.GregorianCalendar`

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The `Calendar` class is an `abstract`class that is used to convert between `Date` objects, which represent points in time, and calendar fields, like months or days of the week. The JDK 1.0 `Date` class included calendar and text-formatting methods. As of JDK 1.1, both of these functions have been split off from `Date` in order to support internationalization. As of JDK 1.1, `Date` represents only a point in time, measured in milliseconds. A subclass of `Calendar` examines the `Date` in the context of a particular calendar system; a `Calendar` instance is a locale-sensitive object. Also as of JDK 1.1, the `java.text.DateFormat` class generates and parses strings representing points in time.

`Calendar` defines a number of symbolic constants. They represent either fields or values. For example, `MONTH` is a field constant. It can be passed to `get()` and `set()` to retrieve and adjust the month. `AUGUST`, on the other hand, represents a particular month value. Calling `get(Calendar.MONTH)` could return `Calendar.AUGUST`.

Internally, `Calendar` keeps track of a point in time in two ways. First, a "raw" value is maintained, which is simply a count of milliseconds since midnight, January 1, 1970 GMT, or, in other words, a `Date` object. Second, the calendar keeps track of a number of fields, which are the values that are specific to the `Calendar` type. These are values such as day of the week, day of the month, and month. The raw millisecond value can be calculated from the field values, or vice versa.

When a `Date` object is computed from the time fields, there may be insufficient information to compute the raw millisecond value. For example, the year and the month could be set, but not the day of the month. In this case, `Calendar` uses default information to fill in the missing fields. For `GregorianCalendar`, the default field values are taken from the date of the epoch, or midnight, January 1, 1970 GMT.

Another problem that can arise when computing a `Date` object from the time fields is that of inconsistent information in the fields. For example, the time fields could specify "Sunday, March 8, 1997" when in fact March 8, 1997 is a Saturday. If the time fields contain inconsistent information, `Calendar` gives preference to the combinations of fields in the following order:

1. month and day of the week
2. month, week of the month, and day of the week
3. month, day of the week in the month, and day of the week
4. day of the year
5. day of the week and week of the year
6. hour of the day
7. A.M./P.M. and hour of A.M./P.M.

There is also the possibility of ambiguity for certain points in time, so the following rules apply. The time 24:00:00 belongs to the next day and midnight is an A.M. time, while noon is a P.M. time.

Constants

AM

public final static int AM

Description

A constant value that represents morning times.

AM_PM

public final static int AM_PM

Description

A field constant that represents the A.M./P.M. flag of this object.

APRIL

public final static int APRIL

Description

A constant value that represents the month of April.

AUGUST

public final static int AUGUST

Description

A constant value that represents the month of August.

DATE

public final static int DATE

Description

A field constant that represents the day of the month of this object.

DAY_OF_MONTH

public final static int DAY_OF_MONTH

Description

> A field constant that represents the day of the month of this object. This field is synonymous with `DATE`.

DAY_OF_WEEK

public final static int DAY_OF_WEEK

Description

> A field constant that represents the day of the week of this object.

DAY_OF_WEEK_IN_MONTH

public final static int DAY_OF_WEEK_IN_MONTH

Description

> A field constant that represents the day of the week in the current month. For example, February 10, 1997, has a `DAY_OF_WEEK_IN_MONTH` value of `2` because it is the second Monday in February for that year.

DAY_OF_YEAR

public final static int DAY_OF_YEAR

Description

> A field constant that represents the day of the year of this object. January 1 is the first day of the year.

DECEMBER

public final static int DECEMBER

Description

> A constant value that represents the month of December.

DST_OFFSET

public final static int DST_OFFSET

Description

A field constant that represents the offset due to daylight savings time, in milliseconds, of this object.

ERA

public final static int ERA

Description

A field constant that represents the era of this object. A Gregorian calendar has two eras, BC and AD.

FEBRUARY

public final static int FEBRUARY

Description

A constant value that represents the month of February.

FIELD_COUNT

public final static int FIELD_COUNT

Description

A constant that represents the number of attribute fields for `Calendar` objects.

FRIDAY

public final static int FRIDAY

Description

A constant value that represents the day Friday.

HOUR

public final static int HOUR

Description

A field constant that represents the hour of this object.

HOUR_OF_DAY

public final static int HOUR_OF_DAY

Description

> A field constant that represents the hour of the day of this object. A time of 1:00 P.M. has an `HOUR` value of 1, but an `HOUR_OF_DAY` value of 13.

JANUARY

public final static int JANUARY

Description

> A constant value that represents the month of January.

JULY

public final static int JULY

Description

> A constant value that represents the month of July.

JUNE

public final static int JUNE

Description

> A constant value that represents the month of June.

MARCH

public final static int MARCH

Description

> A constant value that represents the month of March.

MAY

public final static int MAY

Description

A constant value that represents the month of May.

MILLISECOND

public final static int MILLISECOND

Description

A field constant that represents the milliseconds of this object.

MINUTE

public final static int MINUTE

Description

A field constant that represents the minutes of this object.

MONDAY

public final static int MONDAY

Description

A constant value that represents the day Monday.

MONTH

public final static int MONTH

Description

A field constant that represents the month of this object.

NOVEMBER

public final static int NOVEMBER

Description

A constant value that represents the month of November.

OCTOBER

public final static int OCTOBER

Description

A constant value that represents the month of October.

PM

public final static int PM

Description

A constant value that represents afternoon and evening times.

SATURDAY

public final static int SATURDAY

Description

A constant value that represents the day Saturday.

SECOND

public final static int SECOND

Description

A field constant that represents the seconds of this object.

SEPTEMBER

public final static int SEPTEMBER

Description

A constant value that represents the month of September.

SUNDAY

public final static int SUNDAY

Description

A constant value that represents the day Sunday.

THURSDAY

public final static int THURSDAY

Description

A constant value that represents the day Thursday.

TUESDAY

public final static int TUESDAY

Description

A constant value that represents the day Tuesday.

UNDECIMBER

public final static int UNDECIMBER

Description

A constant value that represents the thirteenth month used in lunar calendars.

WEDNESDAY

public final static int WEDNESDAY

Description

A constant value that represents the day Wednesday.

WEEK_OF_MONTH

public final static int WEEK_OF_MONTH

Description

A field constant that represents the week of the month of this object.

WEEK_OF_YEAR

public final static int WEEK_OF_YEAR

Description

> A field constant that represents the week of the year of this object.

YEAR

public final static int YEAR

Description

> A field constant that represents the year of this object.

ZONE_OFFSET

public final static int ZONE_OFFSET

Description

> A field constant that represents the raw time zone offset, in milliseconds, of this object. The value should be added to GMT to get local time.

Variables

areFieldsSet

protected boolean areFieldsSet

Description

> A `boolean` value that indicates if the time fields of this `Calendar` have been set. These fields can be computed from the raw millisecond time value.

fields

protected int[] fields

Description

> An array that stores the time field values for this `Calendar`.

isSet

protected boolean[] isSet

Description

An array that contains a flag for each entry in the `fields` array. The value of each flag indicates if the corresponding entry in `fields` has been set for this `Calendar`.

isTimeSet

protected boolean isTimeSet

Description

A `boolean` value that indicates if the raw millisecond time value of this `Calendar` has been set. The value can be computed from the time fields.

time

protected long time

Description

The raw time value for this `Calendar`. The value is the number of milliseconds since midnight, January 1, 1970 GMT.

Constructors

Calendar

protected Calendar()

Description

This constructor creates `a Calendar` that uses the system's default time zone and locale. The default time zone is that returned by `TimeZone.getDefault()`. The default locale is that returned by `Locale.getDefault()`.

protected Calendar(TimeZone zone, Locale aLocale)

Parameters

`zone`

The `TimeZone` to use.

aLocale

The Locale to use.

Description

This constructor creates a Calendar that uses the supplied time zone and locale.

Class Methods

getAvailableLocales

public static synchronized Locale[] getAvailableLocales()

Returns

An array of Locale objects for which Calendar objects are installed.

Description

This method returns an array of locales that have corresponding Calendar objects.

getInstance

public static synchronized Calendar getInstance()

Returns

A Calendar for the default time zone and locale.

Description

This method returns a newly constructed Calendar for the default time zone and locale. Future implementations of this method may infer the subclass of Calendar to instantiate based on the default locale. However, the current implementation always returns a GregorianCalendar. The default time zone is that returned by TimeZone.getDefault(). The default locale is that returned by Locale.getDefault().

public static synchronized Calendar getInstance(TimeZone zone)

Parameters

zone

The `TimeZone` to use.

Returns

A `Calendar` for the given time zone and the default locale.

Description

This method returns a newly constructed `Calendar` for the given time zone and the default locale. Future implementations of this method may infer the subclass of `Calendar` to instantiate based on the default locale. However, the current implementation always returns a `GregorianCalendar`. The default locale is that returned by `Locale.getDefault()`.

public static synchronized Calendar getInstance(Locale aLocale)

Parameters

`aLocale`

The `Locale` to use.

Returns

A `Calendar` for the given locale and the default time zone.

Description

This method returns a newly constructed `Calendar` for the given locale and the default time zone. Future implementations of this method may infer the subclass of `Calendar` to instantiate based on the given locale. However, the current implementation always returns a `GregorianCalendar`. The default time zone is that returned by `TimeZone.getDefault()`.

public static synchronized Calendar getInstance(TimeZone zone, Locale aLocale)

Parameters

`zone`

The `TimeZone` to use.

`aLocale`

The `Locale` to use.

Returns

A `Calendar` for the given time zone and locale.

Description

This method returns a newly constructed `Calendar` for the given time zone and locale. Future implementations of this method may infer the subclass of `Calendar` to instantiate based on the given locale. However, the current implementation always returns a `GregorianCalendar`.

Instance Methods

add

public abstract void add(int field, int amount)

Parameters

`field`

The time field to be modified.

`amount`

The amount to add to the specified field value. This value can be negative.

Description

This method adds the given amount to the specified time field. For example, you can compute a date 90 days beyond the current date of this `Calendar` by calling `add(Calendar.DATE, 90)`.

after

public abstract boolean after(Object when)

Parameters

`when`

The object to compare to this `Calendar`.

Returns

`true` if this object is after `when`; `false` otherwise.

Description

This method returns `true` if `when` is a `Calendar` object whose value falls before the value of this `Calendar`.

before

public abstract boolean before(Object when)

Parameters

`when`

The object to compare to this `Calendar`.

Returns

`true` if this object is before `when`; `false` otherwise.

Description

This method returns `true` if `when` is a `Calendar` object whose value falls after the value of this `Calendar`.

clear

public final void clear()

Description

This method clears the values of all of the time fields of this `Calendar`.

public final void clear(int field)

Parameters

`field`

The time field to be cleared.

Description

This method clears the specified time field by setting its value to 0.

clone

public Object clone()

Returns

A copy of this `Calendar`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `Calendar` and returns it. In other words, the returned `Calendar` has the same time field values and raw time value as this `Calendar`.

equals

public abstract boolean equals(Object when)

Parameters

`when`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `when` is an instance of `Calendar` and it contains the same value as the object this method is associated with.

get

public final int get(int field)

Parameters

`field`

The time field to be retrieved.

Returns

The value of the given time field.

Description

This method returns the value of the specified time field. If the fields of this `Calendar` have not been set, they are set from the raw time value before the requested field is returned.

getFirstDayOfWeek

public int getFirstDayOfWeek()

Returns

The first day of the week for this Calendar.

Description

This method returns the day that is considered the beginning of the week for this `Calendar`. This value is determined by the `Locale` of this `Calendar`. For example, the first day of the week in the United States is Sunday, while in France it is Monday.

getGreatestMinimum

public abstract int getGreatestMinimum(int field)

Parameters

`field`

A time field constant.

Returns

The highest minimum value for the given time field.

Description

This method returns the highest minimum value for the given time field, if the field has a range of minimum values. If the field does not have a range of minimum values, this method is equivalent to `getMinimum()`.

getLeastMaximum

public abstract int getLeastMaximum(int field)

Parameters

`field`

A time field constant.

Returns

The lowest maximum value for the given time field.

Description

This method returns the lowest maximum value for the given time field, if the field has a range of maximum values. If the field does not have a range of maximum values, this method is equivalent to `getMaximum()`. For example, for a `GregorianCalendar`, the lowest maximum value of `DATE_OF_MONTH` is 28.

getMaximum

public abstract int getMaximum(int field)

Parameters

`field`

A time field constant.

Returns

The maximum value for the given time field.

Description

This method returns the maximum value for the given time field. For example, for a `GregorianCalendar`, the maximum value of `DATE_OF_MONTH` is 31.

getMinimalDaysInFirstWeek

public int getMinimalDaysInFirstWeek()

Returns

The number of days that must be in the first week of the year.

Description

This method returns the number of days that must be in the first week of the year. For example, a value of 7 indicates that the first week of the year must be a full week, while a value of 1 indicates that the first week of the year can contain a single day. This value is determined by the `Locale` of this `Calendar`.

getMinimum

public abstract int getMinimum(int field)

Parameters

`field`

A time field constant.

Returns

The minimum value for the given time field.

Description

This method returns the minimum value for the given time field. For example, for a `GregorianCalendar`, the minimum value of `DATE_OF_MONTH` is 1.

getTime

public final Date getTime()

Returns

A `Date` object that represents the point in time represented by this `Calendar`.

Description

This method returns a newly created `Date` object that is constructed from the value returned by `getTimeInMillis()`.

getTimeZone

public TimeZone getTimeZone()

Returns

The `TimeZone` of this `Calendar`.

Description

This method returns the `TimeZone` object for this `Calendar`.

isLenient

public boolean isLenient()

Returns

A `boolean` value that indicates the leniency of this `Calendar`.

Description

This method returns the current leniency of this `Calendar`. A value of `false` indicates that the `Calendar` throws exceptions when questionable data is passed to it, while a value of `true` indicates that the `Calendar` makes its best guess to interpret questionable data. For example, if the `Calendar` is being lenient, a date such as March 135, 1997 is interpreted as the 134th day after March 1, 1997.

isSet

public final boolean isSet(int field)

Parameters

`field`

A time field constant.

Returns

`true` if the time field has been set; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not the specified time field has been set.

roll

public abstract void roll(int field, boolean up)

Parameters

`field`

The time field to be adjusted.

`up`

A `boolean` value that indicates if the given field should be incremented.

Description

This method adds or subtracts one time unit from the given time field. For example, to increase the current date by one day, you can call `roll(Calendar.DATE, true)`.

The method maintains the field being rolled within its valid range. For example, in a calendar system that uses hours and minutes to measure time, rolling the minutes up from 59 sets that field to 0. By the same token, rolling that field down from 0 sets it to 59.

The `roll()` method does not adjust the value of any other field than the one specified by its `field` argument. In particular, for calendar systems that have months with different numbers of days, it may be necessary to adjust the month and also year when the day of the month is rolled up. It is the responsibility of the caller of `roll()` to perform that adjustment.

set

public final void set(int field, int value)

Parameters

`field`

The time field to be set.

`value`

The new value.

Description

This method sets the value of the specified time field.

public final void set(int year, int month, int date)

Parameters

`year`

The value for the year field.

`month`

The value for the month field, where 0 represents the first month.

`date`

The value for the day-of-the-month field.

Description

This method sets the values of the year, month, and day-of-the-month fields of this `Calendar`.

`public final void set(int year, int month, int date, int hour, int minute)`

Parameters

`year`

The value for the year field.

`month`

The value for the month field, where 0 represents the first month.

`date`

The value for the day-of-the-month field.

`hour`

The value for the hour field.

`minute`

The value for the minute field.

Description

This method sets the values of the year, month, day-of-the-month, hour, and minute fields of this `Calendar`.

`public final void set(int year, int month, int date, int hour, int minute, int second)`

Parameters

`year`

The value for the year field.

`month`

The value for the month field, where 0 represents the first month.

`date`

The value for the day-of-the-month field.

`hour`

The value for the hour field.

`minute`

The value for the minute field.

`second`

The value for the second field.

Description

This method sets the values of the year, month, day-of-the-month, hour, minute, and second fields of this `Calendar`.

setFirstDayOfWeek

public void setFirstDayofWeek(int value)

Parameters

`value`

The value for the first day of the week.

Description

This method sets the day that is considered the beginning of the week for this `Calendar`. This value should be determined by the `Locale` of this `Calendar`. For example, the first day of the week in the United States is Sunday; in France it's Monday.

setLenient

public void setLenient(boolean lenient)

Parameters

`lenient`

A `boolean` value that specifies the leniency of this `Calendar`.

Description

This method sets the leniency of this `Calendar`. A value of `false` specifies that the `Calendar` throws exceptions when questionable data is passed to it, while a value of `true` indicates that the `Calendar` makes its best guess to interpret questionable data. For example, if the `Calendar` is being lenient, a date such as March 135, 1997 is interpreted as the 135th day after March 1, 1997.

setMinimalDaysInFirstWeek

public void setMinimalDaysInFirstWeek(int value)

Parameters

`value`

The value for the minimum number of days in the first week of the year.

Description

This method sets the minimum number of days in the first week of the year. For example, a value of 7 indicates the first week of the year must be a full week, while a value of 1 indicates the first week of the year can contain a single day. This value should be determined by the `Locale` of this `Calendar`.

setTime

public final void setTime(Date date)

Parameters

`date`

A `Date` object that represents the new time value.

Description

This method sets the point in time that is represented by this `Calendar`.

setTimeZone

public void setTimeZone(TimeZone value)

Parameters

> `value`
>
> > A `TimeZone` object that represents the new time zone.

Description

> This method is used to set the time zone of this `Calendar`.

Protected Instance Methods

complete

protected void complete()

Description

> This method fills out the fields of this `Calendar` as much as possible by calling `computeTime()` and `computeFields()`.

computeFields

protected abstract void computeFields()

Description

> This method calculates the time fields of this `Calendar` from its raw time value.

computeTime

protected abstract void computeTime()

Description

> This method calculates the raw time value of this `Calendar` from its time field values.

getTimeInMillis

protected long getTimeInMillis()

Returns

The raw time value of this `Calendar`.

Description

This method returns the raw time value of this `Calendar`. The value is measured as the number of milliseconds since midnight, January 1, 1970 GMT.

internalGet

protected final int internalGet(int field)

Parameters

`field`

A time field constant.

Returns

The value of the given time field.

Description

This method returns the value of the specified time field without first checking to see if it needs to be computed from the raw time value.

setTimeInMillis

protected void setTimeInMillis(long millis)

Parameters

`millis`

The new raw time value for this `Calendar`.

Description

This method sets the raw time value of this `Calendar`. The value is measured as the number of milliseconds since midnight, January 1, 1970 GMT.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Date

Name

Date

Synopsis

Class Name:

`java.util.Date`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `Date` class encapsulates a point in time with millisecond precision. The value of a `Date` is represented internally by a `long` value that contains the number of milliseconds since midnight, January 1, 1970 GMT.

Prior to JDK 1.1, the `Date` class was used for two purposes that are now encapsulated by other classes. First, the `Date` class included methods for calculating calendar values, like months and days of the week. This functionality is now embedded in the `Calendar` class. Second, the `Date` class included methods for generating and parsing a string representation of a date. This functionality is now provided by `java.text.DateFormat`. Thus, as of JDK 1.1, most of the methods of `Date` are deprecated; the class is used only to represent a point in time.

The accurate measurement of time is a subject of considerable complexity and multifarious acronyms. There are two main methods of measuring time, atomic and astronomical. The U.S. Naval Observatory (*http://tycho.usno.navy.mil*) maintains a set of atomic clocks that provide the basis for Coordinated Universal Time (UTC). These clocks adhere to precise definitions of the second based on atomic decay.

Outside of the U.S. Navy, people tend to measure time in terms of Greenwich Mean Time (GMT). In the scientific community, GMT is called UT, which is a system of time predicated on the assumption that each rotation of the earth is exactly 24 * 60 * 60 seconds long. Because the earth's rotation is gradually slowing down, the seconds in UT are a little bit longer than the seconds in UTC. Now and then a "leap second" is added in UTC to keep it close to UT. Because the `Date` class simply measures milliseconds since a point in time, without regard for leap seconds, it is a good representation of UT or GMT.

Class Summary

```
public class java.util.Date extends java.lang.Object
             implements java.lang.Cloneable, java.io.Serializable {
  // Constructors
  public Date();
  public Date(long date);
  public Date(int year, int month, int date);       // Deprecated in 1.1
  public Date(int year, int month, int date,
              int hrs, int min);                    // Deprecated in 1.1
  public Date(int year, int month, int date,
              int hrs, int min, int sec);           // Deprecated in 1.1
  public Date(String s);                            // Deprecated in 1.1
  // Class Methods
  public static long parse(String s);               // Deprecated in 1.1
  public static long UTC(int year, int month,
                         int date, int hrs,
                         int min, int sec);         // Deprecated in 1.1
  // Instance Methods
  public boolean after(Date when);
  public boolean before(Date when);
  public boolean equals(Object obj);
  public int getDate();                             // Deprecated in 1.1
  public int getDay();                              // Deprecated in 1.1
  public int getHours();                            // Deprecated in 1.1
  public int getMinutes();                          // Deprecated in 1.1
  public int getMonth();                            // Deprecated in 1.1
  public int getSeconds();                          // Deprecated in 1.1
  public long getTime();
  public int getTimezoneOffset();                   // Deprecated in 1.1
  public int getYear();                             // Deprecated in 1.1
  public int hashCode();
  public void setDate(int date);                    // Deprecated in 1.1
  public void setHours(int hours);                  // Deprecated in 1.1
  public void setMinutes(int minutes);              // Deprecated in 1.1
  public void setMonth(int month);                  // Deprecated in 1.1
  public void setSeconds(int seconds);              // Deprecated in 1.1
  public void setTime(long time);
  public void setYear(int year);                    // Deprecated in 1.1
  public String toGMTString();                      // Deprecated in 1.1
  public String toLocaleString();                   // Deprecated in 1.1
  public String toString();
}
```

Constructors

Date

public Date()

Description

This constructor creates a `Date` object that is initialized to the current time.

public Date(long date)

Parameters

`date`

A time value, measured as the number of milliseconds since midnight, January 1, 1970 GMT.

Description

This constructor creates a `Date` object that represents the given time.

public Date(int year, int month, int day)

Availability

Deprecated as of JDK 1.1

Parameters

`year`

The year specified as a value that is added to 1900 to get the actual year.

`month`

The month specified in the range 0 to 11.

`day`

The day of the month specified in the range 1 to 31.

Description

This constructor creates a `Date` that represents midnight local time on the specified date.

public Date(int year, int month, int day, int hrs, int min)

Availability

Deprecated as of JDK 1.1

Parameters

`year`

The year specified as a value that is added to 1900 to get the actual year.

`month`

The month specified in the range 0 to 11.

`day`

The day of the month specified in the range 1 to 31.

`hrs`

The hours specified in the range 0 to 23.

`min`

The minutes specified in the range 0 to 59.

Description

This constructor creates a `Date` that represents the given date and time.

`public Date(int year, int month, int day, int hrs, int min, int sec)`

Availability

Deprecated as of JDK 1.1

Parameters

`year`

The year specified as a value that is added to 1900 to get the actual year.

`month`

The month specified in the range 0 to 11.

`day`

The day of the month specified in the range 1 to 31.

`hrs`

The hours specified in the range 0 to 23.

`min`

The minutes specified in the range 0 to 59.

`sec`

The seconds specified in the range 0 to 59.

Description

This constructor creates a `Date` that represents the given date and time.

public Date(String s)

Availability

Deprecated as of JDK 1.1

Parameters

`s`

The string to parse.

Description

This constructor creates a `Date` that represents the date and time specified by the given string. The syntax of the date in the string must satisfy the requirements of the `parse()` method. The following is an example of a string that this constructor can understand:

```
Sat, 8 Feb 1997 13:30:00 GMT
```

Class Methods

parse

public static long parse(String s)

Availability

Deprecated as of JDK 1.1

Parameters

`s`

The string to parse.

Returns

A time value represented as the number of milliseconds since midnight, January 1, 1970 GMT.

Throws

`IllegalArgumentException`

If the string cannot be parsed.

Description

This method returns the raw time value specified by the given string. This method understands a number of different formats. The following are examples of strings that this method can understand:

```
Sat, 8 Feb 1997 13:30:00 GMT
4/6/97
4/6/1997
January 5, 1997
2/4/97 11:03 AM
2/4/97 10:25 PM
2/4/97 17:03 GMT-6
2/4/97 17:03:24
March 16, 97 17:03 EST
March (comment)16, 97 (comment) 17:03 EST
16 march 1996 17:03 pdt
```

```
Sat 16 march 97 17:03 cst
```

The JDK 1.0.2 implementation of `parse()` has a serious bug. It incorrectly interprets date formats that specify the month as a number by making the month one greater than it should be. So `2/4/97` is incorrectly interpreted as March 4, 1997.

For the purposes of this method, UTC and GMT are considered equivalent.

UTC

`public static long UTC(int year, int month, int date, int hrs, int min, int sec)`

Availability

Deprecated as of JDK 1.1

Parameters

`year`

The year specified as a value that is added to 1900 to get the actual year.

`month`

The month specified in the range 0 to 11.

`day`

The day of the month specified in the range 1 to 31.

`hrs`

The hours specified in the range 0 to 23.

`min`

The minutes specified in the range 0 to 59.

`sec`

The seconds specified in the range 0 to 59.

Returns

A time value represented as the number of milliseconds since midnight, January 1, 1970 GMT.

Description

This method returns a raw time value that corresponds to the given parameters. Computations are based on GMT, not the local time zone.

Instance Methods

after

public boolean after(Date when)

Parameters

`when`

The object to compare to this `Date`.

Returns

`true` if this object is after `when`; `false` otherwise.

Description

This method returns `true` if the value of `when` falls before the value of this `Date`.

before

public boolean before(Date when)

Parameters

`when`

The object to compare to this `Date`.

Returns

`true` if this object is before `when`; `false` otherwise.

Description

This method returns `true` if the value of `when` falls after the value of this `Date`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `when` is an instance of `Date` and it contains the same value as the object this method is associated with. In other words, the two `Date` objects are equal only if they both represent the same point in time, to the millisecond.

getDate

public int getDate()

Availability

Deprecated as of JDK 1.1

Returns

The day of the month of this `Date`.

Description

This method returns the day of the month represented by this `Date` object. The value is in the range 1 to 31.

getDay

public int getDay()

Availability

Deprecated as of JDK 1.1

Returns

The day of the week of this `Date`.

Description

This method returns the day of the week represented by this `Date` object. The value is in the range 0 to 6, where 0 means Sunday.

getHours

public int getHours()

Availability

Deprecated as of JDK 1.1

Returns

The hour value of this `Date`.

Description

This method returns the hour represented by this `Date` object. The value is in the range 0 to 23, where 0 means midnight.

getMinutes

public int getMinutes()

Availability

Deprecated as of JDK 1.1

Returns

The minute value of this `Date`.

Description

This method returns the number of minutes after the hour represented by this `Date` object. The value is in the range 0 to 59.

getMonth

public int getMonth()

Availability

Deprecated as of JDK 1.1

Returns

The month of this `Date`.

Description

This method returns the month represented by this `Date` object. The value is in the range 0 to 11, where 0 means January.

getSeconds

public int getSeconds()

Availability

Deprecated as of JDK 1.1

Returns

The second value of this `Date`.

Description

This method returns the number of seconds after the minute represented by this `Date` object. The value is in the range 0 to 59.

getTime

public long getTime()

Returns

The raw time value of this `Date`.

Description

This method returns the date and time of this `Date` as the number of milliseconds since midnight, January 1, 1970 GMT.

getTimezoneOffset

public int getTimezoneOffset()

Availability

Deprecated as of JDK 1.1

Returns

The time zone offset for this `Date`.

Description

This method returns the number of minutes between the local time zone and GMT for this `Date` object.

getYear

public int getYear()

Availability

Deprecated as of JDK 1.1

Returns

The year of this `Date`.

Description

This method returns the year represented by this `Date` object. The value is the number of years since 1990.

hashCode

public int hashCode()

Returns

The hashcode for this `Date`.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this object.

setDate

public void setDate(int date)

Availability

Deprecated as of JDK 1.1

Parameters

`date`

The day of the month specified in the range 1 to 31.

Description

This method sets the day of the month of this `Date` object.

setHours

public void setHours(int hours)

Availability

Deprecated as of JDK 1.1

Parameters

`hours`

The hours specified in the range 0 to 23.

Description

This method sets the hour of this `Date` object.

setMinutes

public void setMinutes(int minutes)

Availability

Deprecated as of JDK 1.1

Parameters

`minutes`

The minutes specified in the range 0 to 59.

Description

This method sets the minute value of this `Date` object.

setMonth

public void setMonth(int month)

Availability

Deprecated as of JDK 1.1

Parameters

`month`

The month specified in the range 0 to 11.

Description

This method sets the month of this `Date` object

setSeconds

public void setSeconds(int seconds)

Availability

Deprecated as of JDK 1.1

Parameters

`seconds`

The seconds specified in the range 0 to 59.

Description

This method sets the second value of this `Date` object.

setTime

public void setTime(long time)

Parameters

`time`

A time value specified as the number of milliseconds since midnight, January 1, 1970 GMT.

Description

This method sets the date and time represented by this `Date` to the given raw time value.

setYear

public void setYear(int year)

Availability

Deprecated as of JDK 1.1

Parameters

`year`

The year specified as a value that is added to 1900 to get the actual year.

Description

This method sets the year of this `Date` object.

toGMTString

public String toGMTString()

Availability

Deprecated as of JDK 1.1

Returns

A string that represents this `Date`.

Description

The method returns a string representation of this `Date` object based on Internet GMT conventions. The string is of the form:

```
Sat, 8 Feb 1997 13:30:00 GMT
```

The date is the string is either one or two digits; the rest of the fields always have the width shown. The time zone is always GMT.

toLocaleString

public String toLocaleString()

Availability

Deprecated as of JDK 1.1

Returns

A string that represents this `Date`.

Description

The method returns a string representation of this `Date` based on the conventions of the current locale.

toString

public String toString()

Returns

A string that represents this `Date`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Date`. The string is of the form:

```
Sat Feb 8 2:30:00 MST 1997
```

Inherited Methods

Method	Inherited From	Method	Inherited From

Dictionary

Name

Dictionary

Synopsis

Class Name:

```
java.util.Dictionary
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

```
java.util.Hashtable
```

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

The `Dictionary` class is an `abstract` class that associates keys with values. Any non-`null` object can be used as a key or as a value. Key/value pairs can be stored in a `Dictionary`, and values can be retrieved or removed using their associated keys.

A subclass of `Dictionary` should use the `equals()` method to decide if two keys are equivalent.

Class Summary

```
public abstract class java.util.Dictionary extends java.lang.Object {
  // Instance Methods
  public abstract Enumeration elements();
  public abstract Object get(Object key);
  public abstract boolean isEmpty();
  public abstract Enumeration keys();
  public abstract Object put(Object key, Object value);
  public abstract Object remove(Object key);
  public abstract int size();
}
```

Instance Methods

elements

public abstract Enumeration elements()

Returns

The values in the dictionary as an `Enumeration`.

Description

This method returns an `Enumeration` that iterates through the values in this `Dictionary`.

get

public abstract Object get(Object key)

Parameters

key

The key of the value to retrieve.

Returns

The value that corresponds to this key.

Description

This method returns the value that is associated with the given key.

isEmpty

public abstract boolean isEmpty()

Returns

`true` if there are no values in the `Dictionary`7thinsp;; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not the `Dictionary` is empty.

keys

public abstract Enumeration keys()

Returns

The keys in the dictionary as an `Enumeration`.

Description

This method returns an `Enumeration` that iterates through the keys in this `Dictionary`.

put

public abstract Object put(Object key, Object value)

Parameters

`key`

A key object.

`value`

A value object.

Returns

The previous value associated with the given key or `null` if `key` has not previously been associated with a value.

Throws

`NullPointerException`

If either the key or the value is `null`.

Description

This method associates the given key with the given value in this `Dictionary`.

remove

public abstract Object remove(Object key)

Parameters

`key`

The key of the value to remove.

Returns

The value associated with the given key or `null` if `key` is not associated with a value.

Description

> This method removes a key/value pair from this `Dictionary`. If the given key is not in the `Dictionary`, the method does nothing.

size

public abstract int size()

Returns

> The number of keys in the `Dictionary`.

Description

> This method returns the number of key/value pairs in this `Dictionary`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

GregorianCalendar

Name

GregorianCalendar

Synopsis

Class Name:

`java.util.GregorianCalendar`

Superclass:

`java.util.Calendar`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `GregorianCalendar` class is a subclass of the `abstract Calendar` class. `GregorianCalendar` provides an implementation of the calendar that much of the world uses. `GregorianCalendar` has two eras, `BC` and `AD`.

`GregorianCalendar` provides both Gregorian and Julian dates, depending on the date that is represented by the object. The Gregorian calendar was instituted in October 15, 1582, so any dates before this cut-off time are represented as

Julian dates. Some countries switched from the Julian and the Gregorian calendar after that date, however. The cutoff date can be changed using the `setGregorianChange()` method. When using Julian dates, be aware that this class does not account for the fact that the Julian calendar used March 25 as the beginning of the year. You will have to adjust the year on Julian dates that fall between January 1 and March 24.

You can find a fascinating discussion of the history of Western calendars at *http://barroom.visionsystems.com/serendipity/date/jul_greg.html*.

Class Summary

```
public class java.util.GregorianCalendar extends java.util.Calendar {
  // Constants
  public final static int AD;
  public final static int BC;
  // Constructors
  public GregorianCalendar();
  public GregorianCalendar(TimeZone zone);
  public GregorianCalendar(Locale aLocale);
  public GregorianCalendar(TimeZone zone, Locale aLocale);
  public GregorianCalendar(int year, int month, int date);
  public GregorianCalendar(int year, int month, int date,
                           int hour, int minute);
  public GregorianCalendar(int year, int month, int date,
                           int hour, int minute, int second);
  // Instance Methods
  public void add(int field, int amount);
  public boolean after(Object when);
  public boolean before(Object when);
  public Object clone();
  public boolean equals(Object obj);
  public int getGreatestMinimum(int field);
  public final Date getGregorianChange();
  public int getLeastMaximum(int field);
  public int getMaximum(int field);
  public int getMinimum(int field);
  public synchronized int hashCode();
  public boolean isLeapYear(int year);
  public void roll(int field, boolean up);
  public void setGregorianChange(Date date);
  // Protected Instance Methods
  protected void computeFields();
  protected void computeTime();
}
```

Constants

AD

public final static int AD

Description

A `constant` value that represents the AD era, which stands for *anno Domini*, Latin for "the year of the Lord". People who do not want to measure years with a Christian connotation call this era CE the Common Era.

BC

public final static int BC

Description

A `constant` value that represents the BC era, which stands for *before Christ*, before the birth of Christ. People who do not want to measure years with a Christian connotation call this era BCE, which stands for Before the Common Era.

Constructors

GregorianCalendar

public GregorianCalendar()

Description

This constructor creates `a GregorianCalendar` that represents the current time using the system's default time zone and locale. The default time zone is that returned by `TimeZone.getDefault()`. The default locale is that returned by `Locale.getDefault()`.

public GregorianCalendar(TimeZone zone)

Parameters

`zone`

The `TimeZone` to use.

Description

This constructor creates a `GregorianCalendar` that represents the current time using the supplied time zone and the default locale. The default locale is that returned by `Locale.getDefault()`.

public GregorianCalendar(Locale aLocale)

Parameters

`aLocale`

The `Locale` to use.

Description

This constructor creates a `GregorianCalendar` that represents the current time using the supplied locale and the default time zone. The default time zone is that returned by `TimeZone.getDefault()`.

public GregorianCalendar(TimeZone zone, Locale aLocale)

Parameters

`zone`

The `TimeZone` to use.

`aLocale`

The `Locale` to use.

Description

This constructor creates a `GregorianCalendar` that represents the current time using the supplied time zone and locale.

public GregorianCalendar(int year, int month, int date)

Parameters

`year`

The value for the year field.

`month`

The value for the month field, where 0 represents the first month.

`date`

The value for the day-of-the-month field.

Description

This constructor creates a `GregorianCalendar` that represents the given date in the default time zone and locale. The default time zone is that returned by `TimeZone.getDefault()`. The default locale is that returned by `Locale.getDefault()`.

`public GregorianCalendar(int year, int month, int date, int hour, int minute)`

Parameters

`year`

The value for the year field.

`month`

The value for the month field, where 0 represents the first month.

`date`

The value for the day-of-the-month field.

`hour`

The value for the hour field.

`minute`

The value for the minute field.

Description

This constructor creates a `GregorianCalendar` that represents the given date and time in the default time zone and locale. The default time zone is that returned by `TimeZone.getDefault()`. The default locale is that returned by `Locale.getDefault()`.

`public GregorianCalendar(int year, int month, int date, int hour, int minute, int second)`

Parameters

`year`

The value for the year field.

`month`

The value for the month field, where 0 represents the first month.

`date`

The value for the day-of-the-month field.

`hour`

The value for the hour field.

`minute`

The value for the minute field.

`second`

The value for the second field.

Description

This constructor creates a `GregorianCalendar` that represents the given data and time in the default time zone and locale. The default time zone is that returned by `TimeZone.getDefault()`. The default locale is that returned by `Locale.getDefault()`.

Instance Methods

add

public void add(int field, int amount)

Parameters

`field`

The time field to be modified.

`amount`

The amount to add to the specified field value. This value can be negative.

Throws

`IllegalArgumentException`

If `field` is not a valid time field.

Overrides

`Calendar.add()`

Description

This method adds the given amount to the specified time field. For example, you can compute a date 90 days beyond the current date of this `GregorianCalendar` by calling `add(Calendar.DATE, 90)`.

after

public boolean after(Object when)

Parameters

`when`

The object to compare to this `GregorianCalendar`.

Returns

`true` if this object is after `when`; `false` otherwise.

Overrides

`Calendar.after()`

Description

This method returns `true` if `when` is a `GregorianCalendar` whose value falls before the value of this `GregorianCalendar`.

before

public boolean before(Object when)

Parameters

`when`

The object to compare to this `GregorianCalendar`.

Returns

`true` if this object is before `when`; `false` otherwise.

Overrides

`Calendar.before()`

Description

This method returns `true` if `when` is a `GregorianCalendar` whose value falls after the value of this `GregorianCalendar`.

clone

public Object clone()

Returns

A copy of this `GregorianCalendar`.

Overrides

`Calendar.clone()`

Description

This method creates a copy of this `GregorianCalendar` and returns it. In other words, the returned `GregorianCalendar` has the same time field values and raw time value as this `GregorianCalendar`.

equals

public boolean equals(Object when)

Parameters

`when`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Calendar.equals()`

Description

This method returns `true` if `when` is an instance of `GregorianCalendar`, and it contains the same value as the object this method is associated with.

getGreatestMinimum

public int getGreatestMinimum(int field)

Parameters

`field`

A time field constant.

Returns

The highest minimum value for the given time field.

Overrides

`Calendar.getGreatestMinimum()`

Description

This method returns the highest minimum value for the given time field, if the field has a range of minimum values. If the field has only one minimum value, this method is equivalent to `getMinimum()`. All of the fields in `GregorianCalendar` have only one minimum value.

getGregorianChange

public final Date getGregorianChange()

Returns

The date this `GregorianCalendar` uses as the change date between the Julian and Gregorian calendars.

Description

By default, `GregorianCalendar` considers midnight local time, October 15, 1582, to be the date when the Gregorian calendar was adopted. This value can be changed using `setGregorianChange()`.

getLeastMaximum

public int getLeastMaximum(int field)

Parameters

`field`

A time field constant.

Returns

The lowest maximum value for the given time field.

Overrides

`Calendar.getLeastMaximum()`

Description

This method returns the lowest maximum value for the given time field, if the field has a range of maximum values. If the field has only one maximum value, this method is equivalent to `getMaximum()`. For example, for a `GregorianCalendar`, the lowest maximum value of `DATE_OF_MONTH` is 28.

getMaximum

public int getMaximum(int field)

Parameters

`field`

A time field constant.

Returns

The maximum value for the given time field.

Overrides

`Calendar.getMaximum()`

Description

This method returns the maximum value for the given time field. For example, for a `GregorianCalendar`, the maximum value of `DATE_OF_MONTH` is 31.

getMinimum

public int getMinimum(int field)

Parameters

`field`

A time field constant.

Returns

The minimum value for the given time field.

Overrides

`Calendar.getMinimum()`

Description

This method returns the minimum value for the given time field. For example, for a `GregorianCalendar`, the minimum value of `DATE_OF_MONTH` is 1.

hashCode

public synchronized int hashCode()

Returns

A hashcode for this `GregorianCalendar`.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this object.

isLeapYear

public boolean isLeapYear(int year)

Parameters

`year`

The year to test.

Returns

`true` if the given year is a leap year; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not the specified year is a leap year. Leap years are those years that are divisible by 4, except those that are divisible by 100, unless they are divisible by 400. For example, 1900 is not a leap year because it is divisible by 100 but not by 400. The year 2000 is a leap year.

roll

public void roll(int field, boolean up)

Parameters

`field`

The time field to be adjusted.

`up`

A `boolean` value that indicates if the given field should be incremented.

Throws

`IllegalArgumentException`

If `field` is not a valid time field.

Overrides

`Calendar.roll()`

Description

This method adds or subtracts one time unit from the given time field. For example, to increase the current date by one day, you can call `roll(GregorianCalendar.DATE, true)`.

The method maintains the field being rolled within its valid range. For example, in a calendar system that uses hours and minutes to measure time, rolling the minutes up from 59 sets that field to 0. By the same token, rolling that field down from 0 sets it to 59.

The `roll()` method does not adjust the value of any other field than the one specified by its `field` argument. In particular, for calendar systems that have months with different numbers of days, it may be necessary to adjust the month and also year when the day of the month is rolled up. For example, calling `roll(GregorianCalendar.DAY_OF_MONTH, true)` on a `GregorianCalendar` that represents December 31, 1996 changes the date to December 1, 1996. In addition, calling `roll()` may make the fields inconsistent. For example, calling `roll(GregorianCalendar.MONTH, true)` on a `GregorianCalendar` that represents January 31, 1997 changes the date to February 31, 1997. It is the responsibility of the caller of `roll()` to adjust the other fields.

setGregorianChange

public void setGregorianChange(Date date)

Parameters

`date`

A `Date` object that represents the new time value.

Description

This method sets the date that this `GregorianCalendar` uses as the change date between the Julian and Gregorian calendars. The default is midnight local time, October 15, 1582. This is the date that Pope Gregory instituted the calendar in many Catholic countries in Europe. Most Catholic countries followed within a few years. Protestant England and America did not adopt the new calendar until September 14, 1752.

Protected Instance Methods

computeFields

protected void computeFields()

`Overrides`

`Calendar.computeFields()`

Description

This method calculates the time fields of this `GregorianCalendar` from its raw time value.

computeTime

protected void computeTime()

`Overrides`

`Calendar.computeTime()`

Description

This method calculates the raw time value of this `GregorianCalendar` from its time field values.

Hashtable

Name

Hashtable

Synopsis

Class Name:

`java.util.Hashtable`

Superclass:

`java.util.Dictionary`

Immediate Subclasses:

`java.util.Properties`

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The Hashtable class is a concrete subclass of Dictionary that builds a table of key/value pairs. Any non-null object can be used as a key or as a value. The objects used as keys must implement the equals() and hashCode() methods in a way that computes comparisons and hashcodes from the contents of an object. Once the table is built, a value can be efficiently retrieved by supplying its associated key.

Hashtable is an excellent example of how a well-written class can hide an arcane algorithm. The casual user simply instantiates a Hashtable and uses put() and get() to add and retrieve key and value pairs. However, when performance is an issue, you need to be aware of the considerations discussed in the following paragraphs.

Internally, a Hashtable keeps an array of key/value pairs. When a new key/value pair is added to a Hashtable, it is added to the array at an index that is calculated from the hashcode of the key. If a key/value pair already exists at this index, the new pair is linked to the existing key and value. Thus, a Hashtable has an overall structure of an array of linked lists.

For a given key, the retrieval of the matching value from a Hashtable is quite fast. The Hashtable computes the hashcode of the key and uses it as an index into the array. Then it only needs to search the linked list of key/value pairs at that index to find a match for the given key. If the array is short, but the Hashtable contains many key/value pairs, however, the linked lists will be lengthy, which adversely affects performance.

A Hashtable has a capacity, which is the length of its array, and a load factor, which determines when rehashing is performed. The load factor is a number between 0 and 1. If the number of key/value pairs added to the Hashtable exceeds the capacity multiplied by the load factor, the capacity of the Hashtable is increased and the key/value pairs are rehashed into the new array. Obviously, this is an undesirable performance hit, so if you know approximately how many items you will add to a Hashtable, you should create one with an appropriate initial capacity.

Class Summary

```
public class java.util.Hashtable extends java.util.Dictionary
             implements java.lang.Cloneable, java.io.Serializable {
  // Constructors
  public Hashtable();
  public Hashtable(int initialCapacity);
  public Hashtable(int initialCapacity, float loadFactor);
  // Instance Methods
  public synchronized void clear();
  public synchronized Object clone();
  public synchronized boolean contains(Object value);
  public synchronized boolean containsKey(Object key);
  public synchronized Enumeration elements();
  public synchronized Object get(Object key);
  public boolean isEmpty();
  public synchronized Enumeration keys();
  public synchronized Object put(Object key, Object value);
  public synchronized Object remove(Object key);
  public int size();
  public synchronized String toString();
  // Protected Instance Methods
  protected void rehash();
}
```

Constructors

Hashtable

public Hashtable()

Description

> This constructor creates a `Hashtable` with a default capacity of 101 and a default load factor of .75.

public Hashtable(int initialCapacity)

Parameters

> `initialCapacity`
>
> > The initial capacity.

Throws

> `IllegalArgumentException`
>
> > If `initialCapacity` is less than or equal to zero.

Description

This constructor creates a `Hashtable` with the given capacity and a default load factor of .75.

public Hashtable(int initialCapacity, float loadFactor)

Parameters

`initialCapacity`

The initial capacity.

`loadFactor`

The load factor.

Throws

`IllegalArgumentException`

If `initialCapacity` or `loadFactor` is less than or equal to zero.

Description

This constructor creates a `Hashtable` with the given capacity and load factor.

Instance Methods

clear

public synchronized void clear()

Description

This method removes all of the key/value pairs from this `Hashtable`.

clone

public synchronized Object clone()

Returns

A copy of this `Hashtable`.

Overrides

`Object.clone()`

Description

This method returns a shallow copy of this `Hashtable`. This means that the internal array of the `Hashtable` is copied, but the keys and values themselves are not copied.

contains

public synchronized boolean contains(Object value)

Parameters

`value`

The value to find.

Returns

`true` if this `Hashtable` contains the given value; `false` otherwise.

Throws

`NullPointerException`

If the given value is `null`.

Description

This method returns `true` if the given value is contained in this `Hashtable` object. The entire table is searched, which can be a time-consuming operation.

containsKey

public synchronized boolean containsKey(Object key)

Parameters

`key`

The key to find.

Returns

`true` if this `Hashtable` contains the given value; `false` otherwise.

Description

This method returns `true` if the given key is contained in this `Hashtable` object. Because the key is hashed to perform the search, this method runs quite fast, especially in comparison to `contains()`.

elements

public synchronized Enumeration elements()

Returns

The values in this `Hashtable` as an `Enumeration`.

Overrides

`Dictionary.elements()`

Description

This method returns an `Enumeration` that iterates through the values in this `Hashtable`.

get

public synchronized Object get(Object key)

Parameters

`key`

The key of the value to retrieve.

Returns

The value that corresponds to this key or `null` if the key is not associated with any value.

Overrides

`Dictionary.get()`

Description

This method returns the value that is associated with the given key.

isEmpty

public boolean isEmpty()

Returns

`true` if there are no values in the `Hashtable`; `false` otherwise.

Overrides

`Dictionary.isEmpty()`

Description

This method returns a `boolean` value that indicates whether or not the `Hashtable` is empty.

keys

public synchronized Enumeration keys()

Returns

The keys in the `Hashtable` as an `Enumeration`.

Overrides

`Dictionary.keys()`

Description

This method returns an `Enumeration` that iterates through the keys in this `Hashtable`.

put

public synchronized Object put(Object key, Object value)

Parameters

`key`

A key object.

`value`

A value object.

Returns

The previous value associated with the given key or `null` if `key` has not previously been associated with a value.

Throws

`NullPointerException`

If either the key or the value is `null`.

Overrides

`Dictionary.put()`

Description

This method associates the given key with the given value in this `Hashtable`.

remove

public synchronized Object remove(Object key)

Parameters

`key`

A key of the value to remove.

Returns

The value associated with the given key, or `null` if `key` is not associated with a value.

Overrides

`Dictionary.remove()`

Description

This method removes a key/value pair from this `Hashtable`. If the given key is not in the `Hashtable`, the method does nothing.

size

public int size()

Returns

The number of key in the `Hashtable`.

Overrides

`Dictionary.size()`

Description

This method returns the number of key/value pairs in the `Hashtable`.

toString

public String toString()

Returns

A string that represents this `Hashtable`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Hashtable`. The string includes every key/value pair that is contained in the `Hashtable`, so the string returned by `toString()` can be quite long.

Protected Instance Methods

rehash

protected void rehash()

Description

This method increases the capacity of this `Hashtable`. A larger internal array is created and all existing key/value pairs are rehashed into the new array.

Inherited Methods

Method	Inherited From	Method	Inherited From
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Locale

Name

Locale

Synopsis

Class Name:

`java.util.Locale`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The `Locale` class is used for internationalization. Instances of `Locale` specify language and formatting customs by identifying a language and a country. A `Locale` object may also specify a platform-specific variant. Other classes throughout the JDK use `Locale` objects to determine how to represent themselves to the user. The tasks performed by these classes are called locale-sensitive tasks; the tasks should be done in a way that conforms with the conventions of a particular country and language.

There are a number of classes provided with Java that have `static` methods that create instances of locale-specific subclasses. For example, the `NumberFormat` class contains `static` methods named `getInstance()` that create and return locale-specific instances of subclasses of `NumberFormat`. A particular `NumberFormat` instance knows how to format numbers, currency values, and percentages appropriately for a particular locale. Note that it is the responsibiity of a class like `NumberFormat` to implement the logic needed to translate locale-identifying information into actual subclass instances.

Classes like `NumberFormat` that can create locale-specific instances are expected to follow certain conventions:

- Methods like `getInstance()` in `NumberFormat` are expected to have two variants: one that takes a `Locale` argument and one that does not. The variant that does not take a locale argument is expected to use the default locale, which is normally determined by calling `Locale.getDefault()`.

- Classes that can create a variety of locale-specific instances are expected to implement a method that has the following signature:

  ```
  public static Locale[] getAvailableLocales()
  ```

  This requirement is not specified through an interface declaration because interfaces cannot declare `static` methods. The purpose of this method is to facilitate presenting the user with a list or menu of locale choices. The `getAvailableLocales()` method should return an array of `Locale` objects that identifies all of the locales for which the class can create locale-specific instances.

  Two additional methods are recommended for helping to display the locale choices:

  ```
  public static final String getDisplayName(Locale objectLocale)
  public static String getDisplayName(Locale objectLocale,
                                      Locale displayLocale)
  ```

  The first form of `getDisplayName()` should return a description of `objectLocale` that is suitable for display in the default locale. The second form should return a description of `objectLocale` that is suitable for display in the locale specified by `displayLocale`. Implementations of these methods generally call the `getDisplayName()` method of the `Locale` object.

The language, country and variant information that are encapsulated by a `Locale` object are specified to a constructor as strings. The language for a `Locale` should be specified as one of the two-letter lowercase language codes defined by ISO-639. Look for a complete list at *http://www.ics.uci.edu/pub/ietf/http/related/iso639.txt*.

The country for a `Locale` object should be specified as either `""` to indicate that no country is specified, or as one of the two-letter uppercase country codes defined by ISO-3166. Check the site, *http://www.chemie.fu-berlin.de/diverse/doc/ISO_3166.html*, for a complete list

Variant codes are platform-specific.

Although the `Locale` is constructed from these three types of codes, human-readable names can be obtained by calling `getDisplayLanguage()`, `getDisplayCountry()`, and `getDisplayVariant()`.

The `Locale` class defines a number of constant `Locale` objects that represent some of the major languages and countries of the world.

Class Summary

```
public abstract class java.util.Locale extends java.lang.Object
                      implements java.lang.Cloneable, java.io.Serializable {

  public final String getDisplayVariant();
  public String getDisplayVariant(Locale inLocale);
  public String getISO3Country();
  public String getISO3Language();
  public String getLanguage();
  public String getVariant();
  public synchronized int hashCode();
  public final String toString();
}
```

Constants

CANADA

public final static Locale CANADA

Description

> A locale that represents English-speaking Canada.

CANADA_FRENCH

public final static Locale CANADA_FRENCH

Description

> A locale that represents French-speaking Canada.

CHINA

public final static Locale CHINA

Description

A locale that represents China.

CHINESE

public final static Locale CHINESE

Description

A locale that represents the Chinese language.

ENGLISH

public final static Locale ENGLISH

Description

A locale that represents the English language.

FRANCE

public final static Locale FRANCE

Description

A locale that represents France.

FRENCH

public final static Locale FRENCH

Description

A locale that represents the French language.

GERMAN

public final static Locale GERMAN

Description

A locale that represents the German language.

GERMANY

public final static Locale GERMANY

Description

A locale that represents Germany.

ITALIAN

public final static Locale ITALIAN

Description

A locale that represents the Italian language.

ITALY

public final static Locale ITALY

Description

A locale that represents Italy.

JAPAN

public final static Locale JAPAN

Description

A locale that represents Japan.

JAPANESE

public final static Locale JAPANESE

Description

A locale that represents the Japanese language.

KOREA

public final static Locale KOREA

Description

A locale that represents Korea.

KOREAN

public final static Locale KOREAN

Description

A locale that represents the Korean language.

PRC

public final static Locale PRC

Description

A locale that represents the People's Republic of China. It is equivalent to `CHINA`.

SIMPLIFIED_CHINESE

public final static Locale SIMPLIFIED_CHINESE

Description

A locale that represents the Chinese language as used in mainland China.

TAIWAN

public final static Locale TAIWAN

Description

A locale that represents Taiwan.

TRADITIONAL_CHINESE

public final static Locale TRADITIONAL_CHINESE

Description

A locale that represents the Chinese language as used in Taiwan.

UK

public final static Locale UK

Description

A locale that represents the United Kingdom.

US

public final static Locale US

Description

A locale that represents the United States.

Constructors

Locale

public Locale(String language, String country)

Parameters

`language`

A two-letter ISO-639 language code.

`country`

A two-letter ISO-3166 country code or `""` to omit the country specification.

Description

This constructor creates a `Locale` that represents the given language and country.

public Locale(String language, String country, String variant)

Parameters

`language`

A two-letter ISO-639 language code.

`country`

A two-letter ISO-3166 country code or `""` to omit the country specification.

`variant`

A vendor-specific variant code.

Description

This constructor creates a `Locale` that represents the given language, country, and variant.

Class Methods

getDefault

public static synchronized Locale getDefault()

Returns

The default `Locale`.

Description

This method returns the current default `Locale`. An application or applet uses this method to find out how to present locale-sensitive information, such as textual strings and numbers. The method is generally called during application initialization to get the default `Locale`. Once the locale is set, it almost never changes. If you do change the locale, you should probably reload the GUI for your application, so that any locale-sensitive information in the interface is changed.

The initial default `Locale` is set by the host system.

setDefault

public static synchronized void setDefault(Locale newLocale)

Parameters

`newLocale`

The new default locale.

Description

This method changes the current default locale to `newLocale`. Note that calling `setDefault()` does not change the default locale of the host system.

Instance Methods

clone

public Object clone()

Returns

A copy of this `Locale`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `Locale` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `Locale`, and it contains the same value as the object this method is associated with.

getCountry

public String getCountry()

Returns

`The country of this Locale`.

Description

This method returns a `String` that represents the country of this `Locale`. This `String` is the same `String` that was passed to the constructor of this `Locale` object. The `String` is normally a two-letter ISO-3166 country code.

getDisplayCountry

public final String getDisplayCountry()

Returns

`The country of this Locale`.

Description

This method returns the country of this `Locale` as a country name in a form appropriate for this `Locale`. If the country name cannot be found, this method returns the same value as `getCountry()`.

public String getDisplayCountry(Locale inLocale)

Parameters

`inLocale`

The locale to use when finding the country name.

Returns

The country of this `Locale`, localized to the given locale.

Description

This method returns the country of this `Locale` as a country name in a form appropriate for `inLocale`. For example, `Locale.ITALY.getDisplayCountry(Locale.GERMAN)` returns the German name for Italy, Italien.

getDisplayLanguage

public final String getDisplayLanguage()

Returns

The language of this `Locale`.

Description

This method returns the language of this `Locale` as a language name in a form appropriate for this `Locale`. If the language name cannot be found, this method returns the same value as `getLanguage()`.

public String getDisplayLanguage(Locale inLocale)

Parameters

`inLocale`

The locale to use when finding the language name.

Returns

The language of this `Locale`, localized to the given locale.

Description

This method returns the language of this `Locale` as a language name in a form appropriate for `inLocale`. For example, `Locale.ITALY.getDisplayLanguage(Locale.GERMAN)` returns the German name for the Italian language, Italienisch.

getDisplayName

public final String getDisplayName()

Returns

A string that represents this `Locale`.

Description

This method constructs a string that represents this `Locale` by calling `getDisplayLanguage()`, `getDisplayCountry()`, and `getDisplayVariant()`. In other words, the method returns a string that contains the country name, language name, and variant in a form appropriate for this `Locale`. If any of the names cannot be found, the `String` that was passed to the constructor of this `Locale` object is used instead. These strings are normally two-letter ISO codes.

public String getDisplayName(Locale inLocale)

Parameters

`inLocale`

The locale to use when constructing the string representation.

Returns

A string that represents this `Locale`.

Description

This method constructs a string that represents this `Locale` by calling `getDisplayLanguage(inLocale)`, `getDisplayCountry(inLocale)`, and `getDisplayVariant(inLocale)`. In other words, the method returns a string that contains the country name, language name, and variant in a form appropriate for `inLocale`. If any of the names cannot be found, the `String` that was passed to the constructor of this `Locale` object is used instead. These strings are normally two-letter ISO codes.

getDisplayVariant

public final String getDisplayVariant()

Returns

`The variant of this Locale`.

Description

This method returns the variant of this `Locale` as a human-readable string in a form appropriate for this

Locale. If the variant name cannot be found, this method returns the same value as getVariant().

public String getDisplayVariant(Locale inLocale)

Parameters

inLocale

The locale to use when finding the variant name.

Returns

The variant of this Locale, localized to the given locale.

Description

This method returns the variant of this Locale as a human-readable string in a form appropriate for inLocale.

getISO3Country

public String getISO3Country() throws MissingResourceException

Returns

The ISO three-letter country code of this Locale.

Throws

MissingResourceException

If the requested code cannot be found.

Description

This method returns the country of this Locale as a three-letter ISO country code. The country code is obtained from a ResourceBundle for this Locale.

getISO3Language

public String getISO3Language() throws MissingResourceException

Returns

The ISO three-letter language code of this `Locale`.

Throws

`MissingResourceException`

If the requested code cannot be found.

Description

This method returns the language of this `Locale` as a three-letter ISO language code. The language code is obtained from a `ResourceBundle` for this `Locale`.

getLanguage

public String getLanguage()

Returns

The language of this `Locale`.

Description

This method returns a `String` that represents the language of this `Locale`. This `String` is the same `String` that was passed to the constructor of this `Locale` object. The `String` is normally a two-letter ISO-639 language code.

getVariant

public String getVariant()

Returns

The variant of this `Locale`.

Description

This method returns the variant code of this `Locale`. If no variant code is specified for this `Locale`, an empty string is returned.

hashCode

public synchronized int hashCode()

Returns

A hashcode for this `Locale`.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this object.

toString

public final String toString()

Returns

A string representation of this `Locale`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Locale`, constructed from the language code, country code, and variant code. The various codes are separated by underscore characters. If a code is missing, it is omitted.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Observable

Name

Observable

Synopsis

Class Name:

```
java.util.Observable
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

Subclasses of the `Observable` class are used to implement the model portion of the model-view paradigm. The idea is that an `Observable` object, the model, represents some data that is being manipulated through a user interface, while `Observer` objects provide the user with a view of the data. When the `Observable` object is modified, it tells the `Observer` objects that the model has been modified by calling `notifyObservers()`. An `Observer` object registers with an `Observable` object to receive notifications when the `Observable` is modified. The `Observer` object is then notified of changes via the `update()` method.

Class Summary

```
public class java.util.Observable extends java.lang.Object {
  // Constructors
  public Observable();
  // Instance Methods
  public synchronized void addObserver(Observer o);
  public synchronized int countObservers();
  public synchronized void deleteObserver(Observer o);
  public synchronized void deleteObservers();
  public synchronized boolean hasChanged();
  public void notifyObservers();
  public void notifyObservers(Object arg);
  // Protected Instance Methods
  protected synchronized void clearChanged();
  protected synchronized void setChanged();
}
```

Constructors

Observable

public Observable()

Description

> This constructor `creates an Observable` object with no registered `Observer` objects.

InstanceMethods

addObserver

public synchronized void addObserver(Observer o)

Parameters

o

The `Observer` to be added.

Description

This method registers the given `Observer` with this `Observable` object. The given `Observer` is then notified when `notifyObservers()` is called.

countObservers

public synchronized int countObservers()

Returns

The number of registered `Observer` objects for this `Observable` object.

Description

This method returns the number of `Observer` objects that are registered with this `Observable` object.

deleteObserver

public synchronized void deleteObserver(Observer o)

Parameters

o

The `Observer` to be removed.

Description

This method unregisters the given `Observer` with this `Observable` object. The given `Observer` is no longer notified when `notifyObservers()` is called.

deleteObservers

public synchronized void deleteObservers()

Description

This method unregisters all of the `Observer` objects of this `Observable` object. Thus, no objects are notified if `notifyObservers()` is called.

hasChanged

public synchronized boolean hasChanged()

Returns

`true` if this object has been flagged as changed; `false` otherwise.

Description

This method returns the value of an internal "dirty" flag. The flag can be modified using the `protected` methods `setChanged()` and `clearChanged()`.

notifyObservers

public void notifyObservers()

Description

This method calls the `update()` method of all registered `Observer` objects. The value passed as the second argument to each of the `update()` method calls is `null`.

public void notifyObservers(Object arg)

Parameters

`arg`

A "hint" object that describes a change.

Description

This method calls the `update()` method of all registered `Observer` objects. The value passed as the second argument to each of the `update()` method calls is the given object `arg`.

This "hint" object can be used to efficiently update the views of a model. For example, an `Observable` object could represent satellite image data. A set of `Observer` objects would provide different graphical views of the data. If the model data changes, the `arg` object describes the part of the data that changed, and the `Observer` views could use this "hint" to update only parts of their displays.

Protected Instance Methods

clearChanged

protected synchronized void clearChanged()

Description

This method sets an internal "dirty" flag to `false`. After this method is called, this object's `hasChanged()` method returns `false`.

setChanged

protected synchronized void setChanged()

Description

This method sets an internal "dirty" flag to `true`. After this method is called, this object's `hasChanged()` method returns `true`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`

`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

SimpleTimeZone

Name

SimpleTimeZone

Synopsis

Class Name:

`java.util.SimpleTimeZone`

Superclass:

`java.util.TimeZone`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `SimpleTimeZone` class is a concrete subclass of the `abstract` `TimeZone` class. `SimpleTimeZone` represents a time zone offset for use with `GregorianCalendar`. `SimpleTimeZone` does not take into account the historical vicissitudes of daylight savings time, however. Instead, it assumes that the shifts to and from daylight savings time always occur at the same time of the year.

Normally, `SimpleTimeZone` objects are not created directly, but instead obtained by calling

TimeZone.getDefault(). This method creates a subclass of TimeZone that is appropriate for the current locale. You can also call TimeZone.getTimeZone() to obtain a TimeZone object for a specific time zone.

Class Summary

```
public class java.util.SimpleTimeZone extends java.util.TimeZone {
  // Constructors
  public SimpleTimeZone(int rawOffset, String ID);
  public SimpleTimeZone(int rawOffset, String ID, int startMonth,
                        int startDayOfWeekInMonth, int startDayOfWeek,
                        int startTime, int endMonth, int endDayOfWeekInMonth,
                        int endDayOfWeek, int endTime);
  // Instance Methods
  public Object clone();
  public boolean equals(Object obj);
  public int getOffset(int era, int year, int month, int day,
                       int dayOfWeek, int millis);
  public int getRawOffset();
  public synchronized int hashCode();
  public boolean inDaylightTime(Date date);
  public void setEndRule(int month, int dayOfWeekInMonth,
                         int dayOfWeek, int time);
  public void setRawOffset(int offsetMillis);
  public void setStartRule(int month, int dayOfWeekInMonth,
                           int dayOfWeek, int time);
  public void setStartYear(int year);
  public boolean useDaylightTime();
}
```

Constructors

SimpleTimeZone

public SimpleTimeZone(int rawOffset, String ID)

Parameters

rawOffset

The raw offset of this time zone from GMT, in milliseconds.

ID

The ID of this time zone.

Description

This constructor creates a SimpleTimeZone that uses the given offset from GMT and has the specified ID. This constructor creates a `SimpleTimeZone` that does not use daylight savings time.

`public SimpleTimeZone(int rawOffset, String ID, int startMonth, int startDayOfWeekInMonth, int startDayOfWeek, int startTime, int endMonth, int endDayOfWeekInMonth, int endDayOfWeek, int endTime)`

Parameters

`rawOffset`

The raw offset of this time zone from GMT, in milliseconds.

`ID`

The ID of this time zone.

`startMonth`

The month when daylight savings time begins.

`startDayOfWeekInMonth`

The week in the month when daylight savings time begins.

`startDayOfWeek`

The day of the week when daylight savings time begins.

`startTime`

The time of day when daylight savings time begins, in milliseconds.

`endMonth`

The month when daylight savings time ends.

`endDayOfWeekInMonth`

The week in the month when daylight savings time ends.

`endDayOfWeek`

The day of the week when daylight savings time ends.

`endTime`

The time of day when daylight savings time ends, in milliseconds.

Description

This constructor creates a `SimpleTimeZone` that uses the given offset from GMT, has the specified ID, and uses daylight savings time. Daylight savings time begins and ends at the specified dates and times.

For example, Brazil Eastern Time (BET) is three hours behind GMT. Daylight savings time for BET starts on the first Sunday in April at 2:00 AM, and ends on the last Sunday in October, also at 2:00 A.M. To construct a `TimeZone` that represents BET, you would use the following:

```
new SimpleTimeZone(-3 * 60 * 60 * 1000, "BET",
                   Calendar.APRIL, 1,
                   Calendar.SUNDAY, 2 * 60 * 60 * 1000,
                   Calendar.OCTOBER, -1,
                   Calendar.SUNDAY, 2 * 60 * 60 * 1000)
```

Instance Methods

clone

public Object clone()

Returns

A copy of this `SimpleTimeZone`.

Overrides

`TimeZone.clone()`

Description

This method creates a copy of this `SimpleTimeZone` and returns it.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `SimpleTimeZone`, and it contains the same value as the object this method is associated with.

getOffset

`public int getOffset(int era, int year, int month, int day, int dayOfWeek, int millis)`

Parameters

`era`

The era.

`year`

The year.

`month`

The month.

`day`

The day.

`dayOfWeek`

The day of the week.

`millis`

The time of day in milliseconds.

Returns

An offset from GMT, in milliseconds.

Overrides

`TimeZone.getOffset()`

Description

This method calculates an offset from GMT for the given date for this `SimpleTimeZone`. In other words, the offset takes daylight savings time into account. The return value should be added to GMT to get local time.

getRawOffset

public int getRawOffset()

Returns

An offset from GMT, in milliseconds.

Overrides

`TimeZone.getRawOffset()`

Description

This method returns the raw offset from GMT for this `SimpleTimeZone`. In other words, the offset does not take daylight savings time into account.

hashCode

public synchronized int hashCode()

Returns

A hashcode for this SimpleTimeZone.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this object.

inDaylightTime

public boolean inDaylightTime(Date date)

Parameters

`date`

The date to be tested.

Returns

`true` if the given date is between the start and end of daylight savings time for this `SimpleTimeZone`; `false` otherwise.

Overrides

`TimeZone.inDaylightTime()`

Description

This method returns a `boolean` value that indicates if the given date is in daylight savings time for this `SimpleTimeZone`.

setEndRule

`public void setEndRule(int month, int dayOfWeekInMonth, int dayOfWeek, int time)`

Parameters

`month`

The month when daylight savings time ends.

`DayOfWeekInMonth`

The week of the month when daylight savings time ends.

`dayOfWeek`

The day of the week when daylight savings time ends.

`time`

The time of day when daylight savings time ends, in milliseconds.

Description

This method sets the time when daylight savings time ends for this `SimpleTimeZone`. For example, to set the end of daylight savings time to 2 A.M. on the last Sunday in October, you would use the following:

```
setEndRule(Calendar.OCTOBER, -1, Calendar.SUNDAY,
           2 * 60 * 60 * 1000)
```

setRawOffset

public void setRawOffset(int offsetMillis)

Parameters

`offsetMillis`

The new raw offset from GMT, in milliseconds.

Overrides

`TimeZone.setRawOffset()`

Description

This method is used to set the raw offset value for this `SimpleTimeZone`.

setStartRule

```
public void setStartRule(int month, int dayOfWeekInMonth, int dayOfWeek, int time)
```

Parameters

`month`

The month when daylight savings time begins.

`DayOfWeekInMonth`

The week of the month when daylight savings time begins.

`dayOfWeek`

The day of the week when daylight savings time begins.

`time`

The time of day when daylight savings time begins, in milliseconds.

Description

This method sets the time when daylight savings time begins for this `SimpleTimeZone`. For example, to set the beginning of daylight savings time to 2 A.M. on the first Sunday in April, you would use the following:

```
setEndRule(Calendar.APRIL, 1, Calendar.SUNDAY,
           2 * 60 * 60 * 1000)
```

setStartYear

public void setStartYear(int year)

Parameters

`year`

The year when daylight savings time begins.

Description

This method sets the year after which the start and end rules for daylight savings time are observed.

useDaylightTime

public boolean useDaylightTime()

Returns

`true` if this `SimpleTimeZone` uses daylight savings time; `false` otherwise.

Overrides

`TimeZone.useDaylightTime()`

Description

This method returns a `boolean` value that indicates whether or not this `SimpleTimeZone` uses daylight savings time.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`getID()`	`TimeZone`	`notify()`	`Object`
`notifyAll()`	`Object`	`setID()`	`TimeZone`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

StringTokenizer

Name

StringTokenizer

Synopsis

Class Name:

```
java.util.StringTokenizer
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

```
java.util.Enumeration
```

Availability:

JDK 1.0 or later

Description

The StringTokenizer class implements a simple, delimiter-based string tokenizer. In other words, a StringTokenizer is used to break a String into tokens separated by delimiter characters. By default, the class uses the standard whitespace characters as delimiters, but you can specify any delimiter characters you want, either when the StringTokenizer is created or on a token-by-token basis. You can also specify whether the delimiters are returned as tokens or not. A StringTokenizer returns the tokens in its String in order, either as String objects or as Objects in an Enumeration.

StringTokenizer shouldn't be confused with the more complex java.io.StreamTokenizer, which parses a stream into tokens that are similar to those used in the Java language.

Class Summary

```
public class java.util.StringTokenizer extends java.lang.Object
             implements java.util.Enumeration {
  // Constructors
  public StringTokenizer(String str);
  public StringTokenizer(String str, String delim);
  public StringTokenizer(String str, String delim, boolean returnTokens);
  // Instance Methods
  public int countTokens();
  public boolean hasMoreElements();
  public boolean hasMoreTokens();
  public Object nextElement();
  public String nextToken();
  public String nextToken(String delim);
}
```

Constructors

StringTokenizer

public StringTokenizer(String str)

Parameters

    str

        The String to be tokenized.

Description

This constructor creates a `StringTokenizer` that breaks apart the given string using the default delimiter characters. The default delimiters are the standard whitespace characters: space, tab (`\t`), carriage return (`\r`), and newline (`\n`).

public StringTokenizer(String str, String delim)

Parameters

`str`

The `String` to be tokenized.

`delim`

The delimiter characters.

Description

This constructor creates a `StringTokenizer` that breaks apart the given string using the characters in `delim` as delimiter characters.

`public StringTokenizer(String str, String delim, boolean returnTokens)`

Parameters

`str`

The `String` to be tokenized.

`delim`

The delimiter characters.

`returnTokens`

A `boolean` value that indicates whether or not delimiters should be returned as tokens.

Description

This constructor creates a `StringTokenizer` that breaks apart the given string using the characters in `delim` as delimiter characters. If `returnTokens` is `true`, the delimiters are returned as tokens; otherwise they are skipped.

Instance Methods

countTokens

public int countTokens()

Returns

> The number of tokens remaining in the string.

Description

> This method returns the number of tokens that remain in the string, which is the same as the number of times `nextToken()` can be called before an exception is thrown.

hasMoreElements

public boolean hasMoreElements()

Returns

> `true` if there are more tokens to be returned; `false` otherwise.

Implements

> `Enumeration.hasMoreElements()`

Description

> This method returns the result of calling `hasMoreTokens()`.

hasMoreTokens

public boolean hasMoreTokens()

Returns

> `true` if there are more tokens to be returned; `false` otherwise.

Description

This method returns `true` if this object has more tokens to return.

nextElement

public Object nextElement()

Returns

The next token as an `Object`.

Throws

`NoSuchElementException`

If there are no more tokens in the string.

Implements

`Enumeration.nextElement()`

Description

This method returns result of calling `nextToken()`.

nextToken

public String nextToken()

Returns

The next token as a `String`.

Throws

`NoSuchElementException`

If there are no more tokens in the string.

Description

This method returns the next token.

public String nextToken(String delim)

Parameters

delim

The delimiter characters.

Returns

The next token as a String.

Throws

NoSuchElementException

If there are no more tokens in the string.

Description

This method sets the delimiter characters to the characters in the given string and then returns the next token. The change in delimiters persists until another call to this method changes them again.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	equals(Object)	Object
finalize()	Objxect	getClass()	Object
hashCode()	Object	notify()	Object
notifyAll()	Object	toString()	Object
wait()	Object	wait(long)	Object
wait(long, int)	Object

TimeZone

Name

TimeZone

Synopsis

Class Name:

`java.util.TimeZone`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.util.SimpleTimeZone`

Interfaces Implemented:

`java.io.Serializable`, `java.lang.Cloneable`

Availability:

New as of JDK 1.1

Description

The `TimeZone` class is an `abstract` class that represents a time zone offset. In addition, the class incorporates knowledge about daylight savings time. Usually, you get a `TimeZone` object by calling `getDefault()`. This method creates a `TimeZone` that is appropriate for the current locale. You can also call `getTimeZone()` to obtain a `TimeZone` object for a specific time zone.

Class Summary

```
public abstract class java.util.TimeZone extends java.lang.Object
                      implements java.io.Serializable, java.lang.Cloneable {
  // Class Methods
  public static synchronized String[] getAvailableIDs();
  public static synchronized String[] getAvailableIDs(int rawOffset);
  public static synchronized TimeZone getDefault();
  public static synchronized TimeZone getTimeZone(String ID);
  public static synchronized void setDefault(TimeZone zone);
  // Instance Methods
  public Object clone();
  public String getID();
  public abstract int getOffset(int era, int year, int month,
                               int day, int dayOfWeek, int milliseconds);
  public abstract int getRawOffset();
  public abstract boolean inDaylightTime(Date date);
  public void setID(String ID);
  public abstract void setRawOffset(int offsetMillis);
  public abstract boolean useDaylightTime();
}
```

Class Methods

getAvailiableIDs

public static synchronized String[] getAvailableIDs()

Returns

An array of strings that contains the predefined time zone IDs.

Description

This method returns a list of the predefined time zone IDs. Time zones are defined for the following ID values, starting from Greenwich, England, and progressing eastward around the world:

GMT	Greenwich Mean Time
ECT	European Central Time
EET	Eastern European Time
ART	(Arabic) Egypt Standard Time
EAT	Eastern African Time
MET	Middle East Time
NET	Near East Time
PLT	Pakistan Lahore Time
IST	India Standard Time
BST	Bangladesh Standard Time
VST	Vietnam Standard Time

CTT	China Taiwan Time
JST	Japan Standard Time
ACT	Australia Central Time
AET	Australia Eastern Time
SST	Solomon Standard Time
NST	New Zealand Standard Time
MIT	Midway Islands Time
HST	Hawaii Standard Time
AST	Alaska Standard Time
PST	Pacific Standard Time
PNT	Phoenix Standard Time
MST	Mountain Standard Time
CST	Central Standard Time
EST	Eastern Standard Time
IET	Indiana Eastern Standard Time
PRT	Puerto Rico and U.S. Virgin Islands Time
CNT	Canada Newfoundland Time
AGT	Argentina Standard Time
BET	Brazil Eastern Time
CAT	Central African Time

public static synchronized String[] getAvailableIDs(int rawOffset)

Returns

An array of strings that contains the predefined time zone IDs with the given raw offset value.

Description

This method returns a list of the predefined time zone IDs that have the given raw offset value from `GMT`. For example, both `PNT` and `MST` have an offset of GMT-07:00.

getDefault

public static synchronized TimeZone getDefault()

Returns

A `TimeZone` that represents the local time zone.

Description

This method returns the default `TimeZone` object for the local system.

getTimeZone

public static synchronized TimeZone getTimeZone(String ID)

Parameters

`ID`

The ID of a time zone.

Returns

A `TimeZone` that represents the time zone with the given ID.

Description

This method returns the `TimeZone` object that corresponds to the time zone with the given ID.

setDefault

public static synchronized void setDefault(TimeZone zone)

Parameters

`zone`

The new default time zone.

Description

This method sets the `TimeZone` that is returned by `getDefault()`.

Instance Methods

clone

public Object clone()

Returns

A copy of this `TimeZone`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `TimeZone` and returns it.

getID

public String getID()

Returns

`The ID of this TimeZone`.

Description

This method returns the ID string of this `TimeZone`.

getOffset

`public abstract int getOffset(int era, int year, int month, int day, int dayOfWeek, int millis)`

Parameters

`era`

The era.

`year`

The year.

`month`

The month.

`day`

The day.

`dayOfWeek`

The day of the week.

`millis`

The time of day in milliseconds.

Returns

An offset from GMT, in milliseconds.

Description

This method calculates an offset from GMT for the given date for this `TimeZone`. In other words, the offset takes daylight savings time into account. The return value should be added to GMT to get local time.

getRawOffset

public abstract int getRawOffset()

Returns

An offset from GMT, in milliseconds.

Description

This method returns the raw offset from GMT for this `TimeZone`. In other words, the offset does not take daylight savings time into account.

inDaylightTime

public abstract boolean isDaylightTime(Date date)

Parameters

`date`

The date to be tested.

Returns

`true` if the given date is between the start and end of daylight savings time for this `TimeZone`; `false` otherwise.

Description

This method returns a `boolean` value that indicates if the given date is in daylight savings time for this `TimeZone`.

setID

public void setID(String ID)

Parameters

`ID`

The new time zone ID.

Description

This method sets the ID of this `TimeZone`.

setRawOffset

public abstract void setRawOffset(int offsetMillis)

Parameters

`offsetMillis`

The new raw offset from GMT, in milliseconds.

Description

This method is used to set the raw offset value for this `TimeZone`.

useDaylightTime

public abstract boolean useDaylightTime()

Returns

`true` if this `TimeZone` uses daylight savings time; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not this `TimeZone` uses daylight savings time.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Vector

Name

Vector

Synopsis

Class Name:

`java.util.Vector`

Superclass:

`java.lang.Object`

Immediate Subclasses:

`java.util.Stack`

Interfaces Implemented:

`java.io.Serializable`, `java.lang.Cloneable`

Availability:

JDK 1.0 or later

Description

The Vector class implements a variable-length array that can hold any kind of object. Like an array, the elements in a Vector are accessed with an integer index. However, unlike an array, the size of a Vector can grow and shrink as needed to accommodate a changing number of objects. Vector provides methods to add and remove elements, as well as ways to search for objects in a Vector and iterate through all of the objects.

The initial capacity of a Vector specifies how many objects it can contain before more space must be allocated. The capacity increment specifies how much more space is allocated each time the Vector needs to increase its capacity. You can fine-tune the performance of a Vector by adjusting the initial capacity and capacity increment.

Class Summary

```
public class java.util.Vector extends java.lang.Object
             implements java.io.Serializable, java.lang.Cloneable {
  // Variables
  protected int capacityIncrement;
  protected int elementCount;
  protected Object[] elementData;
  // Constructors
  public Vector();
  public Vector(int initialCapacity);
  public Vector(int initialCapacity, int capacityIncrement);
  // Instance Methods
  public final synchronized void addElement(Object obj);
  public final int capacity();
  public synchronized Object clone();
  public final boolean contains(Object elem);
  public final synchronized void copyInto(Object[] anArray);
  public final synchronized Object elementAt(int index);
  public final synchronized Enumeration elements();
  public final synchronized void ensureCapacity(int minCapacity);
  public final synchronized Object firstElement();
  public final int indexOf(Object elem);
  public final synchronized int indexOf(Object elem, int index);
  public final synchronized void insertElementAt(Object obj, int index);
  public final boolean isEmpty();
  public final synchronized Object lastElement();
  public final int lastIndexOf(Object elem);
  public final synchronized int lastIndexOf(Object elem, int index);
  public final synchronized void removeAllElements();
  public final synchronized boolean removeElement(Object obj);
  public final synchronized void removeElementAt(int index);
  public final synchronized void setElementAt(Object obj, int index);
  public final synchronized void setSize(int newSize);
  public final int size();
  public final synchronized String toString();
  public final synchronized void trimToSize();
}
```

Variables

capacityIncrement

protected int capacityIncrement

Description

> The amount by which the internal array grows when more space is needed. If the value is 0, the internal array doubles in size when more space is needed.

elementCount

protected int elementCount

Description

> The count of how many objects are contained in this `Vector`.

elementData

protected Object[] elementData

Description

> The array that holds the contents of this `Vector`.

Constructors

Vector

public Vector()

Description

This constructor creates an empty `Vector` with the default capacity of 10 and the default capacity increment of 0.

public Vector(int initialCapacity)

Parameters

`initialCapacity`

The initial capacity of the `Vector`.

Description

This constructor creates an empty `Vector` with the given capacity and the default capacity increment of 0.

public Vector(int initialCapacity, int capacityIncrement)

Parameters

`initialCapacity`

The initial capacity of the `Vector`.

`CapacityIncrement`

The amount to increase the capacity when more space is needed.

Description

This constructor creates an empty `Vector` with the given capacity and capacity increment.

Instance Methods

addElement

public final synchronized void addElement(Object obj)

Parameters

`obj`

The object to be added.

Description

This method adds the given object to this `Vector` as its last element and increases its size by 1. The capacity of the `Vector` is increased if its size becomes greater than its capacity. Any kind of object can be added to a `Vector`.

capacity

public final int capacity()

Returns

`The capacity of this Vector`.

Description

This method returns the size of the internal array of this `Vector`.

clone

public synchronized Object clone()

Returns

A copy of this `Vector`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `Vector` and returns it.

contains

public final boolean contains(Object elem)

Parameters

`elem`

The object to be found.

Returns

`true` if the given object is contained in this `Vector`; `false` otherwise.

Description

This method determines whether or not the given object is contained in this `Vector`.

copyInto

public final synchronized void copyInto(Object[] anArray)

Parameters

`anArray`

The array to be filled.

Throws

`ArrayIndexOutOfBoundsException`

If the given array is too small to hold all of the objects in this `Vector`.

Description

This method copies the object references in this `Vector` to the given array.

elementAt

public final synchronized Object elementAt(int index)

Parameters

`index`

The index of the object to be returned.

Returns

The object at the position given by `index`.

Throws

`ArrayIndexOutOfBoundsException`

If `index` is less than zero or greater than the size of this `Vector`.

Description

This method returns the object at the given index in this `Vector`.

elements

public final synchronized Enumeration elements()

Returns

The objects in this `Vector` as an `Enumeration`.

Description

This method returns an `Enumeration` that iterates through the objects in this `Vector`.

ensureCapacity

public final synchronized void ensureCapacity(int minCapacity)

Parameters

`minCapacity`

The minimum new capacity.

Description

This method expands the internal array, if necessary, to make the capacity of the `Vector` at least `minCapacity`.

firstElement

public final synchronized Object firstElement()

Returns

The first object in this Vector.

Throws

`NoSuchElementException`

If the `Vector` is empty.

Description

This method returns the object at index 0 in this `Vector`.

indexOf

public final int indexOf(Object elem)

Parameters

`elem`

The object to be found.

Returns

The index of the given object or `-1` if it cannot be found.

Description

This method returns the index of the first occurrence of the given object in this `Vector`.

public final int indexOf(Object elem, int index)

Parameters

`elem`

The object to be found.

`index`

The starting index.

Returns

The index of the next occurrence of the given object after the specified index or `-1` if it cannot be found.

Description

This method returns the index of the next occurrence of the given object in this `Vector` after the given index.

insertElementAt

public final synchronized void insertElementAt(Object obj, int index)

Parameters

`obj`

The object to be inserted.

`index`

The index at which to insert the object.

Throws

`ArrayIndexOutOfBoundsException`

If `index` is less than zero or greater than the size of this `Vector`.

Description

This method inserts the given object at the given index in this `Vector`. Each object in the `Vector` with an index greater than or equal to `index` is shifted upward in the `Vector`, so that it has an index of one greater than it did previously.

isEmpty

public final boolean isEmpty()

Returns

`true` if there are no objects in the `Vector`; `false` otherwise.

Description

This method returns a `boolean` value that indicates whether or not the `Vector` is empty.

lastElement

public final synchronized Object lastElement()

Returns

The last object in this `Vector`.

Throws

`NoSuchElementException`

If the `Vector` is empty.

Description

This method returns the last object in this `Vector`.

lastIndexOf

public final int lastIndexOf(Object elem)

Parameters

`elem`

The object to be found.

Returns

The index of the given object or `-1` if it cannot be found.

Description

This method returns the index of the last occurrence of the given object in this `Vector`.

public final synchronized int lastIndexOf(Object elem, int index)

Parameters

`elem`

The object to be found.

`index`

The starting index.

Returns

The index of the last occurrence of the given object before the specified index or `-1` if it cannot be found.

Description

This method returns the index of the last occurrence of the given object in this `Vector` before the given index. In other words, the method searches backwards from `index` for the next occurrence.

removeAllElements

public final synchronized void removeAllElements()

Description

This method removes all of the objects from this `Vector`, but does not change its capacity or capacity increment.

removeElement

public final synchronized boolean removeElement(Object obj)

Parameters

`obj`

The object to be removed.

Returns

`true` if the given object is found and removed; `false` otherwise.

Description

This method searches for the first occurrence of the given object in this `Vector` and removes it. If the object is found, each object in the `Vector` with an index greater than or equal to the index of the removed object is shifted downward in the `Vector`, so that it has an index of one less than it did previously.

removeElementAt

public final synchronized void removeElementAt(int index)

Parameters

`index`

The index of the object to be removed.

Throws

`ArrayIndexOutOfBoundsException`

If `index` is less than zero or greater than the size of this `Vector`.

Description

This method removes the object at the given index from this `Vector`. Each object in the `Vector` with an index greater than or equal to `index` is shifted downward in the `Vector`, so that it has an index of one less than it did previously.

setElementAt

public final synchronized void setElementAt(Object obj, int index)

Parameters

`obj`

The object to be put in the `Vector`.

`index`

The index at which to put the object.

Throws

`ArrayIndexOutOfBoundsException`

If `index` is less than zero or greater than the size of this `Vector`.

Description

This method puts the given object at the given index in this `Vector`, replacing the object that was previously there.

setSize

public final synchronized void setSize(int newSize)

Parameters

`newSize`

The new size.

Description

This method sets the size (not the capacity) of this `Vector`. If the new size is bigger than the current size, `null` elements are added to the end of the `Vector`. If the new size is smaller than the current size, elements are discarded from index `newSize` to the end of the `Vector`.

size

public final int size()

Returns

The size of this `Vector`.

Description

This method returns the number of objects contained in this `Vector`.

toString

public final synchronized String toString()

Returns

A string that represents this `Vector`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `Vector`. The string includes every object that is contained in the `Vector`, so the string returned by `toString()` can be quite long.

trimToSize

public final synchronized void trimToSize()

Description

This method sets the capacity of this `Vector` equal to its size. You can use this method to minimize the storage space used by the `Vector`, but any subsequent calls to `addElement()` or `insertElement()` forces the `Vector` to allocate more space.

Inherited Methods

Method	Inherited From	Method	Inherited From
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

CheckedInputStream

Name

CheckedInputStream

Synopsis

Class Name:

```
java.util.zip.CheckedInputStream
```

Superclass:

```
java.io.FilterInputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `CheckedInputStream` class represents an `InputStream` with an associated checksum. In other words, a `CheckedInputStream` wraps a regular input stream and computes a checksum value as data is read from the stream. The checksum can verify the integrity of the data. When you create a `CheckedInputStream`, you must specify an object that implements the `Checksum` interface that computes the checksum.

Class Summary

```
public class java.util.zip.CheckedInputStream
             extends java.io.FilterInputStream {
  // Constructors
  public CheckedInputStream(InputStream in, Checksum cksum);

  // Instance Methods
  public Checksum getChecksum();
  public int read();
  public int read(byte[] buf, int off, int len);
  public long skip(long n);
}
```

Constructors

CheckedInputStream

public CheckedInputStream(InputStream in, Checksum cksum)

Parameters

`in`

The underlying input stream to use as a data source.

`cksum`

The checksum object.

Description

This constructor creates a `CheckedInputStream` that reads data from the given `InputStream` and updates the given `Checksum`.

Instance Methods

getChecksum

public Checksum getChecksum()

Returns

The `Checksum` associated with this input stream.

Description

This method returns the `Checksum` object associated with this input stream.

read

public int read() throws IOException

Returns

The next byte from the stream or `-1` if the end of the stream has been reached.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read()`

Description

This method reads the next byte from the underlying `InputStream` and then updates the checksum. The method blocks until some data is available, the end of the stream is detected, or an exception is thrown.

public int read(byte[] buf, int off, int len) throws IOException

Parameters

`buf`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read(byte[], int, int)`

Description

This method reads up to `len` bytes from the underlying `InputStream` and places them into the given array starting at `off`. The checksum is then updated with the data that has been read. The method blocks until some data is available.

skip

public long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.skip()`

Description

This method skips over the specified number of bytes in the underlying `InputStream`. The skipped bytes are not calculated into the checksum.

Inherited Methods

Method	Inherited From	Method	Inherited From
`available()`	`FilterInputStream`	`clone()`	`Object`
`close()`	`FilterInputStream`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`mark(int)`	`FilterInputStream`
`markSupported()`	`FilterInputStream`	`notify()`	`Object`
`notifyAll()`	`Object`	`read(byte[])`	`FilterInputStream`
`reset()`	`FilterInputStream`	`toString()`	`Object`

`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

CheckedOutputStream

Name

CheckedOutputStream

Synopsis

Class Name:

`java.util.zip.CheckedOutputStream`

Superclass:

`java.io.FilterOutputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `CheckOutputStream` class represents an `OutputStream` with an associated checksum. In other words, a `CheckedOutputStream` wraps a regular output stream and computes a checksum value as data is written to the stream. The checksum can verify the integrity of the data. When you create a `CheckedOutputStream`, you must specify an object that implements the `Checksum` interface that computes the checksum.

Class Summary

```
public class java.util.zip.CheckedOutputStream
             extends java.io.FilterOutputStream {
  // Constructors
  public CheckedOutputStream(OutputStream out, Checksum cksum);

  // Instance Methods
  public Checksum getChecksum();
  public void write(int b);
  public void write(byte[] b, int off, int len);
}
```

Constructors

CheckedOutputStream

public CheckedOutputStream(OutputStream out, Checksum cksum)

Parameters

`out`

The underlying output stream.

`cksum`

The checksum object.

Description

This constructor creates a `CheckedOutputStream` that writes data to the given `OutputStream` and updates the given `Checksum`.

Instance Methods

getChecksum

public Checksum getChecksum()

Returns

The `Checksum` associated with this output stream.

Description

This method returns the `Checksum` object associated with this output stream.

write

public void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.write(int)`

Description

This method writes a byte that contains the lowest eight bits of the given integer value to the underlying `OutputStream` and then updates the checksum.

public void write(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.write(byte[], int, int)`

Description

This method writes `len` bytes to the underlying `OutputStream` from the given array, starting at `off`. The checksum is then updated with the data that has been written.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`close()`	`FilterOutputStream`

`equals(Object)`	`Object`	`finalize()`	`Object`
`flush()`	`FilterOutputStream`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`	`write(byte[])`	`FilterOutputStream`

See Also

`Checksum`, `FilterOutputStream`, `IOException`, `OutputStream`

Checksum

Name

Checksum

Synopsis

Interface Name:

`java.util.zip.Checksum`

Super-interface:

None

Immediate Sub-interfaces:

None

Implemented By:

`java.util.zip.Adler32`, `java.util.zip.CRC32`

Availability:

New as of JDK 1.1

Description

The `Checksum` interface defines the methods that are needed to compute a checksum value for a stream of data. The checksum value can be used for error checking purposes. Note, however, that the checksum value must fit into a `long` value, so this interface is not suitable for cryptographic checksum algorithms.

The `Adler32` and `CRC32` classes implement the `Checksum` interface, using the Adler-32 and CRC-32 algorithms, respectively. The `CheckedInputStream` and `CheckedOutputStream` classes provide a higher-level mechanism for computing checksums on data streams.

Class Summary

```
public abstract interface java.util.zip.Checksum {
  // Methods
  public abstract long getValue();
  public abstract void reset();
  public abstract void update(int b);
  public abstract void update(byte[] b, int off, int len);
}
```

Methods

getValue

public abstract long getValue()

Returns

> The current checksum value.

Description

> This method returns the current value of this checksum.

reset

public abstract void reset()

Description

This method resets the checksum to its initial value, making it appear as though it has not been updated by any data.

update

public abstract void update(int b)

Parameters

`b`

The value to be added to the data stream for the checksum calculation.

Description

This method adds the specified value to the data stream and updates the checksum value. The method uses only the lowest eight bits of the given `int`.

public abstract void update(byte[] b, int off, int len)

Parameters

`b`

An array of bytes to be added to the data stream for the checksum calculation.

`off`

An offset into the byte array.

`len`

The number of bytes to use.

Description

This method adds `len` bytes from the specified array, starting at `off`, to the data stream and updates the checksum value.

CRC32

Name

CRC32

Synopsis

Class Name:

    java.util.zip.CRC32

Superclass:

    java.lang.Object

Immediate Subclasses:

None

Interfaces Implemented:

    java.util.zip.Checksum

Availability:

New as of JDK 1.1

Description

The `CRC32` class implements the `Checksum` interface using the CRC-32 algorithm. This algorithm is significantly slower than Adler-32 and only slightly more reliable.

Class Summary

```
public class java.util.zip.CRC32 extends java.lang.Object
             implements java.util.zip.Checksum {
  // Constructors
  public CRC32();

  // Instance Methods
  public long getValue();
  public void reset();
  public void update(int b);
  public void update(byte[] b);
  public native void update(byte[] b, int off, int len);
}
```

Constructors

CRC32

public CRC32()

Description

> This constructor creates an `CRC32` object.

Instance Methods

getValue

public long getValue()

Returns

The current checksum value.

Implements

`Checksum.getValue()`

Description

This method returns the current value of this checksum.

reset

public void reset()

Implements

`Checksum.reset()`

Description

This method resets the checksum to its initial value, making it appear as though it has not been updated by any data.

update

public void update(int b)

Parameters

`b`

The value to be added to the data stream for the checksum calculation.

Implements

`Checksum.update(int)`

Description

This method adds the specified value to the data stream and updates the checksum value. The method uses only the lowest eight bits of the given `int`.

public void update(byte[] b)

Parameters

`b`

An array of bytes to be added to the data stream for the checksum calculation.

Description

This method adds the bytes from the specified array to the data stream and updates the checksum value.

public native void update(byte[] b, int off, int len)

Parameters

`b`

An array of bytes to be added to the data stream for the checksum calculation.

`off`

An offset into the byte array.

`len`

The number of bytes to use.

Implements

`Checksum.update(byte[], int, int)`

Description

This method adds `len` bytes from the specified array, starting at `off`, to the data stream and updates the checksum value.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`

DataFormatException

Synopsis

Class Name:

    java.util.zip.DataFormatException

Superclass:

    java.lang.Exception

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `DataFormatException` is thrown when data is not in the expected format, which can mean that the data is invalid or corrupt. In particular, the `inflate()` methods of `Inflater` throw this exception if they encounter data in an unexpected format.

Class Summary

```
public class java.util.zip.DataFormatException
             extends java.lang.Exception {
  // Constructors
  public DataFormatException();
  public DataFormatException(String s);
}
```

Constructors

DataFormatException

protected DataFormatException()

Description

> This constructor creates a `DataFormatException` with no associated detail message.

public DataFormatException(String s)

Parameters

> `s`
>
> > The detail message.

Description

> This constructor creates a `DataFormatException` with the specified detail message.

CRC32 BOOK INDEX Deflater

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Deflater

Name

Deflater

Synopsis

Class Name:

`java.util.zip.Deflater`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `Deflater` class provides support for general-purpose data compression. The class uses the ZLIB compression algorithms described in RFC 1950, RFC 1951, and RFC 1952. These documents can be found at:

- *ftp://ds.internic.net/rfc/rfc1950.txt*
- *ftp://ds.internic.net/rfc/rfc1951.txt*
- *ftp://ds.internic.net/rfc/rfc1952.txt*

The `Inflater` class uncompresses data that has been compressed using `Deflater`.

The `DeflaterOutputStream` uses an internal `Deflater` to compress data. Typically, you do not need to create a `Deflater`; instead, you can just use an instance of one of the subclasses of `DeflaterOutputStream` : `GZIPOutputStream` or `ZipOutputStream`.

Class Summary

```
public class java.util.zip.Deflater extends java.lang.Object {
  // Constants
  public static final int BEST_COMPRESSION;
  public static final int BEST_SPEED;
  public static final int DEFAULT_COMPRESSION;
  public static final int DEFAULT_STRATEGY;
  public static final int DEFLATED;
  public static final int FILTERED;
  public static final int HUFFMAN_ONLY;
  public static final int NO_COMPRESSION;
  // Constructors
  public Deflater();
  public Deflater(int level);
  public Deflater(int level, boolean nowrap);
  // Public Instance Methods
  public int deflate(byte[] b);
  public synchronized native int deflate(byte[] b, int off, int len);
  public synchronized native void end();
  public synchronized void finish();
  public synchronized boolean finished();
  public synchronized native int getAdler();
  public synchronized native int getTotalIn();
  public synchronized native int getTotalOut();
  public boolean needsInput();
  public synchronized native void reset();
  public void setDictionary(byte[] b);
  public synchronized native void setDictionary(byte[] b, int off, int len);
  public void setInput(byte[] b);
  public synchronized void setInput(byte[] b, int off, int len);
  public synchronized void setLevel(int level);
  public synchronized void setStrategy(int strategy);
  // Protected Instance Methods
  protected void finalize();
}
```

Constants

BEST_COMPRESSION

public static final int BEST_COMPRESSION = 9

Description

> A constant that represents a compression level that sacrifices speed for the smallest compressed data size. The compression level for a `Deflater` object can be set with `setLevel()`, where the level ranges from 0 to 9.

BEST_SPEED

public static final int BEST_SPEED = 1

Description

> A constant that represents a compression level that sacrifices compressed data size for speed. The compression level for a `Deflater` object can be set with `setLevel()`, where the level ranges from 0 to 9.

DEFAULT_COMPRESSION

public static final int DEFAULT_COMPRESSION = -1

Description

> A constant that represents the default compression level.

DEFAULT_STRATEGY

public static final int DEFAULT_STRATEGY

Description

> A constant that represents the default compression strategy.

DEFLATED

public static final int DEFLATED

Description

> A constant that represents a compression method that uses the deflate algorithm.

FILTERED

public static final int FILTERED

Description

> A constant that represents a compression strategy that works well for small values with a random distribution.

HUFFMAN_ONLY

public static final int HUFFMAN_ONLY

Description

> A constant that represents a compression strategy that uses only Huffman coding.

NO_COMPRESSION

public static final int NO_COMPRESSION = 0

Description

> A constant that represents a compression level that does not compress data at all. The compression level for a `Deflater` object can be set with `setLevel()`, where the level ranges from 0 to 9.

Constructors

Deflater

public Deflater()

Description

This constructor creates a `Deflater` that generates compressed data in the ZLIB format using the `DEFAULT_COMPRESSION` level.

public Deflater(int level)

Parameters

`level`

The compression level, from 0 (`NO_COMPRESSION`) to 9 (`BEST_COMPRESSION`).

Description

This constructor creates a `Deflater` that generates compressed data in the ZLIB format using the given compression level.

public Deflater(int level, boolean nowrap)

Parameters

`level`

The compression level, from 0 (`NO_COMPRESSION`) to 9 (`BEST_COMPRESSION`).

`nowrap`

A `boolean` value that specifies whether or not the ZLIB header and checksum data are omitted from the compressed data.

Description

This constructor creates a `Deflater` that generates compressed data using the given compression level. If `nowrap` is `true`, the ZLIB header and checksum fields are not used, which means that the compressed data is in the format used by GZIP and PKZIP. If the parameter is `false`, the data is compressed into ZLIB format.

Public Instance Methods

deflate

public int deflate(byte[] b)

Parameters

`b`

A byte array to be filled.

Returns

The number of compressed bytes actually written to the array or 0 if more data may be required.

Description

This method compresses the data passed to `setInput()` and fills the given array with the compressed data. If this method returns zero, `needsInput()` should be called to determine whether the `Deflater` needs more data in its input buffer.

public synchronized native int deflate(byte[] b, int off, int len)

Parameters

`b`

A byte array to be filled.

`off`

An offset into the byte array.

`len`

The number of bytes to fill.

Returns

The number of compressed bytes actually written to the array or 0 if more data may be required.

Description

This method compresses the data passed to `setInput()` and writes `len` bytes of the compressed data into the given array, starting at `off`. If this method returns 0, `needsInput()` should be called to determine whether the `Deflater` needs more data in its input buffer.

end

public synchronized native void end()

Description

> This method discards any uncompressed input data and frees up internal buffers.

finish

public synchronized void finish()

Description

> This method tells the `Deflater` that the compression should end with the data that currently occupies the input buffer.

finished

public synchronized boolean finished()

Returns

> A `boolean` value that indicates whether or not the end of the compressed data has been reached.

Description

> This method returns `true` if the last of the compressed data has been read using `deflate()`. Otherwise it returns `false`.

getAdler

public synchronized native int getAdler()

Returns

> The Adler-32 checksum value of the uncompressed data.

Description

> This method returns an Adler32 checksum value that is calculated on the uncompressed data passed to `setInput()`.

getTotalIn

public synchronized native int getTotalIn()

Returns

The total number of bytes that have been input so far.

Description

This method returns the number of bytes that have been passed to `setInput()` since this `Deflater` was created or since `reset()`was last called.

getTotalOut

public synchronized native int getTotalOut()

Returns

The total number of bytes that have been output so far.

Description

This method returns the number of bytes that have been read from `deflate()` since this `Deflater` was created, or since `reset()` was last called.

needsInput

public boolean needsInput()

Returns

A `boolean` value that indicates whether or not the input buffer is empty.

Description

This method returns `true` if the input buffer is empty. Otherwise it returns `false`.

reset

public synchronized native void reset()

Description

This method resets the `Deflater` to the state it was in when it was created, which means that a new set of data can be compressed.

setDictionary

public void setDictionary(byte[] b)

Parameters

`b`

An array of byte values.

Description

This method sets the preset dictionary for compression using the data in the given array.

`public synchronized native void setDictionary(byte[] b, int off, int len)`

Parameters

`b`

An array of byte values.

`off`

An offset into the byte array.

`len`

The number of bytes to use.

Description

This method sets the preset dictionary for compression using `len` bytes from the given array, starting from `off`.

setInput

public void setInput(byte[] b)

Parameters

b

An array of byte values.

Description

This method places the contents of the given array into the input buffer of this `Deflater`. Use the `deflate()` method to compress the data and retrieve it in compressed form.

public synchronized void setInput(byte[] b, int off, int len)

Parameters

b

An array of byte values.

off

An offset into the byte array.

len

The number of bytes to use.

Description

This method places `len` bytes from the given array, starting at `off`, into the input buffer of this `Deflater`. Use the `deflate()` method to compress the data and retrieve it in compressed form.

setLevel

public synchronized void setLevel(int level)

Parameters

level

The compression level, from 0 (`NO_COMPRESSION`) to 9 (`BEST_COMPRESSION`).

Throws

IllegalArgumentException

If `level` is not valid.

Description

This method sets the compression level of this `Deflater`. A value of 0 corresponds to `NO_COMPRESSION`. A value of 1 indicates the fastest, least space-efficient compression level (`BEST_SPEED`). A value of 9 indicates the slowest, most space-efficient compression level (`BEST_COMPRESSION`).

setStrategy

public synchronized void setStrategy(int strategy)

Parameters

`strategy`

The compression strategy.

Throws

`IllegalArgumentException`

If `strategy` is not valid.

Description

This method sets the compression strategy of this `Deflater`, which should be one of `FILTERED`, `HUFFMAN_ONLY`, or `DEFAULT_STRATEGY`.

Protected Instance Methods

finalize

protected void finalize()

Overrides

`Object.finalize()`

Description

This method calls `end()` when this `Deflater` is garbage collected.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

DeflaterOutputStream

Name

DeflaterOutputStream

Synopsis

Class Name:

`java.util.zip.DeflaterOutputStream`

Superclass:

`java.io.FilterOutputStream`

Immediate Subclasses:

`java.util.zip.GZIPOutputStream`, `java.util.zip.ZipOutputStream`

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `DeflaterOutputStream` class represents an `OutputStream` with an associated `Deflater`. In other words, a `DeflaterOutputStream` wraps a regular output stream, so that data written to the stream is compressed and written to the underlying stream. Two subclasses, `GZIPOutputStream` and `ZipOutputStream`, write compressed data in widely-recognized formats.

Class Summary

```
public class java.util.zip.DeflaterOutputStream
             extends java.io.FilterOutputStream {
  // Variables
  protected byte[] buf;
  protected Deflater def;
  // Constructors
  public DeflaterOutputStream(OutputStream out);
  public DeflaterOutputStream(OutputStream out, Deflater def);
  public DeflaterOutputStream(OutputStream out, Deflater def, int size);
  // Public Instance Methods
  public void close();
  public void finish();
  public void write(int b);
  public void write(byte[] b, int off, int len);
  // Protected Instance Methods
  protected void deflate();
}
```

Variables

buf

protected byte[] buf

Description

> A buffer that holds the compressed data that is written to the underlying stream.

def

protected Deflater def

Description

The `Deflater` object that is used internally.

Constructors

DeflaterOutputStream

public DeflaterOutputStream(OutputStream out)

Parameters

`out`

The underlying output stream.

Description

This constructor creates a `DeflaterOutputStream` that writes data to the given `OutputStream`. Before being written, the data is compressed by a default `Deflater`. The `DeflaterOutputStream` uses a compression buffer with the default size of 512 bytes.

public DeflaterOutputStream(OutputStream out, Deflater def)

Parameters

`out`

The underlying output stream.

`def`

The `Deflater` object.

Description

This constructor creates a `DeflaterOutputStream` that writes data to the given `OutputStream`. Before being written, the data is compressed by the given `Deflater`. The `DeflaterOutputStream` uses a compression buffer with the default size of 512 bytes.

`public DeflaterOutputStream(OutputStream out, Deflater def, int size)`

Parameters

`out`

The underlying output stream.

`def`

The `Deflater` object.

`size`

The size of the output buffer.

Description

This constructor creates a `DeflaterOutputStream` that writes data to the given `OutputStream`. Before being written, the data is compressed by the given `Deflater`. The `DeflaterOutputStream` uses a compression buffer of the given size.

Public Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.close()`

Description

This method closes the stream and releases any system resources that are associated with it.

finish

public void finish() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method finishes writing compressed data to the underlying stream without closing it.

write

public void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.write(int)`

Description

This method compresses a byte that contains the lowest eight bits of the given integer value and writes it to the underlying `OutputStream`. The method blocks until the byte is written.

public void write(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.write(byte[], int, int)`

Description

This method takes `len` bytes from the given buffer, starting at `off`, and compresses them. The method then writes the compressed data to the underlying `OutputStream`. The method blocks until all of the bytes have been written.

Protected Instance Methods

deflate

protected void deflate() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

> This method asks the internal `Deflater` to compress the data in the buffer for this `DeflaterOutputStream`. The method then writes the compressed contents of the buffer to the underlying stream. The method is called by both `write()` methods.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`flush()`	`FilterOutputStream`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`
`write(byte[])`	`FilterOutputStream`		

See Also

GZIPInputStream

Name

GZIPInputStream

Synopsis

Class Name:

`java.util.zip.GZIPInputStream`

Superclass:

`java.util.zip.InflaterInputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `GZIPInputStream` class decompresses data that has been compressed using the GZIP format. To use it, simply construct a `GZIPInputStream` that wraps regular input stream and use the `read()` methods to read the compressed data.

Class Summary

```
public class java.util.zip.GZIPInputStream
             extends java.util.zip.InflaterInputStream {
  // Constants
  public static final int GZIP_MAGIC;
  // Variables
  protected CRC32 crc;
  protected boolean eos;
  // Constructors
  public GZIPInputStream(InputStream in);
  public GZIPInputStream(InputStream in, int size);
  // Instance Methods
  public void close();
  public int read(byte[] buf, int off, int len);
}
```

Constants

GZIP_MAGIC

public static final int GZIP_MAGIC

Description

> A constant that contains the "magic number" that appears in the header of GZIP files.

Variables

crc

protected CRC32 crc

Description

A checksum value of the uncompressed data. When an entire file has been read, this checksum is compared to a value stored in the GZIP trailer. If the values do not match, an exception is thrown from `read()`.

eos

protected boolean eos

Description

A flag that indicates whether or not the end of the compressed stream has been reached. It is set to `true` when the compressed data and the GZIP trailer have been read.

Constructors

GZIPInputStream

public GZIPInputStream(InputStream in) throws IOException

Parameters

`in`

The underlying input stream.

Throws

`IOException`

If an error occurs while reading the GZIP header.

Description

This constructor creates a `GZIPInputStream` that inflates data from the given `InputStream`. The `GZIPInputStream` uses a decompression buffer with the default size of 512 bytes. The GZIP header is read immediately.

`public GZIPInputStream(InputStream in, int size) throws IOException`

Parameters

`in`

The underlying input stream.

`size`

The size of the input buffer.

Throws

`IOException`

If an error occurs while reading the GZIP header.

Description

This constructor creates a `GZIPInputStream` that inflates data from the given `InputStream`. The `GZIPInputStream` uses a decompression buffer of the given size. The GZIP header is read immediately.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.close()`

Description

This method closes this stream and releases any system resources that are associated with it.

read

public int read(byte[] buf, int off, int len) throws IOException

Parameters

`buf`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs or the checksum of the uncompressed data does not match that in the GZIP trailer.

Overrides

`InflaterInputStream.read(byte[], int, int)`

Description

This method reads enough data from the underlying `InputStream` to return `len` bytes of uncompressed data. The uncompressed data is placed into the given array starting at `off`. The method blocks until some data is available for decompression.

Inherited Methods

Method	Inherited From	Method	Inherited From
available()	FilterInputStream	clone()	Object
equals(Object)	Object	finalize()	Object
getClass()	Object	hashCode()	Object
mark(int)	FilterInputStream	markSupported()	FilterInputStream
notify()	Object	notifyAll()	Object
read()	InflaterInputStream	read(byte[])	FilterInputStream
reset()	FilterInputStream	skip(long)	InflaterInputStream
toString()	Object	wait()	Object
wait(long)	Object	wait(long, int)	Object

GZIPOutputStream

Name

GZIPOutputStream

Synopsis

Class Name:

```
java.util.zip.GZIPOutputStream
```

Superclass:

```
java.util.zip.DeflaterOutputStream
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `GZIPOutputStream` class compresses data using the GZIP format. To use it, simply construct a `GZIPOutputStream` that wraps a regular output stream and use the `write()` methods to write compressed data.

Class Summary

```
public class java.util.zip.GZIPOutputStream
             extends java.util.zip.DeflaterOutputStream {
  // Variables
  protected CRC32 crc;
  // Constructors
  public GZIPOutputStream(OutputStream out);
  public GZIPOutputStream(OutputStream out, int size);
  // Instance Methods
  public void close();
  public void finish();
  public synchronized void write(byte[] buf, int off, int len);
}
```

Variables

crc

protected CRC32 crc

Description

> A checksum that is updated with the uncompressed stream data. The checksum value is written into the GZIP trailer.

Constructors

GZIPOutputStream

public GZIPOutputStream(OutputStream out) throws IOException

Parameters

`out`

The underlying output stream.

Throws

`IOException`

If an error occurs while writing the GZIP header.

Description

This constructor creates a `GZIPOutputStream` that writes compressed data to the given `OutputStream`. The `GZIPOutputStream` uses a compression buffer with the default size of 512 bytes.

public GZIPOutputStream(OutputStream out, int size) throws IOException

Parameters

`out`

The underlying output stream.

`size`

The size of the output buffer.

Throws

`IOException`

If an error occurs while writing the GZIP header.

Description

This constructor creates a `GZIPOutputStream` that writes compressed data to the given `OutputStream`. The `GZIPOutputStream` uses a compression buffer of the given size.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`DeflaterOutputStream.close()`

Description

This method closes the stream and releases any system resources that are associated with it.

finish

public void finish() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`DeflaterOutputStream.finish()`

Description

This method finishes writing compressed data to the underlying stream without closing it.

write

public void write(byte[] buf, int off, int len) throws IOException

Parameters

`buf`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`DeflaterOutputStream.write(byte[], int, int)`

Description

This method takes `len` bytes from the given buffer, starting at `off`, and compresses them. The method then writes the compressed data to the underlying `OutputStream`. The method blocks until all of the bytes have been written.

Inherited Methods

Method	Inherited From	Method	Inherited From

Inflater

Name

Inflater

Synopsis

Class Name:

`java.util.zip.Inflater`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `Inflater` class provides support for general-purpose data decompression. The class uses the ZLIB compression algorithms described in RFC 1950, RFC 1951, and RFC 1952. These documents can be found at:

- *ftp://ds.internic.net/rfc/rfc1950.txt*
- *ftp://ds.internic.net/rfc/rfc1951.txt*
- *ftp://ds.internic.net/rfc/rfc1952.txt*

The `Deflater` class compresses data that can be uncompressed using `Inflater`.

The `InflaterInputStream` uses an internal `Inflater` to decompress data. Typically, you do not need to create a `Inflater`; instead, you can just use an instance of one of the subclasses of `InflaterInputStream`: `GZIPInputStream` or `ZipInputStream`.

Class Summary

```
public class java.util.zip.Inflater extends java.lang.Object {
  // Constructors
  public Inflater();
  public Inflater(boolean nowrap);
  // Public Instance Methods
  public synchronized native void end();
  public synchronized boolean finished();
  public synchronized native int getAdler();
  public synchronized int getRemaining();
  public synchronized native int getTotalIn();
  public synchronized native int getTotalOut();
  public int inflate(byte[] b);
  public synchronized native int inflate(byte[] b, int off, int len);
  public synchronized boolean needsDictionary();
  public synchronized boolean needsInput();
  public synchronized native void reset();
  public void setDictionary(byte[] b);
  public synchronized native void setDictionary(byte[] b, int off, int len);
  public void setInput(byte[] b);
  public synchronized void setInput(byte[] b, int off, int len);
  // Protected Instance Methods
  protected void finalize();
}
```

Constructors

Inflater

public Inflater()

Description

This constructor creates an `Inflater` that decompresses data in the ZLIB format.

public Inflater(boolean nowrap)

Parameters

`nowrap`

A `boolean` value that specifies whether or not the ZLIB header and checksum data are expected in the compressed data.

Description

This constructor creates an `Inflater` that decompresses data. If `nowrap` is `true`, the ZLIB header and checksum fields are not expected, which means that the compressed data is in the format used by GZIP and PKZIP. If the parameter is `false`, the data is decompressed in the ZLIB format.

Public Instance Methods

end

public synchronized native void end()

Description

This method discards any unprocessed input data and frees up internal buffers.

finished

public synchronized boolean finished()

Returns

A `boolean` value that indicates whether or not the end of the compressed data has been reached.

Description

This method returns `true` if the last of the compressed data has been read using `inflate()`. Otherwise it returns `false`.

getAdler

public synchronized native int getAdler()

Returns

> The Adler32 checksum value of the uncompressed data.

Description

> This method returns an Adler32 checksum value that is calculated from the uncompressed data returned by `inflate()`.

getRemaining

public synchronized int getRemaining()

Returns

> The number of bytes remaining in the input buffer.

Description

> This method returns the number of bytes that are in the input buffer. It can be called to find out how much data remains after a call to `inflate()`.

getTotalIn

public synchronized native int getTotalIn()

Returns

> The total number of bytes that have been input so far.

Description

> This method returns the number of bytes that have been passed to `setInput()` since this `Inflater` was created or since `reset()` was last called.

getTotalOut

public synchronized native int getTotalOut()

Returns

The total number of bytes that have been output so far.

Description

This method returns the number of bytes that have been read from `inflate()` since this `Inflater` was created or since `reset()` was last called.

inflate

public int inflate(byte[] b) throws DataFormatException

Parameters

`b`

A byte array to be filled.

Returns

The number of decompressed bytes actually written to the array or 0 if more data may be required.

Throws

`DataFormatException`

If the data in the input buffer is not in the correct format.

Description

This method decompresses the data passed to `setInput()` and fills the given array with decompressed data. If this method returns 0, `needsInput()` and `needsDictionary()` should be called in order to determine whether the `Inflater` needs more data in its input buffer or whether it needs a preset dictionary.

public synchronized native int inflate(byte[] b, int off, int len) throws DataFormatException

Parameters

`b`

A byte array to be filled.

`off`

An offset into the byte array.

`len`

The number of bytes to fill.

Returns

The number of decompressed bytes written to the array or 0 if more data may be required.

Throws

`DataFormatException`

If the data in the input buffer is not in the correct format.

Description

This method decompresses the data passed to `setInput()` and writes `len` bytes of the decompressed data into the given array, starting at `off`. If this method returns 0, `needsInput()` and `needsDictionary()` should be called in order to determine whether the `Inflater` needs more data in its input buffer or whether it needs a preset dictionary.

needsDictionary

public synchronized boolean needsDictionary()

Returns

A `boolean` value that indicates whether or not a preset dictionary is needed.

Description

This method returns `true` if a preset dictionary is needed for decompression. Otherwise it returns `false`.

needsInput

public synchronized boolean needsInput()

Returns

A `boolean` value that indicates whether or not the input buffer is empty.

Description

This method returns `true` if the input buffer is empty. Otherwise it returns `false`.

reset

public synchronized native void reset()

Description

This method resets the `Inflater` to the state it was in when it was created, which means that a new set of data can be decompressed.

setDictionary

public void setDictionary(byte[] b)

Parameters

`b`

An array of byte values.

Description

This method sets the preset dictionary for decompression using the data in the given array.

`public synchronized native void setDictionary(byte[] b, int off, int len)`

Parameters

`b`

An array of byte values.

`off`

An offset into the byte array.

`len`

The number of bytes to use.

Description

This method sets the preset dictionary for decompression using `len` bytes from the given array, starting from `off`.

setInput

public void setInput(byte[] b)

Parameters

`b`

An array of byte values.

Description

This method places the contents of the given array into the input buffer of this `Inflater`.

public synchronized void setInput(byte[] b, int off, int len)

Parameters

`b`

An array of byte values.

`off`

An offset into the byte array.

`len`

The number of bytes to use.

Description

This method places `len` bytes from the given array, starting at `off`, into the input buffer of this `Inflater`. Use the `inflate()` method to decompress the data and retrieve it in decompressed form.

Protected Instance Methods

finalize

protected void finalize()

Overrides

`Object.finalize()`

Description

This method calls `end()` when this `Inflater` is garbage collected.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

InflaterInputStream

Name

InflaterInputStream

Synopsis

Class Name:

`java.util.zip.InflaterInputStream`

Superclass:

`java.io.FilterInputStream`

Immediate Subclasses:

`java.util.zip.GZIPInputStream`, `java.util.zip.ZipInputStream`

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `InflaterInputStream` class represents an `InputStream` with an associated `Inflater`. In other words, an `InflaterInputStream` wraps a regular input stream, so that data read from the stream is read from an underlying stream and decompressed. Two subclasses, `GZIPInputStream` and `ZipInputStream`, read compressed data in widely recognized formats.

Class Summary

```
public class java.util.zip.InflaterInputStream
             extends java.io.FilterInputStream {
  // Variables
  protected byte[] buf;
  protected Inflater inf;
  protected int len;
  // Constructors
  public InflaterInputStream(InputStream in);
  public InflaterInputStream(InputStream in, Inflater inf);
  public InflaterInputStream(InputStream in, Inflater inf, int size);
  // Public Instance Methods
  public int read();
  public int read(byte[] b, int off, int len);
  public long skip(long n);
  // Protected Instance Methods
  protected void fill();
}
```

Variables

buf

protected byte[] buf

Description

> A buffer that holds the compressed data that is written to the underlying stream.

inf

protected Inflater inf

Description

The `Inflater` that is used internally.

len

protected int len

Description

The amount of data that is in the input buffer.

Constructors

InflaterInputStream

public InflaterInputStream(InputStream in)

Parameters

`in`

The underlying input stream.

Description

This constructor creates an `InflaterInputStream` that reads data from the given `InputStream`. Before being read, the data is decompressed by a default `Inflater`. The `InflaterInputStream` uses a decompression buffer with the default size of 512 bytes.

public InflaterInputStream(InputStream in, Inflater inf)

Parameters

`in`

The underlying input stream.

`inf`

The `Inflater` object.

Description

This constructor creates an `InflaterInputStream` that reads data from the given `InputStream`. Before being read, the data is decompressed by the given `Inflater`. The `InflaterInputStream` uses a decompression buffer with the default size of 512 bytes.

public InflaterInputStream(InputStream in, Inflater inf, int size)

Parameters

`in`

The underlying input stream.

`inf`

The `Inflater` object.

`size`

The size of the input buffer.

Description

This constructor creates an `InflaterInputStream` that reads data from the given `InputStream`. Before being read, the data is decompressed by the given `Inflater`. The `InflaterInputStream` uses a decompression buffer of the given size.

Instance Methods

read

public int read() throws IOException

Returns

The next uncompressed byte or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read()`

Description

This method reads enough data from the underlying `InputStream` to return a byte of uncompressed data. The method blocks until enough data is available for decompression, the end of the stream is detected, or an exception is thrown.

public int read(byte[] b, int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read(byte[], int, int)`

Description

This method reads enough data from the underlying `InputStream` to return `len` bytes of uncompressed data. The uncompressed data is placed into the given array starting at `off`. The method blocks until some data is available for decompression.

skip

public long skip(long n) throws IOException

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.skip()`

Description

This method skips over the specified number of uncompressed data bytes by reading data from the underlying `InputStream` and decompressing it.

Protected Instance Methods

fill

protected void fill() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method fills the input buffer with compressed data from the underlying `InputStream`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`available()`	`FilterInputStream`	`clone()`	`Object`
`close()`	`FilterInputStream`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`mark(int)`	`FilterInputStream`
`markSupported()`	`FilterInputStream`	`notify()`	`Object`
`notifyAll()`	`Object`	`read()`	`InflaterInputStream`
`read(byte[])`	`FilterInputStream`	`reset()`	`FilterInputStream`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

ZipEntry

Name

ZipEntry

Synopsis

Class Name:

```
java.util.zip.ZipEntry
```

Superclass:

```
java.lang.Object
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `ZipEntry` class represents a single entry in a ZIP file, which is either a compressed file or an uncompressed file. `ZipEntry` provides methods that set and retrieve various pieces of information about an entry.

When you are reading a ZIP file, you use `ZipInputStream.getNextEntry()` to return the next entry in the file. Then you can retrieve information about that particular entry. You can also read the entries in a ZIP file in a nonsequential order using the `ZipFile` class.

When you are writing a ZIP file, you use `ZipOutputStream.putNextEntry()` to write an entry, and you must create your own `ZipEntry` objects. If you are storing compressed (deflated) files, you need only specify a name for the `ZipEntry` ; the other fields are filled in automatically. If, however, you are placing uncompressed entries, you need to specify the size of each entry and provide a CRC-32 checksum value.

Class Summary

```
public class java.util.zip.ZipEntry extends java.lang.Object {
  // Constants
  public static final int DEFLATED;
  public static final int STORED;
  // Constructors
  public ZipEntry(String name);
  // Instance Methods
  public String getComment();
  public long getCompressedSize();
  public long getCrc();
  public byte[] getExtra();
  public int getMethod();
  public String getName();
  public long getSize();
  public long getTime();
  public boolean isDirectory();
  public void setComment(String comment);
  public void setCrc(long crc);
  public void setExtra(byte[] extra);
  public void setMethod(int method);
  public void setSize(long size);
  public void setTime(long time);
  public String toString();
}
```

Constants

DEFLATED

public static final int DEFLATED

Description

A constant that represents an entry that is stored using the deflate algorithm.

STORED

public static final int STORED

Description

A constant that represents an entry that is stored verbatim; in other words, with no compression applied.

Constructors

ZipEntry

public ZipEntry(String name)

Parameters

`name`

The name of the entry.

Throws

`NullPointerException`

If `name` is `null`.

`IllegalArgumentException`

If `name` is longer than `0xFFFF` bytes.

Description

This constructor creates a `ZipEntry` with the given name.

Instance Methods

getComment

public String getComment()

Returns

The comment of this entry or `null` if one has not been specified.

Description

This method returns the comment string for this `ZipEntry`.

getCompressedSize

public long getCompressedSize()

Returns

The compressed size of this entry or `-1` is the compressed size is not known.

Description

This method returns the compressed size of this `ZipEntry`.

getCrc

public long getCrc()

Returns

The checksum value for this entry.

Description

This method returns the CRC-32 checksum value for this `ZipEntry`.

getExtra

public byte[] getExtra()

Returns

The extra field data for this entry or `null` if there is none.

Description

This method returns the bytes in the extra field data for this `ZipEntry`.

getMethod

public int getMethod()

Returns

The compression method of this entry or `-1` if it has not been specified.

Description

This method returns the compression method of this `ZipEntry`. Valid values are `DEFLATED` and `STORED`.

getName

public String getName()

Returns

The name of this entry.

Description

This method returns the string name of this `ZipEntry`.

getSize

public long getSize()

Returns

The uncompressed size of this entry or `-1` if the uncompressed size is not known.

Description

This method returns the uncompressed size of this `ZipEntry`.

getTime

public long getTime()

Returns

The modification date of this entry.

Description

This method returns the modification date of this `ZipEntry` as the number of milliseconds since midnight, January 1, 1970 GMT.

isDirectory

public boolean isDirectory()

Returns

A `boolean` value that indicates whether or not this entry is a directory.

Description

This method returns `true` if this `ZipEntry` represents a directory.

setComment

public void setComment(String comment)

Parameters

`comment`

The new comment string.

Throws

`IllegalArgumentException`

If `comment` is longer than `0xFFFF` bytes.

Description

This method sets the comment string of this `ZipEntry`.

setCrc

public void setCrc(long crc)

Parameters

`crc`

The new checksum value.

Description

This method sets the CRC-32 checksum value for this `ZipEntry`.

setExtra

public void setExtra(byte[] extra)

Parameters

`extra`

The extra field data.

Throws

`IllegalArgumentException`

If `extra` is longer than `0xFFFF` bytes.

Description

This method sets the extra field data for this `ZipEntry`.

setMethod

public void setMethod(int method)

Parameters

`method`

The new compression method.

Throws

`IllegalArgumentException`

If `method` is not `DEFLATED` or `STORED`.

Description

This method sets the compression method of this `ZipEntry`. This corresponds to the compression level of `Deflater`.

setSize

public void setSize(long size)

Parameters

`size`

The new uncompressed entry size.

Throws

`IllegalArgumentException`

If `size` is less than 0 or greater than `0xFFFFFFFF` bytes.

Description

This method sets the uncompressed size of this `ZipEntry`.

setTime

public void setTime(long time)

Parameters

`time`

The new modification date, expressed as the number of seconds since midnight, January 1, 1970 GMT.

Description

This method sets the modification date of this `ZipEntry`.

toString

public String toString()

Returns

A string representation of this object.

Overrides

`Object.toString()`

Description

This method returns the name of this `ZipEntry`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`

Synopsis

Class Name:

`java.util.zip.ZipException`

Superclass:

`java.io.IOException`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `ZipException` is thrown when an error occurs when reading or writing a ZIP file. Normally this occurs when data is read that is not in the correct format.

Class Summary

```
public class java.util.ZipException extends java.io.IOException {
  // Constructors
  public ZipException();
  public ZipException(String s);
}
```

Constructors

ZipException

protected ZipException()

Description

This constructor creates a `ZipException` with no associated detail message.

public ZipException(String s)

Parameters

`s`

The detail message.

Description

This constructor creates a `ZipException` with the given detail message.

ZipFile

Name

ZipFile

Synopsis

Class Name:

`java.util.zip.ZipFile`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `ZipFile` class represents a ZIP file. Unlike with a `ZipInputStream`, you can read the entries in a `ZipFile` nonsequentially. Internally, the class uses a `RandomAccessFile` so that you can read the entries from the file in any order. You can obtain a list of the entries in this ZIP file by calling `entries()`. Given an entry, you can get an `InputStream` for that entry using `getInputStream()`.

Class Summary

```
public class java.util.zip.ZipFile extends java.lang.Object {
  // Constructors
  public ZipFile(File file);
  public ZipFile(String name);
  // Instance Methods
  public void close();
  public Enumeration entries();
  public ZipEntry getEntry(String name);
  public InputStream getInputStream(ZipEntry ze);
  public String getName();
}
```

Constructors

ZipFile

public ZipFile(File file) throws ZipException, IOException

Parameters

`file`

The `File` to read.

Throws

`ZipException`

If the ZIP file cannot be read.

`IOException`

If any other kind of I/O error occurs.

Description

This constructor creates a `ZipFile` for reading from the given `File` object.

public ZipFile(String name) throws IOException

Parameters

`name`

A string that contains the path name of the file.

Throws

`ZipException`

If the ZIP file cannot be read.

`IOException`

If any other kind of I/O error occurs.

Description

This constructor creates a `ZipFile` for reading from the file specified by the given path.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Description

This method closes the `ZipFile` and releases its system resources.

entries

public Enumeration entries()

Returns

An `Enumeration` of `ZipEntry` objects.

Description

This method returns an enumeration of `ZipEntry` objects that represents the contents of this `ZipFile`.

getEntry

public ZipEntry getEntry(String name)

Parameters

`name`

The entry name.

Returns

The entry corresponding to the given name or `null` if there is no such entry.

Description

This method returns the `ZipEntry` object that corresponds to the given entry name.

getInputStream

public InputStream getInputStream(ZipEntry ze) throws IOException

Parameters

`ze`

A `ZipEntry` in this file.

Returns

An `InputStream` for the given entry.

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Description

This method returns an input stream that can read the entry described by the supplied `ZipEntry`.

getName

public String getName()

Returns

The path of this file.

Description

This method returns the path name of this `ZipFile`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`

ZipInputStream

Name

ZipInputStream

Synopsis

Class Name:

`java.util.zip.ZipInputStream`

Superclass:

`java.util.zip.InflaterInputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The ZipInputStream class reads files that have been compressed using the ZIP format. To read uncompressed data from a ZIP file, simply construct a ZipInputStream that wraps a regular input stream. The getNextEntry() method returns each entry in the ZIP file in order. Once you have a ZipEntry object, you use the read() method to retrieve uncompressed data from it. If you want to read the entries in a nonsequential order, use a ZipFile instead.

Class Summary

```
public class java.util.zip.ZipInputStream
             extends java.util.zip.InflaterInputStream {
  // Constructors
  public ZipInputStream(InputStream in);
  // Instance Methods
  public void close();
  public void closeEntry();
  public ZipEntry getNextEntry();
  public int read(byte[] b, int off, int len);
  public long skip(long n);
}
```

Constructors

ZipInputStream

public ZipInputStream(InputStream in)

Parameters

in

The underlying input stream.

Description

This constructor creates a ZipInputStream that inflates data from the given InputStream.

Instance Methods

close

public void close() throws IOException

Throws

`IOException`

If any I/O error occurs.

Overrides

`FilterInputStream.close()`

Description

This method closes this stream and releases any system resources that are associated with it.

closeEntry

public void closeEntry() throws IOException

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Description

This method closes the currently open entry in the ZIP file. The stream is then positioned to read the next entry using `getNextEntry()`.

getNextEntry

public ZipEntry getNextEntry() throws IOException

Returns

> The `ZipEntry` for the next entry or `null` if there are no more entries.

Throws

> `ZipException`
>
> > If a ZIP file format error occurs.
>
> `IOException`
>
> > If any other kind of I/O error occurs.

Description

> This method returns a `ZipEntry` that represents the next entry in the ZIP file and positions the stream to read that entry.

read

public int read(byte[] b, int off, int len) throws IOException

Parameters

> `b`
>
> > An array of bytes to be filled from the stream.
>
> `off`
>
> > An offset into the byte array.
>
> `len`
>
> > The number of bytes to read.

Returns

The number of bytes read or `-1` if the end of the entry is encountered immediately.

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Overrides

`InflaterInputStream.read(byte[], int, int)`

Description

This method reads enough data from the underlying `InputStream` to return `len` bytes of uncompressed data. The uncompressed data is placed into the given array starting at `off`. The method blocks until some data is available for decompression.

skip

public long skip(long n) throws IOException

Returns

The actual number of bytes skipped.

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any kind of I/O error occurs.

Overrides

`InflaterInputStream.skip()`

Description

This method skips over the specified number of uncompressed data bytes by reading data from the underlying `InputStream` and decompressing it.

Inherited Methods

Method	Inherited From	Method	Inherited From
`available()`	`FilterInputStream`	`clone()`	`Object`
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`mark(int)`	`FilterInputStream`	`markSupported()`	`FilterInputStream`
`notify()`	`Object`	`notifyAll()`	`Object`
`read()`	`InflaterInputStream`	`read(byte[])`	`FilterInputStream`
`reset()`	`FilterInputStream`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

`Inflater`, `InflaterInputStream`, `InputStream`, `IOException`, `ZipEntry`, `ZipException`, `ZipFile`

ZipOutputStream

Name

ZipOutputStream

Synopsis

Class Name:

`java.util.zip.ZipOutputStream`

Superclass:

`java.util.zip.DeflaterOutputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `ZipOutputStream` class writes compressed files in the ZIP format. To write a ZIP file, construct a `ZipOutputStream` that wraps a regular output stream. You have to create a `ZipEntry` for each entry in the file. The `putNextEntry()` method puts the entry in the file, so that you can then use the `write()` method to write data for that entry. When you finish writing the data for an entry, call `closeEntry()` to close that entry and `putNextEntry()` to start another entry.

The `setMethod()` method specifies whether the data is compressed or uncompressed by default; `setLevel()` specifies the level of compression that is used by default. These values can be overridden by the method and level set for a particular entry. If you are storing compressed (deflated) files, you need only specify a name for each `ZipEntry` ; the other fields are filled in automatically. If, however, you are placing uncompressed entries, you need to specify the size of each entry and provide a CRC-32 checksum value.

Class Summary

```
public class java.util.zip.ZipOutputStream
             extends java.util.zip.DeflaterOutputStream {
  // Constants
  public static final int DEFLATED;
  public static final int STORED;
  // Constructors
  public ZipOutputStream(OutputStream out);
  // Instance Methods
  public void close();
  public void closeEntry();
  public void finish();
  public void putNextEntry(ZipEntry e);
  public void setComment(String comment);
  public void setLevel(int level);
  public void setMethod(int method);
  public synchronized void write(byte[] b, int off, int len);
}
```

Constants

DEFLATED

public static final int DEFLATED

Description

> A constant that represents an entry is stored using the deflate algorithm.

STORED

public static final int STORED

Description

A constant that represents a ZIP file entry is stored verbatim; in other words, with no compression applied.

Constructors

ZipOutputStream

public ZipOutputStream(OutputStream out)

Parameters

`out`

The underlying output stream.

Description

This constructor creates a `ZipOutputStream` that writes compressed data to the given `OutputStream`.

Instance Methods

close

public void close() throws IOException

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Overrides

`DeflaterOutputStream.close()`

Description

This method closes the stream and releases any system resources that are associated with it.

closeEntry

public void closeEntry() throws IOException

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Description

This method closes the currently open entry in the ZIP file. A subsequent entry can be started with `putNextEntry()`.

finish

public void finish() throws IOException

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Overrides

`DeflaterOutputStream.finish()`

Description

This method finishes writing compressed data to the underlying stream without closing it.

putNextEntry

public void putNextEntry(ZipEntry e) throws IOException

Parameters

`e`

The new entry.

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Description

This method writes the information in the given `ZipEntry` to the stream and positions the stream for the entry data. The actual entry data can then be written to the stream using `write()`. The default compression method and level are used if one is not specified for the entry. When all of the entry data has been written, use `closeEntry()` to finish the entry.

If this method is called when there is already an open entry, that entry is closed and this entry is opened.

setComment

public void setComment(String comment)

Parameters

`comment`

The new comment string.

Throws

`IllegalArgumentException`

If `comment` is longer than `0xFFFF` bytes.

Description

This method sets the comment string for this ZIP file.

setLevel

public void setLevel(int level)

Parameters

`level`

A compression level, from 0 (`NO_COMPRESSION`) to 9 (`BEST_COMPRESSION`).

Throws

`IllegalArgumentException`

If `level` is not valid.

Description

This method sets the default compression level of subsequent `DEFLATED` entries. The default value is `Deflater.DEFAULT_COMPRESSION`.

setMethod

public void setMethod(int method)

Parameters

`method`

A compression method, either `DEFLATED` or `STORED`.

Throws

`IllegalArgumentException`

If `method` is not valid.

Description

This method sets the default compression method of this `ZipOutputStream` for entries that do not specify a method.

write

`public synchronized void write(byte[] b, int off, int len) throws IOException`

Parameters

`b`

An array of bytes to write to the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to write.

Throws

`ZipException`

If a ZIP file format error occurs.

`IOException`

If any other kind of I/O error occurs.

Overrides

`DeflaterOutputStream.write(byte[], int, int)`

Description

This method takes `len` bytes from the given buffer, starting at `off`, and compresses them. The method then writes the compressed data to the underlying `OutputStream` for the current entry. The method blocks until all the bytes have been written.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`flush()`	`FilterOutputStream`
`getClass()`	`Object`	`hashCode()`	`Object`

`notify()`	`Object`	`notifyAll()`	`Object`
`toString()`	`Object`	`wait()`	`Object`
`wait(long)`	`Object`	`wait(long, int)`	`Object`
`write(int)`	`DeflaterOutputStream`	`write(byte[])`	`FilterOutputStream`

See Also

`Deflater`, `DeflaterOutputStream`, `IllegalArgumentException`, `IOException`, `OutputStream`, `ZipEntry`, `ZipException`

ZipInputStream BOOK INDEX The Unicode 2.0 Character Set

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

What This Book Covers

The *Java AWT Reference* is the definitive resource for programmers working with AWT. It covers all aspects of the AWT package, in versions 1.0.2 and 1.1. If there are any changes to AWT after 1.1 (at least two patch releases are expected), we will integrate them as soon as possible. Watch the book's Web site http://www.ora.com/catalog/javawt/ for details on changes.

Specifically, this book completely covers the following packages:

`java.awt` (1.0 and 1.1)
`java.awt.image` (1.0 and 1.1)
`java.awt.event` (new to 1.1)
`java.awt.datatransfer` (new to 1.1)
`java.awt.peer` (1.0 and 1.1)
`java.applet` (1.0 and 1.1)

The book also covers some aspects of the `sun.awt` package (some interesting and useful layout managers) and the `sun.audio` package (some more flexible ways of working with audio files). It also gives a brief overview of the behind-the-scenes machinery for rendering images, much of which is in the `sun.awt.image` package.

Organization

The *Java AWT Reference* is divided into two large parts. The first part is a thorough guide to using AWT. Although this guide is organized by class, it was designed to flow logically, rather than alphabetically. I know that few people read a book like this from beginning to end, but if you want to, it's possible. With a few exceptions, you should be able to read the early chapters without knowing the material that's covered in the later chapters. You'll want to read this section to find out how any chunk of the AWT package works in detail.

The second part is a set of documentation pages typical of what you find in most reference sets. It is organized alphabetically by package, and within each package, alphabetically by class. It is designed to answer questions like "What are the arguments to the `FilteredImageSource` constructor?" The reference section provides brief summaries, rather than detailed discussions and examples. When you use a typical reference book, you're usually trying to look up some detail, rather than learn how something works from scratch.

In other words, this book provides two views of AWT: terse summaries designed to help you when you need to look something up quickly, and much more detailed explanations designed to help you understand how to use AWT to the fullest. In doing so, it goes well beyond the standard reference manual. A reference manual alone gives you a great view of hundreds of individual trees; this book gives you the trees, but also gives you the forest that allows you to put the individual pieces in context. There are dozens of complete examples, together with background information, overview material, and other information that doesn't fit into the standard reference manual format.

About the Source Code

The source code for the programs presented in this book is available online. See http://www.ora.com/catalog/javawt/ for downloading instructions.

Obtaining the Example Programs

The example programs in this book are available electronically in a number of ways: by FTP, Ftpmail, BITFTP, and UUCP. The cheapest, fastest, and easiest ways are listed first. If you read from the top down, the first one that works for you is probably the best. Use FTP if you are directly on the Internet. Use Ftpmail if you are not on the Internet but can send and receive electronic mail to Internet sites (this includes CompuServe users). Use BITFTP if you send electronic mail via BITNET. Use UUCP if none of the above works.

FTP

To use FTP, you need a machine with direct access to the Internet. A sample session is shown, with what you should type in `boldface`.

```
% ftp ftp.ora.com
Connected to ftp.ora.com.
220 FTP server (Version 6.21 Tue Mar 10 22:09:55 EST 1992) ready.
Name (ftp.ora.com:yourname): anonymous
331 Guest login ok, send domain style e-mail address as password.
Password: yourname@yourhost.com (use your user name and host here)
230 Guest login ok, access restrictions apply.
ftp> cd /published/oreilly/java/awt
250 CWD command successful.
ftp> binary (Very important! You must specify binary transfer for compressed files.)
200 Type set to I.
ftp> get examples.tar.gz
200 PORT command successful.
150 Opening BINARY mode data connection for examples.tar.gz.
226 Transfer complete.
ftp> quit
221 Goodbye.
%
```

The file is a compressed *tar* archive; extract the files from the archive by typing:

```
% zcat examples.tar.gz | tar xvf -
```

System V systems require the following *tar* command instead:

```
% zcat examples.tar.gz | tar xof -
```

If *zcat* is not available on your system, use separate *gunzip* and *tar* commands.

```
% gunzip examples.tar.gz
% tar xvf examples.tar
```

Ftpmail

Ftpmail is a mail server available to anyone who can send electronic mail to, and receive it from, Internet sites. This includes any company or service provider that allows email connections to the Internet. Here's how you do it.

You send mail to *ftpmail@online.ora.com*. (Be sure to address the message to *ftpmail* and not to *ftp*.) In the message body, give the FTP commands you want to run. The server will run anonymous FTP for you and mail the files back to you. To get a complete help file, send a message with no subject and the single word "help" in the body. The following is a sample mail session that should get you the examples. This command sends you a listing of the files in the selected directory and the requested example files. The listing is useful if there's a later version of the examples you're interested in.

```
% mail ftpmail@online.ora.com
Subject:
reply-to yourname@yourhost.com    Where you want files mailed
open
cd /published/oreilly/java/awt
dir
mode binary
uuencode
get examples.tar.gz
quit
.
```

A signature at the end of the message is acceptable as long as it appears after "quit."

BITFTP

BITFTP is a mail server for BITNET users. You send it electronic mail messages requesting files, and it sends you back the files by electronic mail. BITFTP currently serves only users who send it mail from nodes that are directly on BITNET, EARN, or NetNorth. BITFTP is a public service of Princeton University. Here's how it works.

To use BITFTP, send mail containing your FTP commands to *BITFTP@PUCC*. For a complete help file, send HELP as the message body.

The following is the message body you send to BITFTP:

```
FTP  ftp.uu.net  NETDATA
USER  anonymous
PASS  yourname@yourhost.edu Put your Internet email address here (not your BITNET
address)
```

```
CD  /published/oreilly/java/awt
DIR
BINARY
GET  examples.tar.gz
QUIT
```

Once you've got the desired file, follow the directions under FTP to extract the files from the archive. Since you are probably not on a UNIX system, you may need to get versions of *uudecode*, *uncompress*, *atob*, and *tar* for your system. VMS, DOS, and Mac versions are available. The VMS versions are on *gatekeeper.dec.com* in */pub/VMS*.

UUCP

UUCP is standard on virtually all UNIX systems and is available for IBM-compatible PCs and Apple Macintoshes. The examples are available by UUCP via modem from UUNET; UUNET's connect-time charges apply.

If you or your company has an account with UUNET, you have a system somewhere with a direct UUCP connection to UUNET. Find that system, and type:

```
uucp uunet\!~/published/oreilly/java/awt/examples.tar.gz yourhost\!~/yourname/
```

The backslashes can be omitted if you use the Bourne shell (*sh*) instead of *csh*. The file should appear some time later (up to a day or more) in the directory */usr/spool/uucppublic/*`yourname`. If you don't have an account, but would like one so that you can get electronic mail, contact UUNET at 703-204-8000.

Once you've got the desired file, follow the directions under FTP to extract the files from the archive.

Other Java Books and Resources

This book is part of a series of Java books from O'Reilly & Associates that covers everything you wanted to know, and then some. The *Java AWT Reference* is paired with the *Java Fundamental Class Reference* to document the entire Core Java API. Other books in the series provide an introduction (*Exploring Java*) and document the virtual machine (*Java Virtual Machine*), the language (*Java Language Reference*), multithreaded programming (*Java Threads*), and network programming (*Java Network Programming*), with more to come. *Java in a Nutshell* is another popular Java book in the Nutshell series from O'Reilly. For a complete up-to-date list of the available Java resources, refer to http://www.ora.com/info/java/.

In addition to the resources from O'Reilly, Sun's online documentation on Java is maintained at http://www.javasoft.com/nav/download/index.html. Information on specific Java-capable browsers can be found at their respective Web sites, which are listed in Table 0.1. More are sure to be on the way. (Some browsers are platform specific, while others are multi-platform.)

Table 0.1: Popular Web Browsers that Support Java

Browser	**Location**
Netscape Navigator	http://home.netscape.com/comprod/products/navigator/
Microsoft's Internet Explorer	http://www.microsoft.com/ie
Sun's HotJava	http://www.javasoft.com/HotJava/
Oracle's PowerBrowser	http://www.oracle.com/products/websystem/powerbrowser
Apple's Cyberdog	http://cyberdog.apple.com/

Newsgroups also serve as a discussion area for Java-related topics. The *comp.lang.java* group has formally split into several others. The new groups are:

comp.lang.java.advocacy
comp.lang.java.announce
comp.lang.java.beans
comp.lang.java.databases
comp.lang.java.gui
comp.lang.java.help
comp.lang.java.machine
comp.lang.java.programmer
comp.lang.java.security
comp.lang.java.setup
comp.lang.java.softwaretools
comp.lang.java.tech

For folks without time to dig through all the noise, *Digital Espresso* provides a periodic digest of the newsfeed at http://www.io.org./~mentor/DigitalEspresso.html. A list of Java FAQs is at http://www-net.com/java/faq/; one of the most interesting is *Cafe Au Lait*, at http://sunsite.unc.edu/javafaq/. (*Cafe Au Lait* is written by Elliotte Rusty Harold, author of *Java Network Programming*.)

Local Java user groups are another good resource. (Having founded one myself, I'm biased.) What they offer varies greatly, but unless you look at one, you are potentially leaving out a vast resource for knowledge and experience. Lists of area user groups are available from JavaSoft at http://www.javasoft.com/Mail/usrgrp.html; also check out the Sun User Group's Special Interest Group for Users of Java at http://www.sug.org/Java/groups.html. In addition to the usual monthly meetings and forums, some maintain a mailing list for technical exchanges.

Security is a major issue with Java. If you are interested in reading more about Java security issues, Princeton University's Safe Internet Programming Web site at http://www.cs.princeton.edu/sip/News.html is an excellent resource.

1.3 Layouts

Layouts allow you to format components on the screen in a platform-independent way. Without layouts, you would be forced to place components at explicit locations on the screen, creating obvious problems for programs that need to run on multiple platforms. There's no guarantee that a `TextArea` or a `Scrollbar` or any other component will be the same size on each platform; in fact, you can bet they won't be. In an effort to make your Java creations portable across multiple platforms, Sun created a `LayoutManager` interface that defines methods to reformat the screen based on the current layout and component sizes. Layout managers try to give programs a consistent and reasonable appearance, regardless of the platform, the screen size, or actions the user might take.

The standard JDK provides five classes that implement the `LayoutManager` interface. They are `FlowLayout`, `GridLayout`, `BorderLayout`, `CardLayout`, and `GridBagLayout`. All of these layouts are covered in much greater detail in Chapter 7, *Layouts*. This chapter also discusses how to create complex layouts by combining layout managers and how to write your own `LayoutManager`. The Java 1.1 JDK includes the `LayoutManager2` interface. This interface extends the `LayoutManager` interface for managers that provide constraint-based layouts.

FlowLayout

The `FlowLayout` is the default layout for the `Panel` class, which includes its most famous subclass, `Applet`. When you add components to the screen, they flow left to right (centered within the applet) based upon the order added and the width of the applet. When there are too many components to fit, they "wrap" to a new row, similar to a word processor with word wrap enabled. If you resize an applet, the components' flow will change based upon the new width and height. Figure 1.11 shows an example both before and after resizing. FlowLayout contains all the `FlowLayout` details.

Figure 1.11: A FlowLayout before and after resizing

[Graphic: Figure 1-11]

GridLayout

The GridLayout is widely used for arranging components in rows and columns. As with FlowLayout, the order in which you add components is relevant. You start at row one, column one, move across the row until it's full, then continue on to the next row. However, unlike FlowLayout, the underlying components are resized to fill the row-column area, if possible. GridLayout can reposition or resize objects after adding or removing components. Whenever the area is resized, the components within it are resized. Figure 1.12 shows an example before and after resizing. GridLayout contains all the details about GridLayout.

Figure 1.12: A GridLayout before and after resizing

[Graphic: Figure 1-12]

BorderLayout

BorderLayout is one of the more unusual layouts provided. It is the default layout for Window, along with its children, Frame and Dialog. BorderLayout provides five areas to hold components. These areas are named after the four different borders of the screen, North, South, East, and West, with any remaining space going into the Center area. When you add a component to the layout, you must specify which area to place it in. The order in which components are added to the screen is not important, although you can have only one component in each area. Figure 1.13 shows a `BorderLayout` that has one button in each area, before and after resizing. BorderLayout covers the details of the `BorderLayout`.

Figure 1.13: A BorderLayout

[Graphic: Figure 1-13]

CardLayout

The `CardLayout` is a bit on the strange side. A `CardLayout` usually manages several components, displaying one of them at a time and hiding the rest. All the components are given the same size. Usually, the `CardLayout` manages a group of `Panels` (or some other container), and each `Panel` contains several components of its own. With a little work, you can use the `CardLayout` to create tabbed dialog boxes or property sheets, which are not currently part of AWT. `CardLayout` lets you assign names to the components it is managing and lets you jump to a component by name. You can also cycle through components in order. Figure 1.11, Figure 1.12, and Figure 1.13 show multiple cards controlled by a single `CardLayout`. Selecting the `Choice` button displays a different card. CardLayout discusses the details of `CardLayout`.

GridBagLayout

`GridBagLayout` is the most sophisticated and complex of the layouts provided in the development kit. With the `GridBagLayout`, you can organize components in multiple rows and columns, stretch specific rows or columns when space is available, and anchor objects in different corners. You provide all the details of each component through instances of the `GridBagConstraints` class. Figure 1.14 shows an example of a `GridBagLayout`. `GridBagLayout` and `GridBagConstraints` are discussed in GridBagLayout and GridBagConstraints.

Figure 1.14: A GridBagLayout

[Graphic: Figure 1-14]

PREVIOUS | HOME | NEXT
Peers | BOOK INDEX | Containers

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.4 Containers

A Container is a type of component that provides a rectangular area within which other components can be organized by a LayoutManager. Because Container is a subclass of Component, a Container can go inside another Container, which can go inside another Container, and so on, like Russian nesting dolls. Subclassing Container allows you to encapsulate code for the components within it. This allows you to create reusable higher-level objects easily. Figure 1.15 shows the components in a layout built from several nested containers.

Figure 1.15: Components within containers

[Graphic: Figure 1-15]

Panels

A Panel is the basic building block of an applet. It provides a container with no special features. The default layout for a Panel is FlowLayout. The details of Panel are discussed in Panel. Figure 1.16 shows an applet that contains panels within panels within panels.

Figure 1.16: A multilevel panel

[Graphic: Figure 1-16]

Windows

A Window provides a top-level window on the screen, with no borders or menu bar. It provides a way to implement pop-up messages, among other things. The default layout for a Window is BorderLayout. Window explores the Window class in greater detail. Figure 1.17 shows a pop-up message using a Window in Microsoft Windows and Motif.

Figure 1.17: Pop-up windows

[Graphic: Figure 1-17]

Frames

A Frame is a Window with all the window manager's adornments (window title, borders, window minimize/maximize/close functionality) added. It may also include a menu bar. Since Frame subclasses Window, its default layout is BorderLayout. Frame provides the basic building block for screen-oriented applications. Frame allows you to change the mouse cursor, set an icon image, and have menus. All the details of Frame are discussed in Frames. Figure 1.18 shows an example Frame.

Figure 1.18: A frame

[Graphic: Figure 1-18]

Dialog and FileDialog

A `Dialog` is a `Window` that accepts input from the user. `BorderLayout` is the default layout of `Dialog` because it subclasses `Window`. A `Dialog` is a pop-up used for user interaction; it can be modal to prevent the user from doing anything with the application before responding. A `FileDialog` provides a prebuilt `Dialog` box that interacts with the filesystem. It implements the Open/Save dialog provided by the native windowing system. You will primarily use `FileDialog` with applications since there is no guarantee that an applet can interact with the local filesystem. (Netscape Navigator will throw an exception if you try to use it.) The details of `Dialog` are revealed in Dialogs, while `FileDialog` is discussed in FileDialog. Figure 1.19 shows sample `Dialog` and `FileDialog` boxes.

Figure 1.19: Examples of Dialog and FileDialog boxes

[Graphic: Figure 1-19]

ScrollPane

Java 1.1 introduces the `ScrollPane` container. In version 1.0, if you want to have a scrolling area (for example, to display an image that won't fit onto the screen), you create a panel using `BorderLayout` that contains scrollbars on the right and bottom, and display part of the image in the rest of the screen. When the user scrolls, you capture the event, figure out what part of the image to display, and update the screen accordingly. Although this works, its performance is poor, and it's inconvenient. With version 1.1 of Java, you can tell the `ScrollPane` what needs to scroll; it creates the scrollbars and handles all the events automatically. ScrollPane covers the `ScrollPane`; Figure 1.20 shows a `ScrollPane`. Chapter 11, *Scrolling*, covers the `Adjustable` interface that `Scrollbar` implements and `ScrollPane` utilizes.

Figure 1.20: A ScrollPane

And the Rest

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.5 And the Rest

Several of the remaining classes within `java.awt` are important to mention here but did not fit well into a general category. The following sections are a grab bag that summarize the remaining classes.

Drawing and Graphics

Java provides numerous primitives for drawing lines, squares, circles, polygons, and images. Figure 1.21 shows a simple drawing. The drawing components of AWT are discussed in Chapter 2, *Simple Graphics*.

The `Font`, `FontMetrics`, `Color`, and `SystemColor` classes provide the ability to alter the displayed output. With the `Font` class, you adjust how displayed text will appear. With `FontMetrics`, you can find out how large the output will be, for the specific system the user is using. You can use the `Color` class to set the color of text and graphics. `SystemColor` is new to Java 1.1; it lets you take advantage of desktop color schemes. These classes are discussed in Chapter 3, *Fonts and Colors*.

Figure 1.21: A simple drawing

[Graphic: Figure 1-21]

AWT also includes a number of classes that support more complex graphics manipulations: displaying images, generating images in memory, and transforming images. These classes make up the package `java.awt.image`, which is covered in Chapter 12, *Image Processing*.

Events

Like most windows programming environments, AWT is event driven. When an event occurs (for example, the user presses a key or moves the mouse), the environment generates an event and passes it along to a handler to process the event. If nobody wants to handle the event, the system ignores it. Unlike some windowing environments, you do not have to provide a main loop to catch and process all the events, or an infinite busy-wait loop. AWT does all the event management and passing for you.

Probably the most significant difference between versions 1.0.2 and 1.1 of AWT is the way events work. In older versions of Java, an event is distributed to every component that might conceivably be interested in it, until some component declares that it has handled the event. This event model can still be used in 1.1, but there is also a new event model in which objects listen for particular events. This new model is arguably a little more work for the programmer but promises to be much more efficient, because events are distributed only to objects that want to hear about them. It is also how JavaBeans works.

In this book, examples that are using the older (1.0.2) components use the old event model, unless otherwise indicated. Examples using new components use the new event model. Don't let this mislead you; all components in Java 1.1 support the new event model. The details of `Event` for both version 1.0.2 and 1.1 can be found in Chapter 4, *Events*.

Applets

Although it is not a part of the `java.awt` package, the Core Java API provides a framework for applet development. This includes support for getting parameters from HTML files, changing the web page a browser is displaying, and playing audio files. Chapter 14, *And Then There Were Applets*, describes all the details of the `java.applet` package. Because audio support is part of `java.applet`, portable audio playing is limited to applets. Chapter 14, *And Then There Were Applets* also shows a nonportable way to play audio in applications. Additional audio capabilities are coming to the Java Core API in the announced extensions.

Clipboards

In Java 1.1, programs can access the system clipboard. This process makes it easier to transfer (cut, copy, and paste) data between various other sources and your Java programs and introduces developers to the concepts involved with JavaBeans. Chapter 16, *Data Transfer*, describes the `java.awt.datatransfer` package.

Printing

Java 1.1 adds the ability to print. Adding printing to an existing program is fairly simple: you don't have to do much beside adding a Print menu button. Chapter 17, *Printing*, describes these capabilities.

Containers BOOK INDEX Summary

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.2 Labels

Having covered the features of the `Component` class, we can now look at some of the simplest components. The first component introduced here is a `Label`. A label is a `Component` that displays a single line of static text.[3] It is useful for putting a title or message next to another component. The text can be centered or justified to the left or right. Labels react to all events they receive. However, they do not get any events from their peers.

> [3] *Java in A Nutshell* (from O'Reilly & Associates) includes a multiline `Label` component.

Label Methods

Constants

There are three alignment specifiers for labels. The alignment tells the `Label` where to position its text within the space allotted. Setting an alignment for a `Label` might not do anything noticeable if the `LayoutManager` being used does not resize the `Label` to give it more space. With `FlowLayout`, the alignment is barely noticeable. See Chapter 7, *Layouts*, for more information.

public final static int LEFT

> `LEFT` is the constant for left alignment. If no alignment is specified in the constructor, left alignment is the default.

public final static int CENTER

> `CENTER` is the constant for center alignment.

public final static int RIGHT

> `RIGHT` is the constant for right alignment.

Constructors

public Label ()

> This constructor creates an empty `Label`. By default, the label's text is left justified.

public Label (String label)

> This constructor creates a `Label` whose initial text is `label`. By default, the label's text is left justified.

public Label (String label, int alignment)

> This constructor creates a `Label` whose initial text is `label`. The alignment of the label is `alignment`. If `alignment` is invalid (not `LEFT`, `RIGHT`, or `CENTER`), the constructor throws the run-time exception `IllegalArgumentException`.

Text

public String getText ()

> The `getText()` method returns the current value of `Label`.

public void setText (String label)

> The `setText()` method changes the text of the `Label` to `label`. If the new label is a different size from the old one, you should revalidate the display to ensure the label's entire contents will be seen.

Alignment

public int getAlignment ()

> The `getAlignment()` method returns the current alignment of the `Label`.

public void setAlignment (int alignment)

> The `setAlignment()` method changes the alignment of the `Label` to `alignment`. If

alignment is invalid (not LEFT, RIGHT, or CENTER), setAlignment() throws the run-time exception IllegalArgumentException. Figure 5.2 shows all three alignments.

Figure 5.2: Labels with different alignments

[Graphic: Figure 5-2]

Miscellaneous methods

public synchronized void addNotify ()

The addNotify() method creates the Label peer. If you override this method, first call super.addNotify(), then put in your customizations. Then you will be able to do everything you need with the information about the newly created peer.

protected String paramString ()

The paramString() method overrides Component's paramString() method. It is a protected method that calls the overridden paramString() to build a String from the different parameters of the Component. When the method paramString() is called for a Label, the alignment and label's text are added. Thus, for the Label created by the constructor new Label (`ZapfDingbats`, Label.RIGHT), the results displayed from a call to toString() would be:

```
java.awt.Label[0,0,0x0,invalid,align=right,label=ZapfDingbats]
```

Label Events

The Label component can react to any event it receives, though the Label peer normally does not send any. However, there is nothing to stop you from posting an event yourself.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.3 Buttons

The `Button` component provides one of the most frequently used objects in graphical applications. When the user selects a button, it signals the program that something needs to be done by sending an action event. The program responds in its `handleEvent()` method (for Java 1.0) or its `actionPerformed()` method (defined by Java 1.1's `ActionListener` interface). Next to `Label`, which does nothing, `Button` is the simplest component to understand. Because it is so simple, we will use a lot of buttons in our examples for the next few chapters.

Button Methods

Constructors

public Button ()

> This constructor creates an empty `Button`. You can set the label later with `setLabel()`.

public Button (String label)

> This constructor creates a `Button` whose initial text is `label`.

Button Labels

public String getLabel ()

> The `getLabel()` method retrieves the current text of the label on the `Button` and returns it as a `String`.

public synchronized void setLabel (String label)

> The `setLabel()` method changes the text of the label on the `Button` to `label`. If the new text is a different size from the old, it is necessary to revalidate the screen to ensure that the button size is correct.

Action Commands

With Java 1.1, every button can have two names. One is what the user sees (the button's label); the other is what the programmer sees and is called the button's *action command*. Distinguishing between the label and the action command is a major help to internationalization. The label can be localized for the user's environment. However, this means that labels can vary at run-time and are therefore useless for comparisons within the program. For example, you can't test whether the user pushed the Yes button if that button might read Oui or Ja, depending on some run-time environment setting. To give the programmer something reliable for comparisons, Java 1.1 introduces the action command. The action command for our button might be Yes, regardless of the button's actual label.

By default, the action command is equivalent to the button's label. Java 1.0 code, which only relies on the label, will continue to work. Furthermore, you can continue to write in the Java 1.0 style as long as you're sure that your program will never have to account for other languages. These days, that's a bad bet. Even if you aren't implementing multiple locales now, get in the habit of testing a button's action command rather than its label; you will have less work to do when internationalization does become an issue.

public String getActionCommand () ★

> The `getActionCommand()` method returns the button's current action command. If no action command was explicitly set, this method returns the label.

public void setActionCommand (String command) ★

> The `setActionCommand()` method changes the button's action command to `command`.

Miscellaneous methods

public synchronized void addNotify ()

> The `addNotify()` method creates the `Button` peer. If you override this method, first call `super.addNotify()`, then add your customizations. Then you can do everything you need with the information about the newly created peer.

protected String paramString ()

> The `paramString()` method overrides the component's `paramString()` method. It is a

protected method that calls the overridden `paramString()` to build a `String` from the different parameters of the `Component`. When the method `paramString()` is called for a `Button`, the button's label is added. Thus, for the `Button` created by the constructor `new Button ("ZapfDingbats")`, the results displayed from a call to `toString()` could be:

```
java.awt.Button[77,5,91x21,label=ZapfDingbats]
```

Button Events

With the 1.0 event model, `Button` components generate an `ACTION_EVENT` when the user selects the button.

With the version 1.1 event model, you register an `ActionListener` with the method `addActionListener()`. When the user selects the `Button`, the method `ActionListener.actionPerformed()` is called through the protected `Button.processActionEvent()` method. Key, mouse, and focus listeners are registered through the `Component` methods of `addKeyListener()`, `addMouseListener()`, or `addMouseMotionListener()`, and `addFocusListener()`, respectively. Action

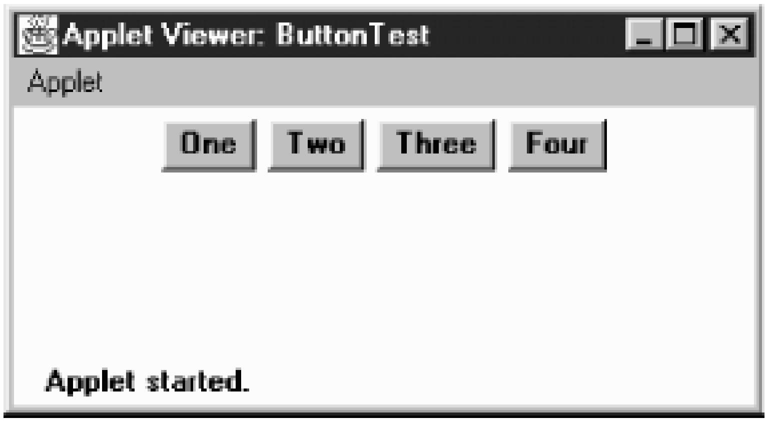
public boolean action (Event e, Object o)

The `action()` method for a `Button` is called when the user presses and releases the button. `e` is the `Event` instance for the specific event, while `o` is the button's label. The default implementation of `action()` does nothing and returns `false`, passing the event to the button's container for processing. For a button to do something useful, you should override either this method or the container's `action()` method. Example 5.1 is a simple applet called `ButtonTest` that demonstrates the first approach; it creates a `Button` subclass called `TheButton`, which overrides `action()`. This simple subclass doesn't do much; it just labels the button and prints a message when the button is pressed. Figure 5.3 shows what `ButtonTest` looks like.

Example 5.1: Button Event Handling

```
import java.awt.*;
import java.applet.*;
class TheButton extends Button {
    TheButton (String s) {
        super (s);
    }
    public boolean action (Event e, Object o) {
        if ("One".equals(o)) {
            System.out.println ("Do something for One");
        } else if ("Two".equals(o)) {
            System.out.println ("Ignore Two");
        } else if ("Three".equals(o)) {
            System.out.println ("Reverse Three");
        } else if ("Four".equals(o)) {
            System.out.println ("Four is the one");
        } else {
            return false;
        }
        return true;
    }
}
public class ButtonTest extends Applet {
   public void init () {
        add (new TheButton ("One"));
        add (new TheButton ("Two"));
        add (new TheButton ("Three"));
        add (new TheButton ("Four"));
   }
}
```

Figure 5.3: The ButtonTest applet



Applet started.

Keyboard

Buttons are able to capture keyboard-related events once the button has the input focus. In order to give a `Button` the input focus without triggering the action event, call `requestFocus()`. The button also gets the focus if the user selects it and drags the mouse off of it without releasing the mouse.

public boolean keyDown (Event e, int key) ☆

The `keyDown()` method is called whenever the user presses a key while the `Button` has the input focus. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) could be either `Event.KEY_PRESS` for a regular key or `Event.KEY_ACTION` for an action-oriented key (i.e., an arrow or a function key). There is no visible indication that the user has pressed a key over the button.

public boolean keyUp (Event e, int key) ☆

The `keyUp()` method is called whenever the user releases a key while the `Button` has the input focus. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) could be either `Event.KEY_RELEASE` for a regular key or `Event.KEY_ACTION_RELEASE` for an action-oriented key (i.e., an arrow or a function key). `keyUp()` may be used to determine how long `key` has been pressed.

Listeners and 1.1 event handling

With the 1.1 event model, you register listeners, which are told when the event happens.

public void addActionListener(ActionListener listener) ★

The `addActionListener()` method registers `listener` as an object interested in receiving notifications when an `ActionEvent` passes through the `EventQueue` with this `Button` as its target. The `listener.actionPerformed()` method is called when these events occur. Multiple listeners can be registered. The following code demonstrates how to use an `ActionListener` to handle the events that occur when the user selects a button. This applet has the same display as the previous one, shown in Figure 5.3.

```
// Java 1.1 only
import java.awt.*;
import java.applet.*;
import java.awt.event.*;
public class ButtonTest11 extends Applet implements ActionListener {
    Button b;
    public void init () {
        add (b = new Button ("One"));
        b.addActionListener (this);
        add (b = new Button ("Two"));
        b.addActionListener (this);
        add (b = new Button ("Three"));
        b.addActionListener (this);
        add (b = new Button ("Four"));
        b.addActionListener (this);
    }
    public void actionPerformed (ActionEvent e) {
        String s = e.getActionCommand();
        if ("One".equals(s)) {
            System.out.println ("Do something for One");
        } else if ("Two".equals(s)) {
            System.out.println ("Ignore Two");
        } else if ("Three".equals(s)) {
            System.out.println ("Reverse Three");
        } else if ("Four".equals(s)) {
            System.out.println ("Four is the one");
        }
    }
}
```

public void removeActionListener(ActionListener listener) ★

The `removeActionListener()` method removes `listener` as an interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives `AWTEvent` with this `Button` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `Button`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processActionEvent(ActionEvent e) ★

The `processActionEvent()` method receives `ActionEvent` with this `Button` as its target. `processActionEvent()` then passes them along to any listeners for processing. When you subclass `Button`, overriding `processActionEvent()` allows you to process all action events yourself, before sending them to any listeners. In a way, overriding processActionEvent() is like overriding action() using the 1.0 event model.

If you override the processActionEvent() method, you must remember to call super.processActionEvent(e) last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call enableEvents() (inherited from Component) to ensure that events are delivered even in the absence of registered listeners.

5.5 Canvas

A `Canvas` is a class just waiting to be subclassed. Through `Canvas`, you can create additional AWT objects that are not provided by the base classes. `Canvas` is also useful as a drawing area, particularly when additional components are on the screen. It is tempting to draw directly onto a `Container`, but this often isn't a good idea. Anything you draw might disappear underneath the components you add to the container. When you are drawing on a container, you are essentially drawing on the background. The container's layout manager doesn't know anything about what you have drawn and won't arrange components with your artwork in mind. To be safe, do your drawing onto a `Canvas` and place that `Canvas` in a `Container`.

Canvas Methods

Constructors

public Canvas () ★

> The constructor creates a new `Canvas` with no default size. If you place the canvas in a container, the container's layout manager sizes the canvas for you. If you aren't placing the canvas in a container, call `setBounds()` to specify the canvas's size.
>
> Java 1.0 used the default constructor for `Canvas`; there was no explicit constructor.

Miscellaneous methods

public void paint (Graphics g) ★

> The default implementation of the `paint()` method colors the entire `Canvas` with the current background color. When you subclass this method, your `paint()` method needs to draw whatever should be shown on the canvas.

public synchronized void addNotify ()

> The `addNotify()` method creates the `Canvas` peer. If you override this method, first call `super.addNotify()`, then add your customizations. Then you can do everything you need with the information about the newly created peer.

Canvas Events

The `Canvas` peer passes all events to you, which is why it's well suited to creating your own components.

2.2 Point

The `Point` class encapsulates x and y coordinates within a single object. It is probably one of the most underused classes within Java. Although there are numerous places within AWT where you would expect to see a `Point`, its appearances are surprisingly rare. Java 1.1 is starting to use `Point` more heavily. The `Point` class is most often used when a method needs to return a pair of coordinates; it lets the method return both x and y as a single object. Unfortunately, `Point` usually is not used when a method requires x and y coordinates as arguments; for example, you would expect the `Graphics` class to have a version of `translate()` that takes a point as an argument, but there isn't one.

The `Point` class does *not* represent a point on the screen. It is not a visual object; there is no `drawPoint()` method.

Point Methods

Variables

The two public variables of `Point` represent a pair of coordinates. They are accessible directly or use the `getLocation()` method. There is no predefined origin for the coordinate space.

public int x

> The coordinate that represents the horizontal position.

public int y

> The coordinate that represents the vertical position.

Constructors

public Point ()

The first constructor creates an instance of `Point` with an initial x value of 0 and an initial y value of 0.

public Point (int x, int y)

The next constructor creates an instance of `Point` with an initial x value of `x` and an initial y value of `y`.

public Point (Point p)

The last constructor creates an instance of `Point` from another point, the x value of `p.x` and an initial y value of `p.y`.

Locations

public Point getLocation () ★

The `getLocation()` method retrieves the current location of this point as a new `Point`.

public void setLocation (int x, int y) ★
public void move (int x, int y) ☆

The `setLocation()` method changes the point's location to (`x`, `y`).

`move()` is the Java 1.0 name for this method.

public void setLocation (Point p) ★

This `setLocation()` method changes the point's location to (`p.x`, `p.y`).

public void translate (int x, int y)

The `translate()` method moves the point's location by adding the parameters (`x`, `y`) to the corresponding fields of the `Point`. If the original `Point p` is (3, 4) and you call `p.translate(4, -5)`, the new value of `p` is (7, -1).

Miscellaneous methods

public int hashCode ()

The `hashCode()` method returns a hash code for the point. The system calls this method when a `Point` is used as the key for a hash table.

public boolean equals (Object object)

The `equals()` method overrides the `Object.equals()` method to define equality for points. Two `Point` objects are equal if their x and y values are equal.

public String toString ()

The `toString()` method of `Point` displays the current values of the x and y variables. For example:

```
java.awt.Point[x=100,y=200]
```

2.3 Dimension

The `Dimension` class is similar to the `Point` class, except it encapsulates a width and height in a single object. Like `Point`, `Dimension` is somewhat underused; it is used primarily by methods that need to return a width and a height as a single object; for example, `getSize()` returns a `Dimension` object.

Dimension Methods

Variables

A `Dimension` instance has two variables, one for width and one for height. They are accessible directly or through use of the `getSize()` method.

public int width

> The width variable represents the size of an object along the x axis (left to right). Width should not be negative; however, there is nothing within the class to prevent this from happening.

public int height

> The height variable represents the size of an object along the y axis (top to bottom). Height should not be negative; however, there is nothing within the class to prevent this from happening.

Constructors

public Dimension ()

> This constructor creates a `Dimension` instance with a width and height of 0.

public Dimension (Dimension dim)

This constructor creates a copy of `dim`. The initial width is `dim.width`. The initial height is `dim.height`.

public Dimension (int width, int height)

This constructor creates a `Dimension` with an initial width of `width` and an initial height of `height`.

Sizing

public Dimension getSize () ★

The `getSize()` method retrieves the current size as a new `Dimension`, even though the instance variables are public.

public void setSize (int width, int height) ★

The `setSize()` method changes the dimension's size to `width` x `height`.

public void setSize (Dimension d) ★

The `setSize()` method changes the dimension's size to `d.width` x `d.height`.

Miscellaneous methods

public boolean equals (Object object)

The `equals()` method overrides the `Object.equals()` method to define equality for dimensions. Two `Dimension` objects are equal if their width and height values are equal.

public String toString ()

The `toString()` method of `Dimension` returns a string showing the current width and height settings. For example:

```
java.awt.Dimension[width=0,height=0]
```

2.5 Rectangle

The `Rectangle` class encapsulates x and y coordinates and width and height (`Point` and `Dimension` information) within a single object. It is often used by methods that return a rectangular boundary as a single object: for example, `Polygon.getBounds()`, `Component.getBounds()`, and `Graphics.getClipBounds()`. Like `Point`, the `Rectangle` class is not a visual object and does not represent a rectangle on the screen; ironically, `drawRect()` and `fillRect()` don't take `Rectangle` as an argument.

Rectangle Methods

Variables

The four public variables available for `Rectangle` have the same names as the public instance variables of `Point` and `Dimension`. They are all accessible directly or through use of the `getBounds()` method.

public int x

> The x coordinate of the upper left corner.

public int y

> The y coordinate of the upper left corner.

public int width

> The width variable represents the size of the `Rectangle` along the horizontal axis (left to right). Width should not be negative; however, there is nothing within the class to prevent this from happening.

public int height

> The height variable represents the size of the `Rectangle` along the vertical axis (top to bottom). Height should not be negative; however, there is nothing within the class to prevent this from happening.

Constructors

The following seven constructors create `Rectangle` objects. When you create a `Rectangle`, you provide the location of the top left corner, along with the `Rectangle`'s width and height. A `Rectangle` located at (0,0) with a width and height of 100 has its bottom right corner at (99, 99). The `Point` (100, 100) lies outside the `Rectangle`, since that would require a width and height of 101.

public Rectangle ()

> This `Rectangle` constructor creates a `Rectangle` object in which x, y, width, and height are all 0.

public Rectangle (int width, int height)

> This `Rectangle` constructor creates a `Rectangle` with (`x`, `y`) coordinates of (0,0) and the specified `width` and `height`. Notice that there is no `Rectangle(int x, int y)` constructor because that would have the same method signature as this one, and the compiler would have no means to differentiate them.

public Rectangle (int x, int y, int width, int height)

> The `Rectangle` constructor creates a `Rectangle` object with an initial x coordinate of `x`, y coordinate of `y`, width of `width`, and height of `height`. Height and width should be positive, but the constructor does not check for this.

public Rectangle (Rectangle r)

> This `Rectangle` constructor creates a `Rectangle` matching the original. The (`x`, `y`) coordinates are (`r.x`, `r.y`), with a width of `r.width` and a height of `r.height`.

public Rectangle (Point p, Dimension d)

> This `Rectangle` constructor creates a `Rectangle` with (`x`, `y`) coordinates of (`p.x`, `p.y`), a width of `d.width`, and a height of `d.height`.

public Rectangle (Point p)

This `Rectangle` constructor creates a `Rectangle` with (`x`, `y`) coordinates of (`p.x`, `p.y`). The width and height are both zero.

public Rectangle (Dimension d)

The last `Rectangle` constructor creates a `Rectangle` with (`x`, `y`) coordinates of (0, 0). The initial `Rectangle` width is `d.width` and height is `d.height`.

Shaping and sizing

public Rectangle getBounds() ★

The `getBounds()` method returns a copy of the original `Rectangle`.

public void setBounds (int x, int y, int width, int height) ★
public void reshape (int x, int y, int width, int height) ☆

The `setBounds()` method changes the origin of the `Rectangle` to (`x`, `y`) and changes the dimensions to `width` by `height`.

`reshape()` is the Java 1.0 name for this method.

public void setBounds (Rectangle r) ★

The `setBounds()` method changes the origin of the `Rectangle` to (`r.x`, `r.y`) and changes the dimensions to `r.width` by `r.height`.

public Point getLocation() ★

The `getLocation()`retrieves the current origin of this rectangle as a `Point`.

public void setLocation (int x, int y) ★
public void move (int x, int y) ☆

The `setLocation()` method changes the origin of the `Rectangle` to (`x`, `y`).

`move()` is the Java 1.0 name for this method.

public void setLocation (Point p) ★

The `setLocation()` method changes the `Rectangle`'s origin to (`p.x`, `p.y`).

public void translate (int x, int y)

The `translate()` method moves the `Rectangle`'s origin by the amount (`x`, `y`). If the original `Rectangle`'s location (r) is (3, 4) and you call `r.translate (4, 5)`, then r's location becomes (7, 9). x and y may be negative. `translate()` has no effect on the `Rectangle`'s width and height.

public Dimension getSize () ★

The `getSize()` method retrieves the current size of the rectangle as a `Dimension`.

public void setSize() (int width, int height) ★
public void resize (int width, int height) ☆

The `setSize()` method changes the `Rectangle`'s dimensions to `width` x `height`.

`resize()` is the Java 1.0 name for this method.

public void setSize() (Dimension d) ★

The `setSize()` method changes the `Rectangle`'s dimensions to `d.width` x `d.height`.

public void grow (int horizontal, int vertical)

The `grow()` method increases the `Rectangle`'s dimensions by adding the amount `horizontal` on the left and the right and adding the amount `vertical` on the top and bottom. Therefore, all four of the rectangle's variables change. If the original location is (`x`, `y`), the new location will be (x-`horizontal`, y-`vertical`) (moving left and up if both values are positive); if the original size is (`width, height`), the new size will be (`width+2*horizontal, height+2*vertical`). Either horizontal or vertical can be negative to decrease the size of the `Rectangle`. The following code demonstrates the changes:

```
import java.awt.Rectangle;
public class rect {
    public static void main (String[] args) {
        Rectangle r = new Rectangle (100, 100, 200, 200);
        System.out.println (r);
        r.grow (50, 75);
        System.out.println (r);
        r.grow (-25, -50);
        System.out.println (r);
    }
}
```

This program produces the following output:

```
java.awt.Rectangle[x=100,y=100,width=200,height=200]
java.awt.Rectangle[x=50,y=25,width=300,height=350]
java.awt.Rectangle[x=75,y=75,width=250,height=250]
```

public void add (int newX, int newY)

> The `add()` method incorporates the point (`newX`, `newY`) into the `Rectangle`. If this point is already in the `Rectangle`, there is no change. Otherwise, the size of the `Rectangle` increases to include (`newX`, `newY`) within itself.

public void add (Point p)

> This `add()` method incorporates the point (`p.x`, `p.y`) into the `Rectangle`. If this point is already in the `Rectangle`, there is no change. Otherwise, the size of the `Rectangle` increases to include (`p.x`, `p.y`) within itself.

public void add (Rectangle r)

> This `add()` method incorporates another `Rectangle r` into this `Rectangle`. This transforms the current rectangle into the union of the two `Rectangles`. This method might be useful in a drawing program that lets you select multiple objects on the screen and create a rectangular area from them.
>
> We will soon encounter a method called `union()` that is almost identical. `add()` and `union()` differ in that `add()` modifies the current `Rectangle`, while `union()` returns a new `Rectangle`. The resulting rectangles are identical.

Intersections

public boolean contains (int x, int y) ★
public boolean inside (int x, int y) ☆

The `contains()` method determines if the point (`x`, `y`) is within this `Rectangle`. If so, `true` is returned. If not, `false` is returned.

`inside()` is the Java 1.0 name for this method.

public boolean contains (Point p) ★

The `contains()` method determines if the point (`p.x`, `p.y`) is within this `Rectangle`. If so, `true` is returned. If not, `false` is returned.

public boolean intersects (Rectangle r)

The `intersects()` method checks whether `Rectangle r` crosses this `Rectangle` at any point. If it does, `true` is returned. If not, `false` is returned.

public Rectangle intersection (Rectangle r)

The `intersection()` method returns a new `Rectangle` consisting of all points that are in both the current `Rectangle` and `Rectangle r`. For example, if `r = new Rectangle (50, 50, 100, 100)` and `r1 = new Rectangle (100, 100, 75, 75)`, then `r.intersection (r1)` is the `Rectangle (100, 100, 50, 50)`, as shown in Figure 2.13.

public Rectangle union (Rectangle r)

The `union()` method combines the current `Rectangle` and `Rectangle r` to form a new `Rectangle`. For example, if `r = new Rectangle (50, 50, 100, 100)` and `r1 = new Rectangle (100, 100, 75, 75)`, then `r.union (r1)` is the `Rectangle (50, 50, 125, 125)`. The original rectangle is unchanged. Figure 2.14 demonstrates the effect of `union()`. Because `fillRect()` fills to `width-1` and `height-1`, the rectangle drawn appears slightly smaller than you would expect. However, that's an artifact of how rectangles are drawn; the returned rectangle contains all the points within both.

Figure 2.13: Rectangle intersection

[Graphic: Figure 2-13]

Figure 2.14: Rectangle union

[Graphic: Figure 2-14]

Miscellaneous methods

public boolean isEmpty ()

> The `isEmpty()` method checks whether there are any points within the `Rectangle`. If the width and height of the `Rectangle` are both 0 (or less), the `Rectangle` is empty, and this method returns `true`. If either width or height is greater than zero, `isEmpty()` returns `false`. This method could be used to check the results of a call to any method that returns a `Rectangle` object.

public int hashCode ()

> The `hashCode()` method returns a hash code for the rectangle. The system calls this method when a `Rectangle` is used as the key for a hash table.

public boolean equals (Object object)

The `equals()` method overrides the `Object`'s `equals()` method to define what equality means for `Rectangle` objects. Two `Rectangle` objects are equal if their `x`, `y`, width, and height values are equal.

public String toString ()

The `toString()` method of `Rectangle` displays the current values of the `x`, `y`, width, and height variables. For example:

```
java.awt.Rectangle[x=100,y=200,width=300,height=400]
```

Shape | BOOK INDEX | Polygon

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.6 Polygon

A `Polygon` is a collection of points used to create a series of line segments. Its primary purpose is to draw arbitrary shapes like triangles or pentagons. If the points are sufficiently close, you can create a curve. To display the `Polygon`, call `drawPolygon()` or `fillPolygon()`.

Polygon Methods

Variables

The collection of points maintained by `Polygon` are stored in three variables:

public int npoints

> The `npoints` variable stores the number of points.

public int xpoints[]

> The `xpoints` array holds the x component of each point.

public int ypoints[]

> The `ypoints` array holds the y component of each point.

You might expect the `Polygon` class to use an array of points, rather than separate arrays of integers. More important, you might expect the instance variables to be private or protected, which would prevent them from being modified directly. Since the three instance variables are public, there is no guarantee that the array sizes are in sync with each other or with `npoints`. To avoid trouble, always use `addPoints()` to modify your polygons, and avoid modifying the instance variables directly.
Constructors

public Polygon ()

This constructor creates an empty `Polygon`.

public Polygon (int xPoints[], int yPoints[], int numPoints)

This constructor creates a `Polygon` that consists of `numPoints` points. Those points are formed from the first `numPoints` elements of the `xPoints` and `yPoints` arrays. If the `xPoints` or `yPoints` arrays are larger than `numPoints`, the additional entries are ignored. If the `xPoints` or `yPoints` arrays do not contain at least `numPoints` elements, the constructor throws the run-time exception `ArrayIndexOutOfBoundsException`.

Miscellaneous methods

public void addPoint (int x, int y)

The `addPoint()` method adds the point (`x`, `y`) to the `Polygon` as its last point. If you alter the `xpoints`, `ypoints`, and `npoints` instance variables directly, `addPoint()` could add the new point at a place other than the end, or it could throw the run-time exception `ArrayIndexOutOfBoundsException` with a message showing the position at which it tried to add the point. Again, for safety, don't modify a `Polygon`'s instance variables yourself; always use `addPoint()`.

public Rectangle getBounds () ★
public Rectangle getBoundingBox () ☆

The `getBounds()` method returns the `Polygon`'s bounding `Rectangle` (i.e., the smallest rectangle that contains all the points within the polygon). Once you have the bounding box, it's easy to use methods like `copyArea()` to copy the `Polygon`.

`getBoundingBox()` is the Java 1.0 name for this method.

public boolean contains (int x, int y) ★
public boolean inside (int x, int y) ☆

The `contains()` method checks to see if the (`x`, `y`) point is within an area that would be filled if the `Polygon` was drawn with `Graphics.fillPolygon()`. A point may be within the bounding rectangle of the polygon, but `contains()` can still return `false` if not within a closed part of the polygon.

`inside()` is the Java 1.0 name for this method.

public boolean contains (Point p) ★

The `contains()` method checks to see if the point `p` is within an area that would be filled if the `Polygon` were drawn with `Graphics.fillPolygon()`.

public void translate (int x, int y) ★

The `translate()` method moves all the `Polygon`'s points by the amount (`x`, `y`). This allows you to alter the location of the `Polygon` by shifting the points.

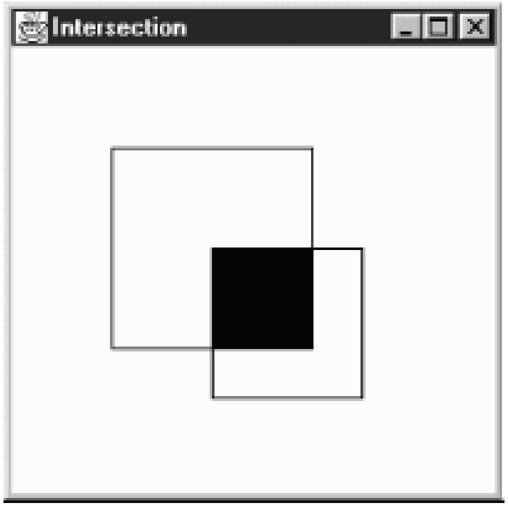
JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.7 Image

An `Image` is a displayable object maintained in memory. AWT has built-in support for reading files in GIF and JPEG format, including GIF89a animation. Netscape Navigator, Internet Explorer, HotJava, and Sun's JDK also understand the XBM image format. Images are loaded from the filesystem or network by the `getImage()` method of either `Component` or `Toolkit`, drawn onto the screen with `drawImage()` from `Graphics`, and manipulated by several objects within the `java.awt.image` package. Figure 2.15 shows an `Image`.

Figure 2.15: An Image



`Image` is an abstract class implemented by many different platform-specific classes. The system that runs your program will provide an appropriate implementation; you do not need to know anything about the platform-specific classes, because the `Image` class completely defines the API for working with images. If you're curious, the platform-specific packages used by the JDK are:

- `sun.awt.win32.Win32Image` on Java 1.0 Windows NT/95 platforms
- `sun.awt.windows.WImage` on Java 1.1 Windows NT/95 platforms
- `sun.awt.motif.X11Image` on UNIX/Motif platforms
- `sun.awt.macos.MacImage` on the Macintosh

This section covers only the `Image` object itself. AWT also includes a package named `java.awt.image` that includes more advanced image processing utilities. The classes in `java.awt.image` are covered in Chapter 12, *Image Processing*.

Image Methods

Constants

public static final Object UndefinedProperty

> In Java 1.0, the sole constant of `Image` is `UndefinedProperty`. It is used as a return value from the `getProperty()` method to indicate that the requested property is unavailable.

Java 1.1 introduces the `getScaledInstance()` method. The final parameter to the method is a set of hints to tell the method how best to scale the image. The following constants provide possible values for this parameter.

public static final int SCALE_DEFAULT ★

> The `SCALE_DEFAULT` hint should be used alone to tell `getScaledInstance()` to use the default scaling algorithm.

public static final int SCALE_FAST ★

> The `SCALE_FAST` hint tells `getScaledInstance()` that speed takes priority over smoothness.

public static final int SCALE_SMOOTH ★

> The `SCALE_SMOOTH` hint tells `getScaledInstance()` that smoothness takes priority over speed.

public static final int SCALE_REPLICATE ★

> The `SCALE_REPLICATE` hint tells `getScaledInstance()` to use `ReplicateScaleFilter` or a reasonable alternative provided by the toolkit. `ReplicateScaleFilter` is discussed in Chapter 12, *Image Processing*.

public static final int SCALE_AREA_AVERAGING ★

> The `SCALE_AREA_AVERAGING` hint tells `getScaledInstance()` to use `AreaAveragingScaleFilter` or a reasonable alternative provided by the toolkit. `AreaAveragingScaleFilter` is discussed in Chapter 12, *Image Processing*.

Constructors

There are no constructors for `Image`. You get an `Image` object to work with by using the `getImage()` method of `Applet` (in an applet), `Toolkit` (in an application), or the `createImage()` method of `Component` or `Toolkit`. `getImage()` uses a separate thread to fetch the image. The thread starts when you call `drawImage()`, `prepareImage()`, or any other method that requires image information. `getImage()` returns immediately. You can also use the `MediaTracker` class to force an image to load before it is needed. `MediaTracker` is discussed in the next section. Characteristics

public abstract int getWidth (ImageObserver observer)

> The `getWidth()` method returns the width of the image object. The width may not be available if the image has not started loading; in this case, `getWidth()` returns -1. An image's size is available long before loading is complete, so it is often useful to call `getWidth()` while the image is loading.

public abstract int getHeight (ImageObserver observer)

> The `getHeight()` method returns the height of the image object. The height may not be available if the image has not started loading; in this case, the `getHeight()` method returns -1. An image's size is available long before loading is complete, so it is often useful to call `getHeight()` while the image is loading.

Miscellaneous methods

public Image getScaledInstance (int width, int height, int hints) ★

> The `getScaledInstance()` method enables you to generate scaled versions of images before they are needed. Prior to Java 1.1, it was necessary to tell the `drawImage()` method to do the scaling. However, this meant that scaling didn't take place until you actually tried to draw the image. Since scaling takes time, drawing the image required more time; the net result was degraded appearance. With Java 1.1, you can generate scaled copies of images before drawing them; then you can use a version of `drawImage()` that does not do scaling, and therefore is much quicker.
>
> The `width` parameter of `getScaledInstance()` is the new width of the image. The `height` parameter is the new height of the image. If either is -1, the scaling retains the aspect ratio of the original image. For instance, if the original image size was 241 by 72 pixels, and `width` and `height` were 100 and -1, the new image size would be 100 by 29 pixels. If both width and height are -1, the `getScaledInstance()` method retains the image's original size. The `hints` parameter is one of the `Image` class constants.

```
Image i = getImage (getDocumentBase(), "rosey.jpg");
Image j = i.getScaledInstance (100, -1, Image.SCALE_FAST);
```

public abstract ImageProducer getSource ()

The getSource() method returns the image's producer, which is an object of type ImageProducer. This object represents the image's source. Once you have the ImageProducer, you can use it to do additional image processing; for example, you could create a modified version of the original image by using a FilteredImageSource. Image producers and image filters are covered in Chapter 12, *Image Processing*.

public abstract Graphics getGraphics ()

The getGraphics() method returns the image's graphics context. The method getGraphics() works only for Image objects created in memory with Component.createImage (int, int). If the image came from a URL or a file (i.e., from getImage()), getGraphics() throws the run-time exception ClassCastException.

public abstract Object getProperty (String name, ImageObserver observer)

The getProperty() method interacts with the image's property list. An object representing the requested property name will be returned for observer. observer represents the Component on which the image is rendered. If the property name exists but is not available yet, getProperty() returns null. If the property name does not exist, the getProperty() method returns the Image.UndefinedProperty object.

Each image type has its own property list. A property named comment stores a comment String from the image's creator. The CropImageFilter adds a property named croprect. If you ask getProperty() for an image's croprect property, you get a Rectangle that shows how the original image was cropped.

public abstract void flush()

The flush() method resets an image to its initial state. Assume you acquire an image over the network with getImage(). The first time you display the image, it will be loaded over the network. If you redisplay the image, AWT normally reuses the original image. However, if you call flush() before redisplaying the image, AWT fetches the image again from its source. (Images created with createImage() aren't affected.) The flush() method is useful if you expect images to change while your program is running. The following program demonstrates flush(). It reloads and displays the file *flush.gif* every time you click the mouse. If you change the file *flush.gif* and click on the mouse, you will see the new file.

```
import java.awt.*;
public class flushMe extends Frame {
    Image im;
    flushMe () {
        super ("Flushing");
        im = Toolkit.getDefaultToolkit().getImage ("flush.gif");
        resize (175, 225);
    }
    public void paint (Graphics g) {
        g.drawImage (im, 0, 0, 175, 225, this);
    }
    public boolean mouseDown (Event e, int x, int y) {
        im.flush();
        repaint();
        return true;
    }
    public static void main (String [] args) {
        Frame f = new flushMe ();
        f.show();
    }
}
```

Simple Animation

Creating simple animation sequences in Java is easy. Load a series of images, then display the images one at a time. Example 2.1 is an application that displays a simple animation sequence. Example 2.2 is an applet that uses a thread to run the application. These programs are far from ideal. If you try them, you'll probably notice some flickering or missing images. We discuss how to fix these problems shortly.

Example 2.1: Animation Application

```
import java.awt.*;
public class Animate extends Frame {
    static Image im[];
    static int numImages = 12;
    static int counter=0;
    Animate () {
        super ("Animate");
    }
    public static void main (String[] args) {
        Frame f = new Animate();
        f.resize (225, 225);
        f.show();
        im = new Image[numImages];
        for (int i=0;i<numImages;i++) {
            im[i] = Toolkit.getDefaultToolkit().getImage ("clock"+i+".jpg");
        }
    }
    public synchronized void paint (Graphics g) {
        g.translate (insets().left, insets().top);
        g.drawImage (im[counter], 0, 0, this);
        counter++;
        if (counter == numImages)
            counter = 0;
        repaint (200);
    }
}
```

This application displays images with the name *clock*n*.jpg*, where *n* is a number between 0 and 11. It fetches the images using the `getImage()` method of the `Toolkit` class--hence, the call to `Toolkit.getDefaultToolkit()`, which gets a `Toolkit` object to work with. The `paint()` method displays the images in sequence, using `drawImage()`. `paint()` ends with a call to `repaint(200)`, which schedules another call to `paint()` in 200 milliseconds.

The `AnimateApplet`, whose code is shown in Example 2.2, does more or less the same thing. It is able to use the `Applet.getImage()` method. A more significant difference is that the applet creates a new thread to control the animation. This thread calls `sleep(200)`, followed by `repaint()`, to display a new image every 200 milliseconds.

Example 2.2: Multithreaded Animation Applet

```
import java.awt.*;
import java.applet.*;
public class AnimateApplet extends Applet implements Runnable {
    static Image im[];
    static int numImages = 12;
    static int counter=0;
    Thread animator;
    public void init () {
        im = new Image[numImages];
        for (int i=0;i<numImages;i++)
            im[i] = getImage (getDocumentBase(), "clock"+i+".jpg");
    }
    public void start() {
        if (animator == null) {
            animator = new Thread (this);
            animator.start ();
        }
    }
    public void stop() {
        if ((animator != null) && (animator.isAlive())) {
            animator.stop();
            animator = null;
        }
    }
    public void run () {
        while (animator != null) {
            try {
                animator.sleep(200);
                repaint ();
                counter++;
                if (counter==numImages)
                    counter=0;
            } catch (Exception e) {
                e.printStackTrace ();
            }
        }
    }
    public void paint (Graphics g) {
        g.drawImage (im[counter], 0, 0, this);
    }
}
```

One quick fix will help the flicker problem in both of these examples. The `update()` method (which is inherited from the `Component` class) normally clears the drawing area and calls `paint()`. In our examples, clearing the drawing area is unnecessary and, worse, results in endless flickering; on slow machines, you'll see `update()` restore the background color between each image. It's a simple matter to override `update()` so that it doesn't clear the drawing area first. Add the following method to both of the previous examples:

```
public void update (Graphics g) {
    paint (g);
}
```

Overriding `update()` helps, but the real solution to our problem is double buffering, which we'll turn to next.

Double Buffering

Double buffering means drawing to an offscreen graphics context and then displaying this graphics context to the screen in a single operation. So far, we have done all our drawing directly on the screen--that is, to the graphics context provided by the `paint()` method. As your programs grow more complex, `paint()` gets bigger and bigger, and it takes more time and resources to update the entire drawing area. On a slow machine, the user will see the individual drawing operations take place, which will make your program look slow and clunky. By using the double buffering technique, you can take your time drawing to another graphics context that isn't displayed. When you are ready, you tell the system to display the completely new image at once. Doing so eliminates the possibility of seeing partial screen updates and flickering.

The first thing you need to do is create an image as your drawing canvas. To get an image object, call the `createImage()` method. `createImage()` is a method of the `Component` class, which we will discuss in Chapter 5, *Components*. Since `Applet` extends `Component`, you can call `createImage()` within an applet. When creating an application and extending `Frame`, `createImage()` returns `null` until the `Frame`'s peer exists. To make sure that the peer exists, call `addNotify()` in the constructor, or make sure you call `show()` before calling `createImage()`. Here's the call to the `createImage()` method that we'll use to get an `Image` object:

```
Image im = createImage (300, 300); // width and height
```

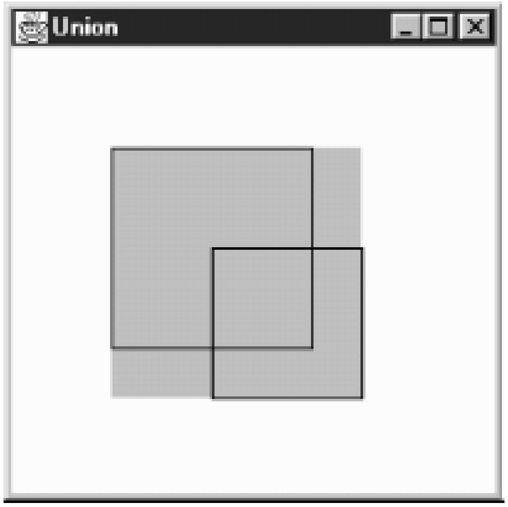
Once you have an `Image` object, you have an area you can draw on. But how do you draw on it? There are no drawing methods associated with `Image`; they're all in the `Graphics` class. So we need to get a `Graphics` context from the `Image`. To do so, call the `getGraphics()` method of the `Image` class, and use that `Graphics` context for your drawing:

```
Graphics buf = im.getGraphics();
```

Now you can do all your drawings with `buf`. To display the drawing, the `paint()` method only needs to call `drawImage(im, . . .)`. Note the hidden connection between the `Graphics` object, `buf`, and the `Image` you are creating, `im`. You draw onto `buf`; then you use `drawImage()` to render the image on the on-screen `Graphics` context within `paint()`.

Another feature of buffering is that you do not have redraw the entire image with each call to `paint()`. The buffered image you're working on remains in memory, and you can add to it at will. If you are drawing directly to the screen, you would have to recreate the entire drawing each time `paint()` is called; remember, `paint()` always hands you a completely new `Graphics` object. Figure 2.16 shows how double buffering works.

Figure 2.16: Double buffering



Example 2.3 puts it all together for you. It plays a game, with one move drawn to the screen each cycle. We still do the drawing within `paint()`, but we draw into an offscreen buffer; that buffer is copied onto the screen by `g.drawImage(im, 0, 0, this)`. If we were doing a lot of drawing, it would be a good idea to move the drawing operations into a different thread, but that would be overkill for this simple applet.

Example 2.3: Double Buffering--Who Won?

```
import java.awt.*;
import java.applet.*;
public class buffering extends Applet {
    Image im;
    Graphics buf;
    int pass=0;
```

```
public void init () {
    // Create buffer
    im = createImage (size().width, size().height);
    // Get its graphics context
    buf = im.getGraphics();
    // Draw Board Once
    buf.setColor (Color.red);
    buf.drawLine (  0,  50, 150,  50);
    buf.drawLine (  0, 100, 150, 100);
    buf.drawLine ( 50,   0,  50, 150);
    buf.drawLine (100,   0, 100, 150);
    buf.setColor (Color.black);
}
public void paint (Graphics g) {
    // Draw image - changes are written onto buf
    g.drawImage (im, 0, 0, this);
    // Make a move
    switch (pass) {
        case 0:
            buf.drawLine (50, 50, 100, 100);
            buf.drawLine (50, 100, 100, 50);
            break;
        case 1:
            buf.drawOval (0, 0, 50, 50);
            break;
        case 2:
            buf.drawLine (100, 0, 150, 50);
            buf.drawLine (150, 0, 100, 50);
            break;
        case 3:
            buf.drawOval (0, 100, 50, 50);
            break;
        case 4:
            buf.drawLine (0, 50, 50, 100);
            buf.drawLine (0, 100, 50, 50);
            break;
        case 5:
            buf.drawOval (100, 50, 50, 50);
            break;
        case 6:
            buf.drawLine (50,  0, 100, 50);
            buf.drawLine (50, 50, 100,  0);
            break;
        case 7:
            buf.drawOval (50, 100, 50, 50);
            break;
        case 8:
                buf.drawLine (100, 100, 150, 150);
                buf.drawLine (150, 100, 100, 150);
                break;
        }
        pass++;
        if (pass <= 9)
            repaint (500);
    }
}
```

2.8 MediaTracker

The `MediaTracker` class assists in the loading of multimedia objects across the network. Tracking is necessary because Java loads images in separate threads. Calls to `getImage()` return immediately; image loading starts only when you call the method `drawImage()`. `MediaTracker` lets you force images to start loading before you try to display them; it also gives you information about the loading process, so you can wait until an image is fully loaded before displaying it.

Currently, `MediaTracker` can monitor the loading of images, but not audio, movies, or anything else. Future versions are rumored to be able to monitor other media types.

MediaTracker Methods

Constants

The `MediaTracker` class defines four constants that are used as return values from the class's methods. These values serve as status indicators.

public static final int LOADING

> The `LOADING` variable indicates that the particular image being checked is still loading.

public static final int ABORTED

> The `ABORTED` variable indicates that the loading process for the image being checked aborted. For example, a timeout could have happened during the download. If something `ABORTED` during loading, it is possible to `flush()` the image to force a retry.

public static final int ERRORED

The ERRORED variable indicates that an error occurred during the loading process for the image being checked. For instance, the image file might not be available from the server (invalid URL) or the file format could be invalid. If an image has ERRORED, retrying it will fail.

public static final int COMPLETE

The COMPLETE flag means that the image being checked successfully loaded.

If COMPLETE, ABORTED, or ERRORED is set, the image has stopped loading. If you are checking multiple images, you can OR several of these values together to form a composite. For example, if you are loading several images and want to find out about any malfunctions, call statusAll() and check for a return value of ABORTED | ERRORED. Constructors

public MediaTracker (Component component)

The MediaTracker constructor creates a new MediaTracker object to track images to be rendered onto component.

Adding images

The addImage() methods add objects for the MediaTracker to track. When placing an object under a MediaTracker's control, you must provide an identifier for grouping purposes. When multiple images are grouped together, you can perform operations on the entire group with a single request. For example, you might want to wait until all the images in an animation sequence are loaded before starting the animation; in this case, assigning the same ID to all the images makes good sense. However, when multiple images are grouped together, you cannot check on the status of a single image. The moral is: if you care about the status of individual images, put each into a group by itself.

Folklore has it that the identifier also serves as a loading priority, with a lower ID meaning a higher priority. This is not completely true. Current implementations start loading lower IDs first, but at most, this is implementation-specific functionality for the JDK. Furthermore, although an object with a lower identifier might be told to start loading first, the MediaTracker does nothing to ensure that it finishes first.

public synchronized void addImage (Image image, int id, int width, int height)

The addImage() method tells the MediaTracker instance that it needs to track the loading of image. The id is used as a grouping. Someone will eventually render the image at a scaled size of width x height. If width and height are both -1, the image will be rendered unscaled. If you forget to notify the MediaTracker that the image will be scaled and ask the MediaTracker to waitForID (id), it is possible that the image may not be fully ready when you try to draw it.

public void addImage (Image image, int id)

The `addImage()` method tells the `MediaTracker` instance that it needs to track the loading of `image`. The `id` is used as a grouping. The `image` will be rendered at its actual size, without scaling.

Removing images

Images that have finished loading are still watched by the `MediaTracker`. The `removeImage()` methods, added in Java 1.1, allow you to remove objects from the `MediaTracker`. Once you no longer care about an image (usually after waiting for it to load), you can remove it from the tracker. Getting rid of loaded images results in better performance because the tracker has fewer objects to check. In Java 1.0, you can't remove an image from `MediaTracker`.

public void removeImage (Image image) ★

The `removeImage()` method tells the `MediaTracker` to remove all instances of `image` from its tracking list.

public void removeImage (Image image, int id) ★

The `removeImage()` method tells the `MediaTracker` to remove all instances of `image` from group `id` of its tracking list.

public void removeImage (Image image, int id, int width, int height) ★

This `removeImage()` method tells the `MediaTracker` to remove all instances of `image` from group `id` and scale `width` x `height` of its tracking list.

Waiting

A handful of methods let you wait for a particular image, image group, all images, or a particular time period. They enable you to be sure that an image has finished trying to load prior to continuing. The fact that an image has finished loading does not imply it has successfully loaded. It is possible that an error condition arose, which caused loading to stop. You should check the status of the image (or group) for actual success.

public void waitForID (int id) throws InterruptedException

The `waitForID()` method blocks the current thread from running until the images added with `id` finish loading. If the wait is interrupted, `waitForID()` throws an `InterruptedException`.

public synchronized boolean waitForID (int id, long ms) throws InterruptedException

> The `waitForID()` method blocks the current thread from running until the images added with `id` finish loading or until `ms` milliseconds have passed. If all the images have loaded, `waitForID()` returns `true`; if the timer has expired, it returns `false`, and one or more images in the `id` set have not finished loading. If `ms` is 0, it waits until all images added with `id` have loaded, with no timeout. If the wait is interrupted, `waitForID()` throws an `InterruptedException`.

public void waitForAll () throws InterruptedException

> The `waitForAll()` method blocks the current thread from running until all images controlled by this `MediaTracker` finish loading. If the wait is interrupted, `waitForAll()` throws an `InterruptedException`.

public synchronized boolean waitForAll (long ms) throws InterruptedException

> The `waitForAll()` method blocks the current thread from running until all images controlled by this `MediaTracker` finish loading or until `ms` milliseconds have passed. If all the images have loaded, `waitForAll()` returns `true`; if the timer has expired, it returns `false`, and one or more images have not finished loading. If `ms` is 0, it waits until all images have loaded, with no timeout. When you interrupt the waiting, `waitForAll()` throws an `InterruptedException`.

Checking status

Several methods are available to check on the status of images loading. None of these methods block, so you can continue working while images are loading.

public boolean checkID (int id)

> The `checkID()` method determines if all the images added with the `id` tag have finished loading. The method returns `true` if all images have completed loading (successfully or unsuccessfully). Since this can return `true` on error, you should also use `isErrorID()` to check for errors. If loading has not completed, `checkID()` returns `false`. This method does not force images to start loading.

public synchronized boolean checkID (int id, boolean load)

The `checkID()` method determines if all the images added with the `id` tag have finished loading. If the `load` flag is `true`, any images in the `id` group that have not started loading yet will start. The method returns `true` if all images have completed loading (successfully or unsuccessfully). Since this can return `true` on error, you should also use `isErrorID()` to check for errors. If loading has not completed, `checkID()` returns `false`.

public boolean checkAll ()

The `checkAll()` method determines if all images associated with the `MediaTracker` have finished loading. The method returns `true` if all images have completed loading (successfully or unsuccessfully). Since this can return `true` on error, you should also use `isErrorAny()` to check for errors. If loading has not completed, `checkAll()` returns `false`. This method does not force images to start loading.

public synchronized boolean checkAll (boolean load)

The `checkAll()` method determines if all images associated with the `MediaTracker` have finished loading. If the `load` flag is `true`, any image that has not started loading yet will start. The method returns `true` if all images have completed loading (successfully or unsuccessfully). Since this can return `true` on error, you should also use `isErrorAny()` to check for errors. If loading has not completed, `checkAll()` returns `false`.

public int statusID (int id, boolean load)

The `statusID()` method checks on the load status of the images in the `id` group. If there are multiple images in the group, the results are ORed together. If the `load` flag is `true`, any image in the `id` group that has not started loading yet will start. The return value is some combination of the class constants `LOADING`, `ABORTED`, `ERRORED`, and `COMPLETE`.

public int statusAll (boolean load)

The `statusAll()` method determines the load status of all the images associated with the `MediaTracker`. If this `MediaTracker` is watching multiple images, the results are ORed together. If the `load` flag is `true`, any image that has not started loading yet will start. The return value is some combination of the class constants `LOADING`, `ABORTED`, `ERRORED`, and `COMPLETE`.

public synchronized boolean isErrorID (int id)

The `isErrorId()` method checks whether any media in the `id` group encountered an error while loading. If any image resulted in an error, `isErrorId()` returns `true`; if there were no errors, it returns `false`.

public synchronized boolean isErrorAny ()

> The `isErrorAny()` method checks to see if any image associated with the `MediaTracker` encountered an error. If there was an error, the method returns `true`; if none, `false`.

public synchronized Object[] getErrorsID (int id)

> The `getErrorsID()` method returns an array of the objects that encountered errors in the group ID during loading. If loading caused no errors, the method returns `null`. The return type is an `Object` array instead of an `Image` array because `MediaTracker` will eventually support additional media types.

public synchronized Object[] getErrorsAny ()

> The `getErrorsAny()` method returns an array of all the objects that encountered an error during loading. If there were no errors, the method returns `null`. The return type is an `Object` array instead of an `Image` array because `MediaTracker` will eventually support additional media types.

Using a MediaTracker

The `init()` method improves the `AnimateApplet` from Example 2.2 to ensure that images load before the animation sequence starts. Waiting for images to load is particularly important if there is a slow link between the computer on which the applet is running and the server for the image files. Note that in a few cases, like interlaced GIF files, you might be willing to display an image before it has completely loaded. However, judicious use of `MediaTracker` will give you much more control over your program's behavior.

The new `init()` method creates a `MediaTracker`, puts all the images in the animation sequence under the tracker's control, and then calls `waitForAll()` to wait until the images are loaded. Once the images are loaded, it calls `isErrorsAny()` to make sure that the images loaded successfully.

```
public void init () {
    MediaTracker mt = new MediaTracker (this);
    im = new Image[numImages];
    for (int i=0;i<numImages;i++) {
        im[i] = getImage (getDocumentBase(), "clock"+i+".jpg");
        mt.addImage (im[i], i);
    }
    try {
        mt.waitForAll();
        if (mt.isErrorAny())
            System.out.println ("Error loading images");
    } catch (Exception e) {
        e.printStackTrace ();
    }
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

3.2 FontMetrics

The abstract `FontMetrics` class provides the tools for calculating the actual width and height of text when displayed on the screen. You can use the results to position objects around text or to provide special effects like shadows and underlining.

Like the `Graphics` class, `FontMetrics` is abstract. The run-time Java platform provides a concrete implementation of `FontMetrics`. You don't have to worry about the actual class; it is guaranteed to implement all the methods of `FontMetrics`. In case you're curious, on a Windows 95 platform, either the class `sun.awt.win32.Win32FontMetrics` (JDK1.0) or the class `sun.awt.windows.WFontMetrics` (JDK1.1) extends `FontMetrics`. On a UNIX/Motif platform, the class is `sun.awt.motif.X11FontMetrics`. With the Macintosh, the class is `sun.awt.macos.MacFontMetrics`. If you're not using the JDK, the class names may be different, but the principle still applies: you don't have to worry about the concrete class.

The FontMetrics Class

Variables

protected Font font

> The font whose metrics are contained in this `FontMetrics` object; use the `getFont()` method to get the value.

Constructors

protected FontMetrics (Font font)

> There is no visible constructor for `FontMetrics`. Since the class is abstract, you cannot create a `FontMetrics` object. The way to get the `FontMetrics` for a font is to ask for it. Through the current graphics context, call the method `getGraphics().getFontMetrics()` to retrieve the `FontMetrics` for the current font. If a graphics context isn't available, you can get a `FontMetrics` object from the default `Toolkit` by calling the method `Toolkit.getDefaultToolkit().getFontMetrics (aFontObject)`.

Font height

Four variables describe the height of a font: leading (pronounced like the metal), ascent, descent, and height. Leading is the amount of space required between lines of the same font. Ascent is the space above the baseline required by the tallest character in the font. Descent is the space required below the baseline by the lowest descender (the "tail" of a character like "y"). Height is the total of the three: ascent, baseline, and descent. Figure 3.1 shows these values graphically.

Figure 3.1: Font height metrics

[Graphic: Figure 3-1]

If that were the entire story, it would be simple. Unfortunately, it isn't. Some special characters (for example, capitals with umlauts or accents) are taller than the "tallest" character in the font; so Java defines a value called `maxAscent` to account for these. Similarly, some characters descend below the "greatest" descent, so Java defines a `maxDescent` to handle these cases.

NOTE:

It seems that on Windows and Macintosh platforms there is no difference between the return values of `getMaxAscent()` and `getAscent()`, or between `getMaxDescent()` and `getDescent()`. On UNIX platforms, they sometimes differ. For developing truly portable applications, the `max` methods should be used where necessary.

public int getLeading ()

The `getLeading()`method retrieves the leading required for the `FontMetrics` of the font. The units for this measurement are pixels.

public int getAscent ()

The `getAscent()`method retrieves the space above the baseline required for the tallest character in the font. The units for this measurement are pixels. You cannot get the ascent value for a specific character.

public int getMaxAscent ()

`getMaxAscent()` retrieves the height above the baseline for the character that's really the tallest character in the font, taking into account accents, umlauts, tildes, and other special marks. The units for this measurement are pixels. If you are using only ordinary ASCII characters below 128 (i.e., the English language character set), `getMaxAscent()` is not necessary.

If you're using `getMaxAscent()`, avoid `getHeight()`; `getHeight()` is based on `getAscent()` and doesn't account for extra space.

For some fonts and platforms, `getAscent()` may include the space for the diacritical marks.

public int getDescent ()

The `getDescent()` method retrieves the space below the baseline required for the deepest character for the font. The units for this measurement are pixels. You cannot get the descent value for a specific character.

public int getMaxDescent ()
public int getMaxDecent ()

Some fonts may have special characters that extend farther below the baseline than the value returned by `getDescent()`. `getMaxDescent()` returns the real maximum descent for the font, in pixels. In most cases, you can still use the `getDescent()` method; visually, it is okay for an occasional character to extend into the space between lines. However, if it is absolutely, positively necessary that the descent space does not overlap with the next line's ascent requirements, use `getMaxDescent()` and avoid `getDescent()` and `getHeight()`.

An early beta release of the AWT API included the method `getMaxDecent()`. It is left for compatibility with early beta code. Avoid using it; it is identical to `getMaxDescent()` in every way except spelling. Unfortunately, it is not flagged as deprecated.

public int getHeight ()

The `getHeight()` method returns the sum of `getDescent()`, `getAscent()`, and `getLeading()`. In most cases, this will be the distance between successive baselines when you are displaying multiple lines of text. The height of a font in pixels is not necessarily the size of a font in points.

Don't use `getHeight()` if you are displaying characters with accents, umlauts, and other marks that increase the character's height. In this case, compute the height yourself using the `getMaxAscent()` method. Likewise, you shouldn't use the method `getHeight()` if you are using `getMaxDescent()` instead of `getDescent()`.

Character width

In the horizontal dimension, positioning characters is relatively simple: you don't have to worry about ascenders and descenders, you only have to worry about how far ahead to draw the next character after you have drawn the current one. The "how far" is called the *advance width* of a character. For most cases, the advance width is the actual width plus the intercharacter space. However, it's not a good idea to think in these terms; in many cases, the intercharacter space is actually negative (i.e., the bounding boxes for two adjacent characters overlap). For example, consider an italic font. The top right corner of one character probably extends beyond the character's advance width, overlapping the next character's bounding box. (To see this, look back at Figure 3.1; in particular, look at the *ll* in *O'Reilly*.) If you think purely in terms of the advance width (the amount to move horizontally after drawing a character), you won't run into trouble. Obviously, the advance width depends on the character, unless you're using a fixed width font.

public int charWidth (char character)

This version of the `charWidth()` method returns the advance width of the given `character` in pixels.

public int charWidth (int character)

The `charWidth()` method returns the advance width of the given `character` in pixels. Note that the argument has type `int` rather than `char`. This version is useful when overriding the `Component.keyDown()` method, which gets the integer value of the character pressed as a parameter. With the `KeyEvent` class, you should use the previous version with its `getKeyChar()` method.

public int stringWidth (String string)

The `stringWidth()` method calculates the advance width of the entire `string` in pixels. Among other things, you can use the results to underline or center text within an area of the screen. Example 3.1 and Figure 3.2 show an example that centers several text strings (taken from the command-line arguments) in a `Frame`.

Example 3.1: Centering Text in a Frame

```
import java.awt.*;
public class Center extends Frame {
    static String text[];
    private Dimension dim;
    static public void main (String args[]) {
        if (args.length == 0) {
            System.err.println ("Usage: java Center <some text>");
            return;
        }
        text = args;
        Center f = new Center();
        f.show();
    }
    public void addNotify() {
        super.addNotify();
        int maxWidth = 0;
        FontMetrics fm = getToolkit().getFontMetrics(getFont());
        for (int i=0;i<text.length;i++) {
            maxWidth = Math.max (maxWidth, fm.stringWidth(text[i]));
        }
        Insets inset = insets();
        dim = new Dimension (maxWidth + inset.left + inset.right,
            text.length*fm.getHeight() + inset.top + inset.bottom);
        resize (dim);
    }
    public void paint (Graphics g) {
        g.translate(insets().left, insets().top);
        FontMetrics fm = g.getFontMetrics();
        for (int i=0;i<text.length;i++) {
            int x,y;
            x = (size().width - fm.stringWidth(text[i]))/2;
            y = (i+1)*fm.getHeight()-1;
            g.drawString (text[i], x, y);
        }
    }
}
```

Figure 3.2: Centering text in a frame

[Graphic: Figure 3-2]

This application extends the `Frame` class. It stores its command-line arguments in the `String` array `text[]`. The `addNotify()` method sizes the frame appropriately. It computes the size needed to display the arguments and resizes the `Frame` accordingly. To compute the width, it takes the longest `stringWidth()` and adds the left and right insets. To compute the height, it takes the current font's height, multiplies it by the number of lines to display, and adds insets. Then it is up to the `paint()` method to use `stringWidth()` and `getHeight()` to figure out where to put each string.

public int charsWidth (char data[], int offset, int length)

> The `charsWidth()` method allows you to calculate the advance width of the char array `data`, without first converting `data` to a `String` and calling the `stringWidth()` method. The `offset` specifies the element of `data` to start with; `length` specifies the number of elements to use. The first element of the array has an `offset` of zero. If `offset` or `length` is invalid, `charsWidth()` throws the run-time exception `ArrayIndexOutOfBoundsException`.

public int bytesWidth (byte data[], int offset, int length)

> The `bytesWidth()` method allows you to calculate the advance width of the byte array `data`, without first converting `data` to a `String` and calling the `stringWidth()`method. The `offset` specifies the element of `data` to start with; `length` specifies the number of elements to use. The first element of the array has an `offset` of zero. If `offset` or `length` is invalid, `bytesWidth()` throws the run-time exception `ArrayIndexOutOfBoundsException`.

public int[] getWidths ()

> The `getWidths()` method returns an integer array of the advance widths of the first 255 characters in the `FontMetrics` font. `getWidths()` is very useful if you are continually looking up the widths of ASCII characters. Obtaining the widths as an array and looking up individual character widths yourself results in less method invocation overhead than making many calls to `charWidth()`.

public int getMaxAdvance ()

> The `getMaxAdvance()` method returns the advance pixel width of the widest character in the font. This allows you to reserve enough space for characters before you know what they are. If you know you are going to display only ASCII characters, you are better off calculating the maximum value returned from `getWidths()`. When unable to determine the width in advance, the method `getMaxAdvance()` returns -1.

Miscellaneous methods

public Font getFont ()

> The `getFont()` method returns the specific font for this `FontMetrics` instance.

public String toString ()

> The `toString()` method of `FontMetrics` returns a string displaying the current font, ascent, descent, and height. For example:

```
sun.awt.win32.Win32FontMetrics[font=java.awt.Font[family=TimesRoman,
name=TimesRoman,style=bolditalic,size=20]ascent=17, descent=6, height=24]
```

Because this is an abstract class, the concrete implementation could return something different.

Font Display Example

Example 3.2 displays all the available fonts in the different styles at 12 points. The code uses the `FontMetrics` methods to ensure that there is enough space for each line. Figure 3.3 shows the results, using the Java 1.0 font names, on several platforms.

Example 3.2: Font Display

```
import java.awt.*;
public class Display extends Frame {
    static String[] fonts;
    private Dimension dim;
    Display () {
        super ("Font Display");
        fonts = Toolkit.getDefaultToolkit().getFontList();
    }
    public void addNotify() {
        Font f;
        super.addNotify();
        int height   = 0;
        int maxWidth = 0;
        final int vMargin  = 5, hMargin = 5;
        for (int i=0;i<fonts.length;i++) {
            f = new Font (fonts[i], Font.PLAIN, 12);
            height += getHeight (f);
            f = new Font (fonts[i], Font.BOLD, 12);
            height += getHeight (f);
            f = new Font (fonts[i], Font.ITALIC, 12);
            height += getHeight (f);
            f = new Font (fonts[i], Font.BOLD | Font.ITALIC, 12);
            height += getHeight (f);
            maxWidth = Math.max (maxWidth, getWidth (f, fonts[i] + " BOLDITALIC"));
        }
        Insets inset = insets();
        dim = new Dimension (maxWidth + inset.left + inset.right + hMargin,
                        height + inset.top + inset.bottom + vMargin);
        resize (dim);
    }
    static public void main (String args[]) {
        Display f = new Display();
        f.show();
    }
    private int getHeight (Font f) {
        FontMetrics fm = Toolkit.getDefaultToolkit().getFontMetrics(f);
        return fm.getHeight();
    }
    private int getWidth (Font f, String s) {
        FontMetrics fm = Toolkit.getDefaultToolkit().getFontMetrics(f);
        return fm.stringWidth(s);
    }
    public void paint (Graphics g) {
        int x = 0;
        int y = 0;
        g.translate(insets().left, insets().top);
        for (int i=0;i<fonts.length;i++) {
            Font plain = new Font (fonts[i], Font.PLAIN, 12);
            Font bold = new Font (fonts[i], Font.BOLD, 12);
            Font italic = new Font (fonts[i], Font.ITALIC, 12);
            Font bolditalic = new Font (fonts[i], Font.BOLD | Font.ITALIC, 12);
            g.setFont (plain);
            y += getHeight (plain);
            g.drawString (fonts[i] + " PLAIN", x, y);
            g.setFont (bold);
            y += getHeight (bold);
            g.drawString (fonts[i] + " BOLD", x, y);
            g.setFont (italic);
            y += getHeight (italic);
            g.drawString (fonts[i] + " ITALIC", x, y);
            g.setFont (bolditalic);
            y += getHeight (bolditalic);
            g.drawString (fonts[i] + " BOLDITALIC", x, y);
        }
        resize (dim);
    }
}
```

3.3 Color

Not so long ago, color was a luxury; these days, color is a requirement. A program that uses only black and white seems hopelessly old fashioned. AWT's `Color` class lets you define and work with `Color` objects. When we discuss the `Component` class (see Chapter 5, *Components*), you will see how to use these color objects, and our discussion of the `SystemColor` subclass (new to Java 1.1; discussed later in this chapter) shows you how to control the colors that are painted on the screen.

A few words of warning: while colors give you the opportunity to make visually pleasing applications, they also let you do things that are incredibly ugly. Resist the urge to go overboard with your use of color; it's easy to make something hideous when you are trying to use every color in the palette. Also, realize that colors are fundamentally platform dependent, and in a very messy way. Java lets you use the same `Color` objects on any platform, but it can't guarantee that every display will treat the color the same way; the result depends on everything from your software to the age of your monitor. What looks pink on one monitor may be red on another. Furthermore, when running in an environment with a limited palette, AWT picks the available color that is closest to what you requested. If you really care about appearance, there is no substitute for testing.

Color Methods

Constants

The `Color` class has predefined constants (all of type `public static final Color`) for frequently used colors. These constants, their RGB values, and their HSB values (hue, saturation, brightness) are given in Table 3.1.

Table 3.1: Comparison of RGB and HSB Colors

Color	Red	Green	Blue	Hue	Saturation	Brightness
black	0	0	0	0	0	0
blue	0	0	255	.666667	1	1
cyan	0	255	255	.5	1	1
darkGray	64	64	64	0	0	.25098

gray	128	128	128	0	0	.501961
green	0	255	0	.333333	1	1
lightGray	192	192	192	0	0	.752941
magenta	255	0	255	.833333	1	1
orange	255	200	0	.130719	1	1
pink	255	175	175	0	.313726	1
red	255	0	0	0	1	1
white	255	255	255	0	0	1
yellow	255	255	0	.166667	1	1

These constants are used like any other class variable: for example, `Color.red` is a constant `Color` object representing the color red. Many other color constants are defined in the `SystemColor` class. Constructors

When you're not using a predefined constant, you create `Color` objects by specifying the color's red, green, and blue components. Depending on which constructor you use, you can specify the components as integers between 0 and 255 (most intense) or as floating point intensities between 0.0 and 1.0 (most intense). The result is a 24-bit quantity that represents a color. The remaining 8 bits are used to represent transparency: that is, if the color is painted on top of something, does whatever was underneath show through? The `Color` class doesn't let you work with the transparency bits; all `Color` objects are opaque. However, you can use transparency when working with images; this topic is covered in Chapter 12, *Image Processing*.

public Color (int red, int green, int blue)

> This constructor is the most commonly used. You provide the specific `red`, `green`, and `blue` values for the color. Valid values for `red`, `green`, and `blue` are between 0 and 255. The constructor examines only the low-order byte of the integer and ignores anything outside the range, including the sign bit.

public Color (int rgb)

> This constructor allows you to combine all three variables in one parameter, `rgb`. Bits 16-23 represent the red component, and bits 8-15 represent the green component. Bits 0-7 represent the blue component. Bits 24-31 are ignored. Going from three bytes to one integer is fairly easy:

```
(((red & 0xFF) << 16 ) | ((green & 0xFF) << 8) | ((blue & 0xFF) << 0))
```

public Color (float red, float green, float blue)

> This final constructor allows you to provide floating point values between 0.0 and 1.0 for each of `red`, `green`, and `blue`. Values outside of this range yield unpredictable results.

Settings

public int getRed ()

> The `getRed()` method retrieves the current setting for the red component of the color.

public int getGreen ()

> The `getGreen()` method retrieves the current setting for the green component of the color.

public int getBlue ()

> The `getBlue()` method retrieves the current setting for the blue component of the color.

public int getRGB ()

> The `getRGB()` method retrieves the current settings for red, green, and blue in one combined value. Bits 16-23 represent the red component. Bits 8-15 represent the green component. Bits 0-7 represent the blue component. Bits 24-31 are the transparency bits; they are always `0xff` (opaque) when using the default RGB `ColorModel`.

public Color brighter ()

> The `brighter()` method creates a new `Color` that is somewhat brighter than the current color. This method is useful if you want to highlight something on the screen.
>
> **NOTE:**

Black does not get any brighter.

public Color darker ()

> The `darker()` method returns a new `Color` that is somewhat darker than the current color. This method is useful if you are trying to de-emphasize an object on the screen. If you are creating your own `Component`, you can use a `darker()` `Color` to mark it inactive.

Color properties

`Color` properties are very similar to `Font` properties. You can use system properties (or resource files) to allow users to select colors for your programs. The settings have the form `0xRRGGBB`, where `RR` is the red component of the color, `GG` represents the green component, and `BB` represents the blue component. `0x` indicates that the number is in hexadecimal. If you (or your user) are comfortable using decimal values for colors (0x112233 is 1122867 in decimal), you can, but then it is harder to see the values of the different components.

NOTE:

The location of the system properties file depends on the run-time environment and version you are using. Ordinarily, the file will go into a subdirectory of the installation directory or, for environment's where users have home directories, in a subdirectory for the user. Sun's HotJava, JDK, and *appletviewer* tools use the *properties* file in the *.hotjava* directory.

Most browsers do not permit modifying properties, so there is no file.

Java 1.1 adds the idea of "resource files," which are syntactically similar to properties files. Resource files are then placed on the server or within a directory found in the `CLASSPATH`. Updating the properties file is no longer recommended.

For example, consider a screen that uses four colors: one each for the foreground, the background, inactive components, and highlighted text. In the system properties file, you allow users to select colors by setting the following properties:

```
myPackage.myClass.foreground
myPackage.myClass.background
myPackage.myClass.inactive
myPackage.myClass.highlight
```

One particular user set two:

```
myPackage.myClass.foreground=0xff00ff        #magenta
myPackage.myClass.background=0xe0e0e0        #light gray
```

These lines tell the program to use magenta as the foreground color and light gray for the background. The program will use its default colors for inactive components and highlighted text.

public static Color getColor (String name)

> The `getColor()` method gets the color specified by the system property `name`. If `name` is not a valid system property, `getColor()` returns `null`. If the property value does not convert to an integer, `getColor()` returns `null`.
>
> For the properties listed above, if you call `getColor()` with `name` set to the property `myPackage.myClass.foreground`, it returns a magenta `Color` object. If called with `name` set to `myPackage.myClass.inactive`, `getColor()` returns `null`.

public static Color getColor (String name, Color defaultColor)

The `getColor()` method gets the color specified by the system property `name`. This version of the `getColor()` method returns `defaultColor` if `name` is not a valid system property or the property's value does not convert to an integer.

For the previous example, if `getColor()` is called with `name` set to `myPackage.myClass.inactive`, the `getColor()` method returns the value of `defaultColor`. This allows you to provide defaults for properties the user doesn't wish to set explicitly.

public static Color getColor (String name, int defaultColor)

This `getColor()` method gets the color specified by the system property `name`. This version of the `getColor()` method returns `defaultColor` if `name` is not a valid system property or the property's value does not convert to an integer. The default color is specified as an integer in which bits 16-23 represent the red component, 8-15 represent the green component, and 0-7 represent the blue component. Bits 24-31 are ignored. If the property value does not convert to an integer, `defaultColor` is returned.

public static Color decode (String name) ★

The `decode()` method provides an explicit means to decipher color property settings, regardless of where the setting comes from. (The `getColor()` method can decipher settings but only if they're in the system properties file.) In particular, you can use `decode()` to look up color settings in a resource file. The format of `name` is the same as that used by `getColor()`. If the contents of `name` do not translate to a 24-bit integer, the `NumberFormatException` run-time exception is thrown. To perform the equivalent of ``getColor(`myPackage.myClass.foreground`)``, without using system properties, see the following example. For a more extensive example using resource files, see Appendix A.

```
// Java 1.1 only
InputStream is = instance.getClass().getResourceAsStream("propfile");
Properties p = new Properties();
try {
    p.load (is);
    Color c = Color.decode(p.getProperty("myPackage.myClass.foreground"));
} catch (IOException e) {
    System.out.println ("error loading props...");
}
```

Hue, saturation, and brightness

So far, the methods we have seen work with a color's red, green, and blue components. There are many other ways to represent colors. This group of methods allows you to work in terms of the HSB (hue, saturation, brightness) model. Hue represents the base color to work with: working through the colors of the rainbow, red is represented by numbers immediately above 0; magenta is represented by numbers below 1; white is 0; and black is 1. Saturation represents the color's purity, ranging from completely unsaturated (either white or black depending upon brightness) to totally saturated (just the base color present). Brightness is the desired level of luminance, ranging from black (0) to the maximum amount determined by the saturation level.

public static float[] RGBtoHSB (int red, int green, int blue, float[] hsbvalues)

> The `RGBtoHSB()` method allows you to convert a specific `red`, `green`, `blue` value to the hue, saturation, and brightness equivalent. `RGBtoHSB()` returns the results in two different ways: the parameter `hsbvalues` and the method's return value. The values of these are the same. If you do not want to pass an `hsbvalues` array parameter, pass `null`. In both the parameter and the return value, the three components are placed in the array as follows:
>
> `hsbvalues[0]` *contains hue*
> `hsbvalues[1]` *contains saturation*
> `hsbvalues[2]` *contains brightness*

public static Color getHSBColor (float hue, float saturation, float brightness)

> The `getHSBColor()` method creates a `Color` object by using `hue`, `saturation`, and `brightness` instead of `red`, `green`, and `blue` values.

public static int HSBtoRGB (float hue, float saturation, float brightness)

> The `HSBtoRGB()` method converts a specific `hue`, `saturation`, and `brightness` to a `Color` and returns the `red`, `green`, and `blue` values as an integer. As with the constructor, bits 16-23 represent the red component, 8-15 represent the green component, and 0-7 represent the blue component. Bits 24-31 are ignored.

Miscellaneous methods

public int hashCode ()

> The `hashCode()` method returns a hash code for the color. The hash code is used whenever a color is used as a key in a `Hashtable`.

public boolean equals (Object o)

> The `equals()` method overrides the `equals()` method of the `Object` to define equality for `Color` objects. Two `Color` objects are equivalent if their `red`, `green`, and `blue` values are equal.

public String toString ()

The `toString()` method of `Color` returns a string showing the color's red, green, and blue settings. For example `System.out.println (Color.orange)` would result in the following:

```
java.awt.Color[r=255,g=200,b=0]
```

3.4 SystemColor

In Java 1.1, AWT provides access to desktop color schemes, or *themes*. To give you an idea of how these themes work, with the Windows Standard scheme for the Windows 95 desktop, buttons have a gray background with black text. If you use the control panel to change to a High Contrast Black scheme, the button's background becomes black and the text white. Prior to 1.1, Java didn't know anything about desktop colors: all color values were hard coded. If you asked for a particular shade of gray, you got that shade, and that was it; applets and applications had no knowledge of the desktop color scheme in effect, and therefore, wouldn't change in response to changes in the color scheme.

Starting with Java 1.1, you can write programs that react to changes in the color scheme: for example, a button's color will change automatically when you use the control panel to change the color scheme. To do so, you use a large number of constants that are defined in the `SystemColor` class. Although these constants are `public static final`, they actually have a very strange behavior. Your program is not allowed to modify them (like any other constant). However, their initial values are loaded at run-time, and their values may change, corresponding to changes in the color scheme. This has one important consequence for programmers: you should not use `equals()`to compare a `SystemColor` with a "regular" `Color`; use the `getRGB()` methods of the colors you are comparing to ensure that you compare the current color value.[1] Using Desktop Colors contains a usage example.

> [1] The omission of an `equals()` method that can properly compare a `SystemColor` with a `Color` is unfortunate.

Because `SystemColor` is a subclass of `Color`, you can use a `SystemColor` anywhere you can use a `Color` object. You will never create your own `SystemColor` objects; there is no public constructor. The only objects in this class are the twenty or so `SystemColor` constants.

SystemColor Methods

Constants

There are two sets of constants within `SystemColor`. The first set provides names for indices into the internal system color lookup table; you will probably never need to use these. All of them have corresponding constants in the second set, except `SystemColor.NUM_COLORS`, which tells you how many `SystemColor` constants are in the second set.

public final static int ACTIVE_CAPTION ★
public final static int ACTIVE_CAPTION_BORDER ★
public final static int ACTIVE_CAPTION_TEXT ★
public final static int CONTROL ★
public final static int CONTROL_DK_SHADOW ★
public final static int CONTROL_HIGHLIGHT ★
public final static int CONTROL_LT_HIGHLIGHT ★
public final static int CONTROL_SHADOW ★
public final static int CONTROL_TEXT ★
public final static int DESKTOP ★
public final static int INACTIVE_CAPTION ★
public final static int INACTIVE_CAPTION_BORDER ★
public final static int INACTIVE_CAPTION_TEXT ★
public final static int INFO ★
public final static int INFO_TEXT ★
public final static int MENU ★
public final static int MENU_TEXT ★
public final static int NUM_COLORS ★
public final static int SCROLLBAR ★
public final static int TEXT ★
public final static int TEXT_HIGHLIGHT ★
public final static int TEXT_HIGHLIGHT_TEXT ★
public final static int TEXT_INACTIVE_TEXT ★
public final static int TEXT_TEXT ★
public final static int WINDOW ★
public final static int WINDOW_BORDER ★
public final static int WINDOW_TEXT ★

The second set of constants is the set of `SystemColor`s you use when creating `Component` objects, to ensure they appear similar to other objects in the user's desktop environment. By using these symbolic constants, you can create new objects that are well integrated into the user's desktop environment, making it easier for the user to work with your program.

public final static SystemColor activeCaption ★

> The `activeCaption` color represents the background color for the active window's title area. This is automatically set for you when you use `Frame`.

public final static SystemColor activeCaptionBorder ★

> The `activeCaptionBorder` color represents the border color for the active window.

public final static SystemColor activeCaptionText ★

> The `activeCaptionText` color represents the text color to use for the active window's title.

public final static SystemColor control ★

> The `control` color represents the background color for the different components. If you are creating your own `Component` by subclassing `Canvas`, this should be the background color of the new object.

public final static SystemColor controlDkShadow ★

> The `controlDkShadow` color represents a dark shadow color to be used with `control` and `controlShadow` to simulate a three-dimensional appearance. Ordinarily, when not depressed, the `controlDkShadow` should be used for the object's bottom and right edges. When depressed, `controlDkShadow` should be used for the top and left edges.

public final static SystemColor controlHighlight ★

> The `controlHighlight` color represents an emphasis color for use in an area or an item of a custom component.

public final static SystemColor controlLtHighlight ★

> The `controlLtHighlight` color represents a lighter emphasis color for use in an area or an item of a custom component.

public final static SystemColor controlShadow ★

The controlShadow color represents a light shadow color to be used with control and controlDkShadow to simulate a three-dimensional appearance. Ordinarily, when not depressed, the controlShadow should be used for the top and left edges. When depressed, controlShadow should be used for the bottom and right edges.

public final static SystemColor controlText ★

The controlText color represents the text color of a component. Before drawing any text in your own components, you should change the color to controlText with a statement like this:

```
g.setColor(SystemColor.controlText);
```

public final static SystemColor desktop ★

The desktop color represents the background color of the desktop workspace.

public final static SystemColor inactiveCaption ★

The inactiveCaption color represents the background color for an inactive window's title area.

public final static SystemColor inactiveCaptionBorder ★

The inactiveCaptionBorder color represents the border color for an inactive window.

public final static SystemColor inactiveCaptionText ★

The inactiveCaptionText color represents the text color to use for each inactive window's title.

public final static SystemColor info ★

The info color represents the background color for mouse-over help text. When a mouse dwells over an object, any pop-up help text should be displayed in an area of this color. In the Microsoft Windows world, these are also called "tool tips."

public final static SystemColor infoText ★

The infoText color represents the text color for mouse-over help text.

public final static SystemColor menu ★

The `menu` color represents the background color of deselected `MenuItem`-like objects. When the menu is selected, the `textHighlight` color is normally the background color.

public final static SystemColor menuText ★

The `menuText` color represents the color of the text on deselected `MenuItem`-like objects. When a menu is selected, the `textHighlightText` color is normally the text color. If the menu happens to be inactive, `textInactiveText` would be used.

public final static SystemColor scrollbar ★

The `scrollbar` color represents the background color for scrollbars. This color is used by default with `Scrollbar`, `ScrollPane`, `TextArea`, and `List` objects.

public final static SystemColor textHighlight ★

The `textHighlight` color represents the background color of highlighted text; for example, it is used for the selected area of a `TextField` or a selected `MenuItem`.

public final static SystemColor textHighlightText ★

The `textHighlightText` color represents the text color of highlighted text.

public final static SystemColor textInactiveText ★

The `textInactiveText` color represents the text color of an inactive component.

public final static SystemColor textText ★

The `textText` color represents the color of text in `TextComponent` objects.

public final static SystemColor window ★

The `window` color represents the background color of the window's display area. For an applet, this would be the display area specified by the `WIDTH` and `HEIGHT` values of the `<APPLET>` tag (`setBackground(SystemColor.window)`), although you would probably use it more for the background of a `Frame`.

public final static SystemColor windowBorder ★

The `windowBorder` color represents the color of the borders around a window. With AWT, instances of `Window` do not have borders, but instances of `Frame` and `Dialog` do.

public final static SystemColor windowText ★

The `windowText` color represents the color of the text drawn within the window.

NOTE:

Every platform does not fully support every system color. However, on platforms that do not provide natural values for some constants, Java selects reasonable alternate colors.

If you are going to be working only with Java's prefabricated components (`Button`, `List`, etc.), you don't have to worry about system colors; the component's default colors will be set appropriately. You are most likely to use system colors if you are creating your own components. In this case, you will use system colors to make your component emulate the behavior of other components; for example, you will use `controlText` as the color for drawing text, `activeCaption` as the background for the caption of an active window, and so on. Constructors

There are no public constructors for `SystemColor`. If you need to create a new color, use the `Color` class described previously. Miscellaneous methods

public int getRGB ()

The `getRGB()` method retrieves the current settings for red, green, and blue in one combined value, like `Color`. However, since the color value is dynamic, `getRGB()` needs to look up the value in an internal table. Therefore, `SystemColor` overrides `Color.getRGB()`.

public String toString ()

The `toString()` method of `SystemColor` returns a string showing the system color's index into its internal table. For example, the following string is returned by `SystemColor.text.toString()`:

```
java.awt.SystemColor[i=12]
```

3.6 Using Desktop Colors

Example 3.4 demonstrates how to use the desktop color constants introduced in Java 1.1. If you run this example under an earlier release, an uncatchable class verifier error will occur.

NOTE:

Notice that the border lines are drawn from `0` to `width-1` or `height-1`. This is to draw lines of length `width` and `height`, respectively.

Example 3.4: Desktop Color Usage

```
// Java 1.1 only
import java.awt.*;
public class TextBox3D extends Canvas {
    String text;
    public TextBox3D (String s, int width, int height) {
        super();
        text=s;
        setSize(width, height);
    }
    public synchronized void paint (Graphics g) {
        FontMetrics fm = g.getFontMetrics();
        Dimension size=getSize();
        int x = (size.width - fm.stringWidth(text))/2;
        int y = (size.height - fm.getHeight())/2;
        g.setColor (SystemColor.control);
        g.fillRect (0, 0, size.width, size.height);
        g.setColor (SystemColor.controlShadow);
        g.drawLine (0, 0, 0, size.height-1);
        g.drawLine (0, 0, size.width-1, 0);
        g.setColor (SystemColor.controlDkShadow);
        g.drawLine (0, size.height-1, size.width-1, size.height-1);
        g.drawLine (size.width-1, 0, size.width-1, size.height-1);
        g.setColor (SystemColor.controlText);
        g.drawString (text, x, y);
    }
}
```

PREVIOUS Displaying Colors | HOME BOOK INDEX | NEXT Events

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

4.2 The Event Class

An instance of the Event class is a platform-independent representation that encapsulates the specifics of an event that happens within the Java 1.0 model. It contains everything you need to know about an event: who, what, when, where, and why the event happened. Note that the Event class is not used in the Java 1.1 event model; instead, Java 1.1 has an AWTEvent class, with subclasses for different event types.

When an event occurs, you decide whether or not to process the event. If you decide against reacting, the event passes through your program quickly without anything happening. If you decide to handle the event, you must deal with it quickly so the system can process the next event. If handling the event requires a lot of work, you should move the event-handling code into its own thread. That way, the system can process the next event while you go off and process the first. If you do not multithread your event processing, the system becomes slow and unresponsive and could lose events. A slow and unresponsive program frustrates users and may convince them to find another solution for their problems.

Variables

Event contains ten instance variables that offer all the specific information for a particular event.
Instance variables

public Object arg

> The arg field contains some data regarding the event, to be interpreted by the recipient. For example, if the user presses Return within a TextField, an Event with an id of ACTION_EVENT is generated with the TextField as the target and the string within it as the arg. See a description of each specific event to find out what its arg means.

public int clickCount

The `clickCount` field allows you to check for double clicking of the mouse. This field is relevant only for `MOUSE_DOWN` events. There is no way to specify the time delta used to determine how quick a double-click needs to be, nor is there a maximum value for `clickCount`. If a user quickly clicks the mouse four times, `clickCount` is four. Only the passage of a system-specific time delta will reset the value so that the next `MOUSE_DOWN` is the first click. The incrementing of `clickCount` does not care which mouse button is pressed.

public Event evt

The `evt` field does not appear to be used anywhere but is available if you wish to pass around a linked list of events. Then your program can handle this event and tell the system to deal with the next one (as demonstrated in the following code), or you can process the entire chain yourself.

```
public boolean mouseDown (Event e, int x, int y) {
    System.out.println ("Coordinates: " + x + "-" + y);
    if (e.evt != null)
        postEvent (e.evt);
    return true;
}
```

public int id

The `id` field of `Event` contains the identifier of the event. The system-generated events are the following `Event` constants:

`WINDOW_DESTROY`
`WINDOW_EXPOSE`
`WINDOW_ICONIFY`
`WINDOW_DEICONIFY`
`KEY_PRESS`
`KEY_RELEASE`
`KEY_ACTION`
`KEY_ACTION_RELEASE`
`MOUSE_DOWN`
`MOUSE_UP`
`MOUSE_MOVE`
`MOUSE_ENTER`
`MOUSE_EXIT`
`MOUSE_DRAG`
`SCROLL_LINE_UP`
`SCROLL_LINE_DOWN`
`SCROLL_PAGE_UP`
`SCROLL_PAGE_DOWN`
`SCROLL_ABSOLUTE`
`LIST_SELECT`
`LIST_DESELECT`
`ACTION_EVENT`

As a user, you can create your own event types and store your own unique event ID here. In Java 1.0, there is no formal way to prevent conflicts between your events and system events, but using a negative IO is a good ad-hoc method. It is up to you to check all the user events generated in your program in order to avoid conflicts among user events.

public int key

For keyboard-related events, the `key` field contains the integer representation of the keyboard element that caused the event. Constants are available for the keypad keys. To examine `key` as a character, just cast it to a `char`. For nonkeyboard-related events, the value is zero.

pubic int modifiers

The `modifiers` field shows the state of the modifier keys when the event happened. A flag is set for each modifier key pressed by the user when the event happened. Modifier keys are Shift, Control, Alt, and Meta. Since the middle and right mouse key are indicated in a Java event by a modifier key, one reason to use the `modifiers` field is to determine which mouse button triggered an event. See Working With Mouse Buttons in Java 1.0 for an example.

public Object target

The `target` field contains a reference to the object that is the cause of the event. For example, if the user selects a button, the button is the target of the event. If the user moves the mouse into a `Frame`, the `Frame` is the target. The `target` indicates where the event happened, not the component that is dealing with it.

public long when

The `when` field contains the time of the event in milliseconds. The following code converts this `long` value to a `Date` to examine its contents:

```
Date d = new Date (e.when);
```

public int x
public int y

The `x` and `y` fields show the coordinates where the event happened. The coordinates are always relative to the top left corner of the target of the event and get translated based on the top left corner of the container as the event gets passed through the containing components. (See the previous Identifying the Target for an example of this translation.) It is possible for either or both of these to be outside the coordinate space of the applet (e.g., if user quickly moves the mouse outside the applet).

Constants

Numerous constants are provided with the `Event` class. Several designate which event happened (the why). Others are available to help in determining the function key a user pressed (the what). And yet more are available to make your life easier.

When the system generates an event, it calls a handler method for it. To deal with the event, you have to override the appropriate method. The different event type sections describe which methods you override.
Key constants

These constants are set when a user presses a key. Most of them correspond to function and keypad keys; since such keys are generally used to invoke an action from the program or the system, Java calls them *action keys* and causes them to generate a different `Event` type (`KEY_ACTION`) from regular alphanumeric keys (`KEY_PRESS`).

Table 4.2 shows the constants used to represent keys and the event type that uses each constant. The values, which are all declared `public static final int`, appear in the `key` variable of the event instance. A few keys represent ASCII characters that have string equivalents such as `\n`. Black stars (★) mark the constants that are new in Java 1.1; they can be used with the 1.0 event model, provided that you are running Java 1.1. Java 1.1 events use a different set of key constants defined in the `KeyEvent` class.

Table 4.2: Constants for Keys in Java 1.0

Constant	Event Type		Constant	Event Type
HOME	KEY_ACTION		F9	KEY_ACTION
END	KEY_ACTION		F10	KEY_ACTION
PGUP	KEY_ACTION		F11	KEY_ACTION
PGDN	KEY_ACTION		F12	KEY_ACTION
UP	KEY_ACTION		PRINT_SCREEN★	KEY_ACTION
DOWN	KEY_ACTION		SCROLL_LOCK★	KEY_ACTION
LEFT	KEY_ACTION		CAPS_LOCK★	KEY_ACTION
RIGHT	KEY_ACTION		NUM_LOCK★	KEY_ACTION
F1	KEY_ACTION		PAUSE★	KEY_ACTION
F2	KEY_ACTION		INSERT★	KEY_ACTION
F3	KEY_ACTION		ENTER (\n)★	KEY_PRESS

F4	KEY_ACTION		BACK_SPACE (\b)★	KEY_PRESS
F5	KEY_ACTION		TAB (\t)★	KEY_PRESS
F6	KEY_ACTION		ESCAPE★	KEY_PRESS
F7	KEY_ACTION		DELETE★	KEY_PRESS
F8	KEY_ACTION			

Modifiers

Modifiers are keys like Shift, Control, Alt, or Meta. When a user presses any key or mouse button that generates an `Event`, the `modifiers` field of the `Event` instance is set. You can check whether any modifier key was pressed by ANDing its constant with the `modifiers` field. If multiple modifier keys were down at the time the event occurred, the constants for the different modifiers are ORed together in the field.

```
public static final int ALT_MASK
public static final int CTRL_MASK
public static final int META_MASK
public static final int SHIFT_MASK
```

When reporting a mouse event, the system automatically sets the `modifiers` field. Since Java is advertised as supporting the single-button mouse model, all buttons generate the same mouse events, and the system uses the `modifiers` field to differentiate between mouse buttons. That way, a user with a one- or two-button mouse can simulate a three-button mouse by clicking on his mouse while holding down a modifier key. Table 4.3 lists the mouse modifier keys; an applet in Working With Mouse Buttons in Java 1.0 demonstrates how to differentiate between mouse buttons.

Table 4.3: Mouse Button Modifier Keys

Mouse Button	**Modifier Key**
Left mouse button	None
Middle mouse button	`ALT_MASK`
Right mouse button	`META_MASK`

For example, if you have a three-button mouse, and click the right button, Java generates some kind of mouse event with the `META_MASK` set in the `modifiers` field. If you have a one-button mouse, you can generate the same event by clicking the mouse while depressing the Meta key.

NOTE:

If you have a multibutton mouse and do an Alt+right mouse or Meta+left mouse, the results are platform specific. You should get a mouse event with two masks set.

Key events

The component peers deliver separate key events when a user presses and releases nearly any key. `KEY_ACTION` and `KEY_ACTION_RELEASE` are for the function and arrow keys, while `KEY_PRESS` and `KEY_RELEASE` are for the remaining control and alphanumeric keys.

public static final int KEY_ACTION

> The peers deliver the `KEY_ACTION` event when the user presses a function or keypad key. The default `Component.handleEvent()` method calls the `keyDown()` method for this event. If the user holds down the key, this event is generated multiple times. If you are using the 1.1 event model, the interface method `KeyListener.keyPressed()` handles this event.

public static final int KEY_ACTION_RELEASE

> The peers deliver the `KEY_ACTION_RELEASE` event when the user releases a function or keypad key. The default `handleEvent()` method for `Component` calls the `keyUp()` method for this event. If you are using the 1.1 event model, the `KeyListener.keyReleased()` interface method handles this event.

public static final int KEY_PRESS

> The peers deliver the `KEY_PRESS` event when the user presses an ordinary key. The default `Component.handleEvent()` method calls the `keyDown()` method for this event. Holding down the key causes multiple `KEY_PRESS` events to be generated. If you are using the 1.1 event model, the interface method `KeyListener.keyPressed()` handles this event.

public static final int KEY_RELEASE

> The peers deliver `KEY_RELEASE` events when the user releases an ordinary key. The default `handleEvent()` method for `Component` calls the `keyUp()` method for this event. If you are using the 1.1 event model, the interface method `KeyListener.keyReleased()` handles this event.

NOTE:

If you want to capture arrow and keypad keys under the X Window System, make sure the key codes are set up properly, using the *xmodmap* command.

> **NOTE:**

Some platforms generate events for the modifier keys by themselves, whereas other platforms require modifier keys to be pressed with another key. For example, on a Windows 95 platform, if Ctrl+A is pressed, you would expect one `KEY_PRESS` and one `KEY_RELEASE`. However, there is a second `KEY_RELEASE` for the Control key. Under Motif, you get only a single `KEY_RELEASE`.

Window events

Window events happen only for components that are children of `Window`. Several of these events are available only on certain platforms. Like other event types, the `id` variable holds the value of the specific event instance.

public static final int WINDOW_DESTROY

> The peers deliver the `WINDOW_DESTROY` event whenever the system tells a window to destroy itself. This is usually done when the user selects the window manager's Close or Quit window menu option. By default, `Frame` instances do not deal with this event, and you must remember to catch it yourself. If you are using the 1.1 event model, the `WindowListener.windowClosing()` interface method handles this event.

public static final int WINDOW_EXPOSE

> The peers deliver the `WINDOW_EXPOSE` event whenever all or part of a window becomes visible. To find out what part of the window has become uncovered, use the `getClipRect()` method (or `getClipBounds()` in Java version 1.1) of the `Graphics` parameter to the `paint()` method. If you are using the 1.1 event model, the `WindowListener.windowOpening()` interface method most closely corresponds to the handling of this event.

public static final int WINDOW_ICONIFY

> The peers deliver the `WINDOW_ICONIFY` event when the user iconifies the window. If you are using the 1.1 event model, the interface method `WindowListener.windowIconified()` handles this event.

public static final int WINDOW_DEICONIFY

> The peers deliver the `WINDOW_DEICONIFY` event when the user de-iconifies the window. If you

are using the 1.1 event model, the interface method `WindowListener.windowDeiconified()` handles this event.

public static final int WINDOW_MOVED

The `WINDOW_MOVED` event signifies that the user has moved the window. If you are using the 1.1 event model, the `ComponentListener.componentMoved()` interface method handles this event.

Mouse events

The component peers deliver mouse events when a user presses or releases a mouse button. Events are also delivered whenever the mouse moves. In order to be platform independent, Java pretends that all mice have a single button. If you press the second or third button, Java generates a regular mouse event but sets the event's `modifers` field with a flag that indicates which button was pressed. If you press the left button, no `modifiers` flags are set. Pressing the center button sets the `ALT_MASK` flag; pressing the right button sets the `META_MASK` flag. Therefore, you can determine which mouse button was pressed by looking at the `Event.modifiers` attribute. Furthermore, users with a one-button or two-button mouse can generate the same events by pressing a mouse button while holding down the Alt or Meta keys.

NOTE:

Early releases of Java (1.0.2 and earlier) only propagated mouse events from `Canvas` and `Container` objects. With the 1.1 event model, the events that different components process are better defined.

public static final int MOUSE_DOWN

The peers deliver the `MOUSE_DOWN` event when the user presses any mouse button. This action must occur over a component that passes along the `MOUSE_DOWN` event. The default `Component.handleEvent()` method calls the `mouseDown()` method for this event. If you are using the 1.1 event model, the `MouseListener.mousePressed()` interface method handles this event.

public static final int MOUSE_UP

The peers deliver the `MOUSE_UP` event when the user releases the mouse button. This action must occur over a component that passes along the `MOUSE_UP` event. The default `handleEvent()` method for `Component` calls the `mouseUp()` method for this event. If you are using the 1.1 event model, the interface method `MouseListener.mouseReleased()` handles this event.

public static final int MOUSE_MOVE

The peers deliver the `MOUSE_MOVE` event whenever the user moves the mouse over any part of the applet. This can happen many, many times more than you want to track, so make sure you really want to do something with this event before trying to capture it. (You can also capture `MOUSE_MOVE` events and without losing much, choose to deal with only every third or fourth movement.) The default `handleEvent()` method calls the `mouseMove()` method for the event. If you are using the 1.1 event model, the interface method `MouseMotionListener.mouseMoved()` handles this event.

public static final int MOUSE_DRAG

The peers deliver the `MOUSE_DRAG` event whenever the user moves the mouse over any part of the applet with a mouse button depressed. The default method `handleEvent()` calls the `mouseDrag()` method for the event. If you are using the 1.1 event model, the interface method `MouseMotionListener.mouseDragged()` handles this event.

public static final int MOUSE_ENTER

The peers deliver the `MOUSE_ENTER` event whenever the cursor enters a component. The default `handleEvent()` method calls the `mouseEnter()` method for the event. If you are using the 1.1 event model, the interface method `MouseListener.mouseEntered()` handles this event.

public static final int MOUSE_EXIT

The peers deliver the `MOUSE_EXIT` event whenever the cursor leaves a component. The default `handleEvent()` method calls the `mouseExit()` method for the event. If you are using the 1.1 event model, the interface method `MouseListener.mouseExited()` handles this event.

Scrolling events

The peers deliver scrolling events for the `Scrollbar` component. The objects that have a built-in scrollbar (like `List`, `ScrollPane`, and `TextArea`) do not generate these events. No default methods are called for any of the scrolling events. They must be dealt with in the `handleEvent()` method of the `Container` or a subclass of the `Scrollbar`. You can determine which particular event occurred by checking the `id` variable of the event, and find out the new position of the thumb by looking at the `arg` variable or calling `getValue()` on the scrollbar. See also the description of the `AdjustmentListener` interface later in this chapter.

public static final int SCROLL_LINE_UP

The scrollbar peers deliver the `SCROLL_LINE_UP` event when the user presses the arrow pointing up for the vertical scrollbar or the arrow pointing left for the horizontal scrollbar. This decreases the scrollbar setting by one back toward the minimum value. If you are using the 1.1 event model, the interface method `AdjustmentListener.adjustmentValueChanged()` handles this event.

public static final int SCROLL_LINE_DOWN

The peers deliver the `SCROLL_LINE_DOWN` event when the user presses the arrow pointing down for the vertical scrollbar or the arrow pointing right for the horizontal scrollbar. This increases the scrollbar setting by one toward the maximum value. If you are using the 1.1 event model, the interface method `AdjustmentListener.adjustmentValueChanged()` handles this event.

public static final int SCROLL_PAGE_UP

The peers deliver the `SCROLL_PAGE_UP` event when the user presses the mouse with the cursor in the area between the slider and the decrease arrow. This decreases the scrollbar setting by the paging increment, which defaults to 10, back toward the minimum value. If you are using the 1.1 event model, the interface method `AdjustmentListener.adjustmentValueChanged()` handles this event.

public static final int SCROLL_PAGE_DOWN

The peers deliver the `SCROLL_PAGE_DOWN` event when the user presses the mouse with the cursor in the area between the slider and the increase arrow. This increases the scrollbar setting by the paging increment, which defaults to 10, toward the maximum value. If you are using the 1.1 event model, the interface method `AdjustmentListener.adjustmentValueChanged()` handles this event.

public static final int SCROLL_ABSOLUTE

The peers deliver the `SCROLL_ABSOLUTE` event when the user drags the slider part of the scrollbar. There is no set time period or distance between multiple `SCROLL_ABSOLUTE` events. If you are using the Java version 1.1 event model, the `AdjustmentListener.adjustmentValueChanged()` interface method handles this event.

public static final int SCROLL_BEGIN ★

The `SCROLL_BEGIN` event is not delivered by peers, but you may wish to use it to signify when a user drags the slider at the beginning of a series of `SCROLL_ABSOLUTE` events.

`SCROLL_END`, described next, would then be used to signify the end of the series.

public static final int SCROLL_END ★

The `SCROLL_END` event is not delivered by peers, but you may wish to use it to signify when a user drags the slider at the end of a series of `SCROLL_ABSOLUTE` events. `SCROLL_BEGIN`, described previously, would have been used to signify the beginning of the series.

List events

Two events specific to the `List` class are passed along by the peers. They signify when the user has selected or deselected a specific choice in the `List`. It is not ordinarily necessary to capture these events, because the peers deliver the `ACTION_EVENT` when the user double-clicks on a specific item in the `List` and it is this `ACTION_EVENT` that triggers something to happen. However, if there is reason to do something when the user has just single-clicked on a choice, these events may be useful. An example of how they would prove useful is if you are displaying a list of filenames with the ability to preview files before loading. Single selection would preview, double-click would load, and deselect would stop previewing.

No default methods are called for any of the list events. They must be dealt with in the `handleEvent()` method of the `Container` of the `List` or a subclass of the `List`. You can determine which particular event occurred by checking the `id` variable of the event.

public static final int LIST_SELECT

The peers deliver the `LIST_SELECT` event when the user selects an item in a `List`. If you are using the 1.1 event model, the interface method `ItemListener.itemStateChanged()` handles this event.

public static final int LIST_DESELECT

The peers deliver the `LIST_DESELECT` event when an item in a `List` has been deselected. This is generated only if the `List` permits multiple selections. If you are using the 1.1 event model, the `ItemListener.itemStateChanged()` interface method handles this event.

Focus events

The peers deliver focus events when a component gains (`GOT_FOCUS`) or loses (`LOST_FOCUS`) the input focus. No default methods are called for the focus events. They must be dealt with in the `handleEvent()` method of the `Container` of the component or a subclass of the component. You can determine which particular event occurred by checking the `id` variable of the event.

NOTE:

Early releases of Java (1.0.2 and before) did not propagate focus events on all platforms. This is fixed in release 1.1 of Java. Still, you should avoid capturing focus events if you want to write portable 1.0 code.

public static final int GOT_FOCUS

> The peers deliver the `GOT_FOCUS` event when a component gets the input focus. If you are using the 1.1 event model, the `FocusListener.focusGained()` interface method handles this event.

public static final int LOST_FOCUS

> The peers deliver the `LOST_FOCUS` event when a component loses the input focus. If you are using the 1.1 event model, the `FocusListener.focusLost()` interface method handles this event.

FileDialog events

The `FileDialog` events are another set of nonportable events. Ordinarily, the `FileDialog` events are completely dealt with by the system, and you never see them. Refer to Chapter 6, *Containers* for exactly how to work with the `FileDialog` object. If you decide to create a generic `FileDialog` object, you can use these events to indicate file loading and saving. These constants would be used in the `id` variable of the specific event instance:

public static final int LOAD_FILE
public static final int SAVE_FILE

Miscellaneous events

`ACTION_EVENT` is probably the event you deal with most frequently. It is generated when the user performs the desired action for a specific component type (e.g., when a user selects a button or toggles a checkbox). This constant would be found in the `id` variable of the specific event instance.

public static final int ACTION_EVENT

> The circumstances that lead to the peers delivering the `ACTION_EVENT` event depend upon the component that is the target of the event and the user's platform. Although the event can be passed along differently on different platforms, users will be accustomed to how the peers work on their specific platforms and will not care that it is different on the other platforms. For example, a Java 1.0 `List` component on a Microsoft Windows platform allows the user to select an item by

pressing the first letter of the choice, whereupon the `List` tries to find an item that starts with the letter. The X Window System `List` component does not provide this capability. It works like a normal X `List`, where the user must scroll to locate the item and then select it.

When the `ACTION_EVENT` is generated, the `arg` variable of the specific `Event` instance is set based upon the component type. In Chapters 5-11, which describe Java's GUI components, the description of each component contains an "Events" subsection that describes the value of the event's `arg` field. If you are using the 1.1 event model, the `ActionListener.actionPerformed()` and `ItemListener.itemStateChanged()` interface methods handle this event, depending upon the component type.

Event Methods

Constructors

Ordinarily, the peers deliver all your events for you. However, if you are creating your own components or want to communicate across threads, it may be necessary to create your own events. You can also create your own events to notify your component's container of application-specific occurrences. For example, if you were implementing your own tab sequencing for text fields, you could create a "next text field" event to tell your container to move to the next text field. Once you create the event, you send it through the system using the `Component.postEvent()` method.

public Event (Object target, long when, int id, int x, int y, int key, int modifiers, Object arg)

The first version of the constructor is the most complete and is what the other two call. It initializes all the fields of the `Event` to the parameters passed and sets `clickCount` to 0. See the descriptions of the instance variables Variables for the meanings of the arguments.

public Event (Object target, long when, int id, int x, int y, int key, int modifiers)

The second constructor version calls the first with `arg` set to null.

public Event (Object target, int id, Object arg)

The final version calls the first constructor with the `when`, `x`, `y`, `key`, and `modifiers` parameters set to 0.

Modifier methods

The modifier methods check to see if the different modifier mask values are set. They report the state of each modifier key at the moment an event occurred. It is possible for multiple masks to be set if multiple modifiers are pressed when the event occurs.

There is no `altDown()` method; to check whether the Alt key is pressed you must directly compare the event's `modifiers` against the `Event.ALT_MASK` constant. The `metaDown()` method is helpful when dealing with mouse events to see if the user pressed the right mouse button.

public boolean shiftDown ()

> The `shiftDown()` method returns `true` if the Shift key was pressed and `false` otherwise. There is no way to differentiate left and right shift keys.

public boolean controlDown ()

> The `controlDown()` method returns `true` if the Control key was pressed and `false` otherwise.

public boolean metaDown ()

> The `metaDown()` method returns `true` if the Meta key was pressed and `false` otherwise.

Miscellaneous methods

public void translate (int x, int y)

> The `translate()` method translates the x and y coordinates of the `Event` instance by `x` and `y`. The system does this so that the coordinates of the event are relative to the component receiving the event, rather than the container of the component. The system takes care of all this for you when passing the event through the containment hierarchy (not the object hierarchy), so you do not have to bother with translating them yourself. Figure 4.3 shows how this method would change the location of an event from a container down to an internal component.

Figure 4.3: Translating an event's location relative to a component

[Graphic: Figure 4-3]

protected String paramString ()

When you call the `toString()` method of `Event`, the `paramString()` method is called in turn to build the string to display. In the event you subclass `Event` to add additional information, instead of having to provide a whole new `toString()` method, you need only add the new information to the string already generated by `paramString()`. Assuming the new information is `foo`, this would result in the following method declaration:

```
protected String paramString() {
    return super.paramString() + ",foo=" + foo;
}
```

public String toString ()

The `toString()` method of `Event` returns a string with numerous components. The only variables that will always be in the output will be the event ID and the x and y coordinates. The others will be present if necessary (i.e., non-null): key (as the integer corresponding to a keyboard event), shift when `shiftDown()` is true; control, when `controlDown()` is true; meta, when `metaDown()` is true; target (if it was a `Component`); and arg (the value depends on the target and ID). `toString()` does not display all pieces of the `Event` information. An event when moving a `Scrollbar` might result in the following:

```
java.awt.Event[id=602,x=374,y=110,target=java.awt.Scrollbar[374,
110,15x50,val=1,vis=true,min=0,max=255,vert],arg=1]
```

Working With Mouse Buttons in Java 1.0

As stated earlier, the `modifiers` component of `Event` can be used to differentiate the different mouse buttons. If the user has a multibutton mouse, the `modifiers` field is set automatically to indicate which button was pressed. If the user does not own a multibutton mouse, he or she can press the mouse button in combination with the Alt or Meta keys to simulate a three-button mouse. Example 4.2 is a sample program called `mouseEvent` that displays the mouse button selected.

Example 4.2: Differentiating Mouse Buttons in Java 1.0

```
import java.awt.*;
import java.applet.*;
public class mouseEvent extends Applet {
    String theString = "Press a Mouse Key";
    public synchronized void setString (String s) {
        theString = s;
    }
    public synchronized String getString () {
        return theString;
    }
    public synchronized void paint (Graphics g) {
        g.drawString (theString, 20, 20);
    }
    public boolean mouseDown (Event e, int x, int y) {
        if (e.modifiers == Event.META_MASK) {
            setString ("Right Button Pressed");
        } else if (e.modifiers == Event.ALT_MASK) {
            setString ("Middle Button Pressed");
        } else {
            setString ("Left Button Pressed");
        }
        repaint ();
        return true;
    }
    public boolean mouseUp (Event e, int x, int y) {
        setString ("Press a Mouse Key");
        repaint ();
        return true;
    }
}
```

Unfortunately, this technique does not always work. With certain components on some platforms, the peer captures the mouse event and does not pass it along; for example, on Windows, the display-edit menu of a `TextField` appears when you select the right mouse button. Be cautious about relying on multiple mouse buttons; better yet, if you want to ensure absolute portability, stick to a single button.

Comprehensive Event List

Unfortunately, there are many platform-specific differences in the way event handling works. It's not clear whether these differences are bugs or whether vendors think they are somehow improving their product by introducing portability problems. We hope that as Java matures, different platforms will gradually come into synch. Until that happens, you might want your programs to assume the lowest common denominator. If you are willing to take the risk, you can program for a specific browser or platform, but should be aware of the possibility of changes.

Appendix C, *Platform-Specific Event Handling*, includes a table that shows which components pass along which events by default in the most popular environments. This table was developed using an interactive program called `compList`, which generates a list of supported events for each component. You can find `compList` on this book's Web site, http://www.ora.com/catalog/javawt. If you want to check the behavior of some new platform, or a newer version of one of the platforms in Appendix C, *Platform-Specific Event Handling*, feel free to use `compList`. It does require a little bit of work on your part. You have to click, toggle, type, and mouse over every object. Hopefully, as Java matures, this program will become unnecessary.

4.3 The Java 1.1 Event Model

Now it's time to discuss the new event model that is implemented by the 1.1 release of the JDK. Although this model can seem much more complex (it does have many more pieces), it is really much simpler and more efficient. The new event model does away with the process of searching for components that are interested in an event--`deliverEvent()`, `postEvent()`, `handleEvent()`--and all that. The new model requires objects be registered to receive events. Then, only those objects that are registered are told when the event actually happens.

This new model is called "delegation"; it implements the `Observer`-`Observable` design pattern with events. It is important in many respects. In addition to being much more efficient, it allows for a much cleaner separation between GUI components and event handling. It is important that any object, not just a `Component`, can receive events. Therefore, you can separate your event-handling code from your GUI code. One set of classes can implement the user interface; another set of classes can respond to the events generated by the interface. This means that if you have designed a good interface, you can reuse it in different applications by changing the event processing. The delegation model is essential to JavaBeans, which allows interaction between Java and other platforms, like OpenDoc or ActiveX. To allow such interaction, it was essential to separate the source of an event from the recipient.[1]

[1] For more information about JavaBeans, see http://splash.javasoft.com/beans/.

The delegation model has several other important ramifications. First, event handlers no longer need to worry about whether or not they have completely dealt with an event; they do what they need to, and return. Second, events can be broadcast to multiple recipients; any number of classes can be registered to receive an event. In the old model, broadcasting was possible only in a very limited sense, if at all. An event handler could declare that it hadn't completely processed an event, thus letting its container receive the event when it was done, or an event handler could generate a new event and deliver it to some other component. In any case, developers had to plan how to deliver events to other recipients. In Java 1.1, that's no longer necessary. An event will be delivered to every object that is registered as a listener for that event, regardless of what other objects do with the event. Any listener can mark an event "consumed," so it will be ignored by the peer or (if they care) other listeners.

Finally, the 1.1 event model includes the idea of an event queue. Instead of having to override `handleEvent()` to see all events, you can peek into the system's event queue by using the `EventQueue` class. The details of this class are discussed at the end of this chapter.

In Java 1.1, each component is an event *source* that can generate certain types of events, which are all subclasses of `AWTEvent`. Objects that are interested in an event are called *listeners*. Each event type corresponds to a listener interface that specifies the methods that are called when the event occurs. To receive an event, an object must implement the appropriate listener interface and must be registered with the event's source, by a call to an "add listener" method of the component that generates the event. Who calls the "add listener" method can vary; it is probably the best design for the component to register any listeners for the events that it generates, but it is also possible for the event handler to register itself, or for some third object to handle registration (for example, one object could call the constructor for a component, then call the constructor for an event handler, then register the event handler as a listener for the component's events).

This sounds complicated, but it really isn't that bad. It will help to think in concrete terms. A `TextField` object can generate action events, which in Java 1.1 are of the class `ActionEvent`. Let's say we have an object of class `TextActionHandler` that is called `myHandler` that is interested in receiving action events from a text field named `inputBuffer`. This means that our object must implement the `ActionListener` interface, and this in turn, means that it must include an `actionPerformed()` method, which is called when an action event occurs. Now, we have to register our object's interest in action events generated by `inputBuffer`; to do so, we need a call to `inputBuffer.addActionListener(myHandler)`. This call would probably be made by the object that is creating the `TextField` but could also be made by our event handler itself. The code might be as simple as this:

```
...
public void init(){
    ...
    inputBuffer = new TextField();
    myHandler = new TextActionHandler();
    inputBuffer.addActionListener(myHandler); // register the handler for the
                                              // buffer's events
    add (inputBuffer);  // add the input buffer to the display
    ...
}
```

Once our object has been registered, `myHandler.actionPerformed()` will be called whenever a user does anything in the text field that generates an action event, like typing a carriage return. In a way, `actionPerformed()` is very similar to the `action()` method of the old event model--except that it is not tied to the `Component` hierarchy; it is part of an interface that can be implemented by any object that cares about events.

Of course, there are many other kinds of events. Figure 4.4 shows the event hierarchy for Java 1.1. Figure 4.5 shows the different listener interfaces, which are all subinterfaces of `EventListener`, along with the related adapter classes.

Figure 4.4: AWTEvent class hierarchy

[Graphic: Figure 4-4]

Figure 4.5: AWT EventListener and Adapter class hierarchies

[Graphic: Figure 4-5]

Some of the listener interfaces are constructed to deal with multiple events. For instance, the `MouseListener` interface declares five methods to handle different kinds of mouse events: mouse down, mouse up, click (both down and up), mouse enter, and mouse exit. Strictly speaking, this means that an object interested in mouse events must implement `MouseListener` and must therefore implement five methods to deal with all possible mouse actions. This sounds like a waste of the programmer's effort; most of the time, you're only interested in one or two of these events. Why should you have to implement all five methods? Fortunately, you don't. The `java.awt.event` package also includes a set of *adapter classes*, which are shorthands that make it easier to write event handlers. The adapter class for any listener interface provides a `null` implementation of all the methods in that interface. For example, the `MouseAdapter` class provides `stub` implementations of the methods `mouseEntered()`, `mouseExited()`, `mousePressed()`, `mouseReleased()`, and `mouseClicked()`. If you want to write an event-handling class that deals with mouse clicks only, you can declare that your class extends `MouseAdapter`. It then inherits all five of these methods, and your only programming task is to override the single method you care about: `mouseClicked()`.

A particularly convenient way to use the adapters is to write an anonymous inner class. For example, the following code deals with the `MOUSE_PRESSED` event without creating a separate listener class:

```
addMouseListener (new MouseAdapter()   {
  public void mousePressed (MouseEvent e)  {
    // do what's needed to handle the event
    System.out.println ("Clicked at: " + e.getPoint());
  }
});
```

This code creates a `MouseAdapter`, overrides its `mousePressed()` method, and registers the resulting unnamed object as a listener for mouse events. Its `mousePressed()` method is called when `MOUSE_PRESSED` events occur. You can also use the adapter classes to implement something similar to a callback. For example, you could override `mousePressed()` to call one of your own methods, which would then be called whenever a `MOUSE_PRESSED` event occurs.

There are adapter classes for most of the listener interfaces; the only exceptions are the listener interfaces that contain only one method (for example, there's no `ActionAdapter` to go with `ActionListener`). When the listener interface contains only one method, an adapter class is superfluous. Event handlers may as well implement the listener interface directly, because they will have to override the only method in the interface; creating a dummy class with the interface method stubbed out doesn't accomplish anything. The different adapter classes are discussed with their related

EventListener interfaces.

With all these adapter classes, listener interfaces, and event classes, it's easy to get confused. Here's a quick summary of the different pieces involved and the roles they play:

- Components generate AWTEvents when something happens. Different subclasses of AWTEvent represent different kinds of events. For example, mouse events are represented by the MouseEvent class. Each component can generate certain subclasses of AWTEvent.

- Event handlers are registered to receive events by calls to an "add listener" method in the component that generates the event. There is a different "add listener" method for every kind of AWTEvent the component can generate; for example, to declare your interest in a mouse event, you call the component's addMouseListener() method.

- Every event type has a corresponding listener interface that defines the methods that are called when that event occurs. To be able to receive events, an event handler must therefore implement the appropriate listener interface. For example, MouseListener defines the methods that are called when mouse events occur. If you create a class that calls addMouseListener(), that class had better implement the MouseListener interface.

- Most event types also have an adapter class. For example, MouseEvents have a MouseAdapter class. The adapter class implements the corresponding listener interface but provides a stub implementation of each method (i.e., the method just returns without taking any action). Adapter classes are shorthand for programs that only need a few of the methods in the listener interface. For example, instead of implementing all five methods of the MouseListener interface, a class can extend the MouseAdapter class and override the one or two methods that it is interested in.

Using the 1.1 Event Model

Before jumping in and describing all the different pieces in detail, we will look at a simple applet that uses the Java 1.1 event model. Example 4.3 is equivalent to Example 4.2, except that it uses the new event model; when you press a mouse button, it just tells you what button you pressed. Notice how the new class, mouseEvent11, separates the user interface from the actual work. The class mouseEvent11 implements a very simple user interface. The class UpDownCatcher handles the events, figures out what to do, and calls some methods in mouseEvent11 to communicate the results. I added a simple interface that is called GetSetString to define the communications between the user interface and the event handler; strictly speaking, this isn't necessary, but it's a good programming practice.

Example 4.3: Handling Mouse Events in Java 1.1

```
// Java 1.1 only
import java.awt.*;
import java.awt.event.*;
import java.applet.*;
interface GetSetString {
    public void setString (String s);
    public String getString ();
}
```

The `UpDownCatcher` class is responsible for handling events generated by the user interface. It extends `MouseAdapter` so that it needs to implement only the `MouseListener` methods that we care about (such as `mousePressed()` and `mouseReleased()`).

```
class UpDownCatcher extends MouseAdapter {
    GetSetString gss;
    public UpDownCatcher (GetSetString s) {
        gss = s;
    }
```

The constructor simply saves a reference to the class that is using this handler.

```
    public void mousePressed (MouseEvent e) {
        int mods = e.getModifiers();
        if ((mods & MouseEvent.BUTTON3_MASK) != 0) {
            gss.setString ("Right Button Pressed");
        } else if ((mods & MouseEvent.BUTTON2_MASK) != 0) {
            gss.setString ("Middle Button Pressed");
        } else {
            gss.setString ("Left Button Pressed");
        }
        e.getComponent().repaint();
    }
```

The `mousePressed` method overrides one of the methods of the `MouseAdapter` class. The method `mousePressed()` is called whenever a user presses any mouse button. This method figures out which button on a three-button mouse was pressed and calls the `setString()` method in the user interface to inform the user of the result.

```
    public void mouseReleased (MouseEvent e) {
        gss.setString ("Press a Mouse Key");
        e.getComponent().repaint();
    }
}
```

The `mouseReleased` method overrides another of the methods of the `MouseAdapter` class. When the user releases the mouse button, it calls `setString()` to restore the user interface to the original message.

```
public class mouseEvent11 extends Applet implements GetSetString {
    private String theString = "Press a Mouse Key";
    public synchronized void setString (String s) {
        theString = s;
    }
    public synchronized String getString () {
        return theString;
    }
    public synchronized void paint (Graphics g) {
        g.drawString (theString, 20, 20);
    }
    public void init () {
        addMouseListener (new UpDownCatcher(this));
    }
}
```

`mouseEvent11` is a very simple applet that implements our user interface. All it does is draw the desired string on the screen; the event handler tells it what string to draw. The `init()` method creates an instance of the event handler, which is `UpDownCatcher`, and registers it as interested in mouse events.

Because the user interface and the event processing are in separate classes, it would be easy to use this user interface for another purpose. You would have to replace only the `UpDownCatcher` class with something else--perhaps a more complex class that reported when the mouse entered and exited the area.

AWTEvent and Its Children

Under the 1.1 delegation event model, all system events are instances of `AWTEvent` or its subclasses. The model provides two sets of event types. The first set are fairly raw events, such as those indicating when a component gets focus, a key is pressed, or the mouse is moved. These events exist in `ComponentEvent` and its subclasses, along with some new events previously available only by overriding non-event-related methods. In addition, higher-level event types (for example, selecting a button) are encapsulated in other subclasses of `AWTEvent` that are not children of `ComponentEvent`.

AWTEvent

Variables

protected int id ★

> The `id` field of `AWTEvent` is protected and is accessible through the `getID()` method. It serves as the identifier of the event type, such as the `ACTION_PERFORMED` type of `ActionEvent` or the `MOUSE_MOVE` type of `Event`. With the delegation event model, it is usually not necessary to look at the event `id` unless you are looking in the event queue; just register the appropriate event listener.

Constants

The constants of `AWTEvent` are used in conjunction with the internal method `Component.eventEnabled()`. They are used to help the program determine what style of event handling (true/false--containment or listening--delegation) the program uses and which events a component processes. If you want to process 1.1 events without providing a listener, you need to set the mask for the type of event you want to receive. Look in Chapter 5, *Components*, for more information on the use of these constants:

public final static long ACTION_EVENT_MASK ★
public final static long ADJUSTMENT_EVENT_MASK ★
public final static long COMPONENT_EVENT_MASK ★

public final static long CONTAINER_EVENT_MASK ★
public final static long FOCUS_EVENT_MASK ★
public final static long ITEM_EVENT_MASK ★
public final static long KEY_EVENT_MASK ★
public final static long MOUSE_EVENT_MASK ★
public final static long MOUSE_MOTION_EVENT_MASK ★
public final static long TEXT_EVENT_MASK ★
public final static long WINDOW_EVENT_MASK ★

In addition to the mask constants, the constant `RESERVED_ID_MAX` is the largest event ID reserved for "official" events. You may use ID numbers greater than this value to create your own events, without risk of conflicting with standard events.

public final static long RESERVED_ID_MAX ★

Constructors

Since `AWTEvent` is an abstract class, you cannot call the constructors directly. They are automatically called when an instance of a child class is created.

public AWTEvent(Event event) ★

The first constructor creates an `AWTEvent` from the parameters of a 1.0 `Event`. The `event.target` and `event.id` are passed along to the second constructor.

public AWTEvent(Object source, int id) ★

This constructor creates an `AWTEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. It is protected and is accessible through the `getID()` method. With the delegation event model, it is usually not necessary to look at the event `id` unless you are looking in the event queue or in the `processEvent()` method of a component; just register the appropriate event listener.

Methods

public int getID() ★

The `getID()` method returns the `id` from the constructor, thus identifying the event type.

protected void consume() ★

The `consume()` method is called to tell an event that it has been handled. An event that has been marked "consumed" is still delivered to the source component's peer and to all other registered listeners. However, the peer will ignore the event; other listeners may also choose to ignore it, but that's up to them. It isn't possible for a listener to "unconsume" an event that has already been marked "consumed."

Noncomponent events cannot be consumed. Only keyboard and mouse event types can be flagged as consumed. Marking an event "consumed" is useful if you are capturing keyboard input and need to reject a character; if you call `consume()`, the key event never makes it to the peer, and the keystroke isn't displayed. In Java 1.0, you would achieve the same effect by writing an event handler (e.g., `keyDown()`) that returns `true`.

You can assume that an event won't be delivered to the peer until all listeners have had a chance to consume it. However, you should not make any other assumptions about the order in which listeners are called.

protected boolean isConsumed() ★

The `isConsumed()` method returns whether the event has been consumed. If the event has been consumed, either by default or through `consume()`, this method returns `true`; otherwise, it returns `false`.

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. Since you are most frequently dealing with children of `AWTEvent`, the children need only to override `paramString()` to add their specific information.

public String toString() ★

The `toString()` method of `AWTEvent` returns a string with the name of the event, specific information about the event, and the source. In the method `MouseAdapter.mouseReleased()`, printing the parameter would result in something like the following:

```
java.awt.event.MouseEvent[MOUSE_RELEASED,(69,107),mods=0,clickCount=1] on panel1
```

ComponentEvent

Constants

public final static int COMPONENT_FIRST ★
public final static int COMPONENT_LAST ★

The `COMPONENT_FIRST` and `COMPONENT_LAST` constants hold the endpoints of the range of identifiers for `ComponentEvent` types.

public final static int COMPONENT_HIDDEN ★

The `COMPONENT_HIDDEN` constant identifies component events that occur because a component was hidden. The interface method `ComponentListener.componentHidden()` handles this event.

public final static int COMPONENT_MOVED ★

The `COMPONENT_MOVED` constant identifies component events that occur because a component has moved. The `ComponentListener.componentMoved()` interface method handles this event.

public final static int COMPONENT_RESIZED ★

The `COMPONENT_RESIZED` constant identifies component events that occur because a component has changed size. The interface method `ComponentListener.componentResized()` handles this event.

public final static int COMPONENT_SHOWN ★

The `COMPONENT_SHOWN` constant identifies component events that occur because a component has been shown (i.e., made visible). The interface method `ComponentListener.componentShown()` handles this event.

Constructors

public ComponentEvent(Component source, int id) ★

This constructor creates a `ComponentEvent` with the given `source`; the source is the object generating the event. The `id` field identifies the event type. If system generated, the `id` will be one of the last four constants above. However, nothing stops you from creating your own `id` for your event types.

Methods

public Component getComponent() ★

The `getComponent()` method returns the `source` of the event--that is, the component initiating the event.

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `ComponentEvent` level, `paramString()` adds a string containing the event `id` (if available) and the bounding rectangle for the `source` (if appropriate). For example:

```
java.awt.event.ComponentEvent[COMPONENT_RESIZED (0, 0, 100x100)] on button0
```

ContainerEvent

The `ContainerEvent` class includes events that result from specific container operations. Constants

public final static int CONTAINER_FIRST ★
public final static int CONTAINER_LAST ★

The `CONTAINER_FIRST` and `CONTAINER_LAST` constants hold the endpoints of the range of identifiers for `ContainerEvent` types.

public final static int COMPONENT_ADDED ★

> The `COMPONENT_ADDED` constant identifies container events that occur because a component has been added to the container. The interface method `ContainerListener.componentAdded()` handles this event. Listening for this event is useful if a common listener should be attached to all components added to a container.

public final static int COMPONENT_REMOVED ★

> The `COMPONENT_REMOVED` constant identifies container events that occur because a component has been removed from the container. The interface method `ContainerListener.componentRemoved()` handles this event.

Constructors

public ContainerEvent(Container source, int id, Component child) ★

> The constructor creates a `ContainerEvent` with the given `source` (the container generating the event), to which the given `child` has been added or removed. The `id` field serves as the identifier of the event type. If system generated, the `id` will be one of the constants described previously. However, nothing stops you from creating your own `id` for your event types.

Methods

public Container getContainer() ★

> The `getContainer()` method returns the container that generated the event.

public Component getComponent() ★

> The `getComponent()` method returns the component that was added to or removed from the container.

public String paramString() ★

> When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is in turn called to build the string to display. At the `ContainerEvent` level, `paramString()` adds a string containing the event `id` (if available) along with the name of the child.

FocusEvent

The `FocusEvent` class contains the events that are generated when a component gets or loses focus. These may be either temporary or permanent focus changes. A temporary focus change is the result of something else happening, like a window appearing in front of you. Once the window is removed, focus is restored. A permanent focus change is usually the result of focus traversal, using the keyboard or the mouse: for example, you clicked in a text field to type in it, or used Tab to move to the next component. More programmatically, permanent focus changes are the result of calls to `Component.requestFocus()`. Constants

public final static int FOCUS_FIRST ★
public final static int FOCUS_LAST ★

> The `FOCUS_FIRST` and `FOCUS_LAST` constants hold the endpoints of the range of identifiers for `FocusEvent` types.

public final static int FOCUS_GAINED ★

> The `FOCUS_GAINED` constant identifies focus events that occur because a component gains input focus. The `FocusListener.focusGained()` interface method handles this event.

public final static int FOCUS_LOST ★

> The `FOCUS_LOST` constant identifies focus events that occur because a component loses input focus. The `FocusListener.focusLost()` interface method handles this event.

Constructors

public FocusEvent(Component source, int id, boolean temporary) ★

> This constructor creates a `FocusEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. If system generated, the `id` will be one of the two constants described previously. However, nothing stops you from creating your own `id` for your event types. The `temporary` parameter is `true` if this event represents a temporary focus change.

public FocusEvent(Component source, int id) ★

> This constructor creates a `FocusEvent` by calling the first constructor with the `temporary` parameter set to `false`; that is, it creates an event for a permanent focus change.

Methods

public boolean isTemporary() ★

> The `isTemporary()` method returns `true` if the focus event describes a temporary focus change, `false` if the event describes a permanent focus change. Once set by the constructor, the setting is permanent.

public String paramString() ★

> When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is in turn called to build the string to display. At the `FocusEvent` level, `paramString()` adds a string showing the event `id` (if available) and whether or not it is temporary.

WindowEvent

The `WindowEvent` class encapsulates the window-oriented events. Constants

public final static int WINDOW_FIRST ★
public final static int WINDOW_LAST ★

The `WINDOW_FIRST` and `WINDOW_LAST` constants hold the endpoints of the range of identifiers for `WindowEvent` types.

public final static int WINDOW_ICONIFIED ★

The `WINDOW_ICONIFIED` constant identifies window events that occur because the user iconifies a window. The `WindowListener.windowIconified()` interface method handles this event.

public final static int WINDOW_DEICONIFIED ★

The `WINDOW_DEICONIFIED` constant identifies window events that occur because the user de-iconifies a window. The interface method `WindowListener.windowDeiconified()` handles this event.

public final static int WINDOW_OPENED ★

The `WINDOW_OPENED` constant identifies window events that occur the first time a `Frame` or `Dialog` is made visible with `show()`. The interface method `WindowListener.windowOpened()` handles this event.

public final static int WINDOW_CLOSING ★

The `WINDOW_CLOSING` constant identifies window events that occur because the user wants to close a window. This is similar to the familiar event `Event.WINDOW_DESTROY` dealt with under 1.0 with frames. The `WindowListener.windowClosing()` interface method handles this event.

public final static int WINDOW_CLOSED ★

The `WINDOW_CLOSED` constant identifies window events that occur because a `Frame` or `Dialog` has finally closed, after `hide()` or `destroy()`. This comes after `WINDOW_CLOSING`, which happens when the user wants the window to close. The `WindowListener.windowClosed()` interface method handles this event.

NOTE:

If there is a call to `System.exit()` in the `windowClosing()` listener, the window will not be around to call `windowClosed()`, nor will other listeners know.

public final static int WINDOW_ACTIVATED ★

The `WINDOW_ACTIVATED` constant identifies window events that occur because the user brings the window to the front, either after showing the window, de-iconifying, or removing whatever was in front. The interface method `WindowListener.windowActivated()` handles this event.

public final static int WINDOW_DEACTIVATED ★

> The `WINDOW_DEACTIVATED` constant identifies window events that occur because the user makes another window the active window. The interface method `WindowListener.windowDeactivated()` handles this event.

Constructors

public WindowEvent(Window source, int id) ★

> This constructor creates a `WindowEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. If system generated, the `id` will be one of the seven constants described previously. However, nothing stops you from creating your own `id` for your event types.

Methods

public Window getWindow() ★

> The `getWindow()` method returns the `Window` that generated the event.

public String paramString() ★

> When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is in turn called to build the string to display. At the `WindowEvent` level, `paramString()` adds a string containing the event `id` (if available). In a call to `windowClosing()`, printing the parameter would yield:

```
java.awt.event.WindowEvent[WINDOW_CLOSING] on frame0
```

PaintEvent

The `PaintEvent` class encapsulates the paint-oriented events. There is no corresponding `PaintListener` class, so you cannot listen for these events. To process them, override the `paint()` and `update()` routines of `Component`. The `PaintEvent` class exists to ensure that events are serialized properly through the event queue.
Constants

public final static int PAINT_FIRST ★
public final static int PAINT_LAST ★

> The `PAINT_FIRST` and `PAINT_LAST` constants hold the endpoints of the range of identifiers for `PaintEvent` types.

public final static int PAINT ★

The `PAINT` constant identifies paint events that occur because a component needs to be repainted. Override the `Component.paint()` method to handle this event.

public final static int UPDATE ★

The `UPDATE` constant identifies paint events that occur because a component needs to be updated before painting. This usually refreshes the display. Override the `Component.update()` method to handle this event.

Constructors

public PaintEvent(Component source, int id, Rectangle updateRect) ★

This constructor creates a `PaintEvent` with the given `source`. The source is the object whose display needs to be updated. The `id` field identifies the event type. If system generated, the `id` will be one of the two constants described previously. However, nothing stops you from creating your own `id` for your event types. `updateRect` represents the rectangular area of `source` that needs to be updated.

Methods

public Rectangle getUpdateRect()

The `getUpdateRect()` method returns the rectangular area within the `PaintEvent`'s source component that needs repainting. This area is set by either the constructor or the `setUpdateRect()` method.

public void setUpdateRect(Rectangle updateRect)

The `setUpdateRect()` method changes the area of the `PaintEvent`'s source component that needs repainting.

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `PaintEvent` level, `paramString()` adds a string containing the event `id` (if available) along with the area requiring repainting (a clipping rectangle). If you peek in the event queue, one possible result may yield:

```
java.awt.event.PaintEvent[PAINT,updateRect=java.awt.Rectangle[x=0,y=0,
width=192,height=173]] on frame0
```

InputEvent

The `InputEvent` class provides the basis for the key and mouse input and movement routines. `KeyEvent` and `MouseEvent` provide the specifics of each. Constants

The constants of `InputEvent` help identify which modifiers are present when an input event occurs, as shown in

Example 4.3. To examine the event modifiers and test for the presence of these masks, call `getModifiers()` to get the current set of modifiers.

public final static int ALT_MASK ★
public final static int CTRL_MASK ★
public final static int META_MASK ★
public final static int SHIFT_MASK ★

> The first set of `InputEvent` masks are for the different modifier keys on the keyboard. They are often set to indicate which button on a multibutton mouse has been pressed.

public final static int BUTTON1_MASK ★
public final static int BUTTON2_MASK ★
public final static int BUTTON3_MASK ★

> The button mask constants are equivalents for the modifier masks, allowing you to write more intelligible code for dealing with button events. `BUTTON2_MASK` is the same as `ALT_MASK`, and `BUTTON3_MASK` is the same as `META_MASK`; `BUTTON1_MASK` currently isn't usable and is never set. For example, if you want to check whether the user pressed the second (middle) mouse button, you can test against `BUTTON2_MASK` rather than `ALT_MASK`. Example 4.3 demonstrates how to use these constants.

Constructors

`InputEvent` is an abstract class with no public constructors. Methods

Unlike the `Event` class, `InputEvent` has an `isAltDown()` method to check the `ALT_MASK` setting.

public boolean isAltDown() ★

> The `isAltDown()` method checks to see if `ALT_MASK` is set. If so, `isAltDown()` returns `true`; otherwise, it returns `false`.

public boolean isControlDown() ★

> The `isControlDown()` method checks to see if `CONTROL_MASK` is set. If so, `isControlDown()` returns `true`; otherwise, it returns `false`.

public boolean isMetaDown() ★

> The `isMetaDown()` method checks to see if `META_MASK` is set. If so, the method `isMetaDown()` returns `true`; otherwise, it returns `false`.

public boolean isShiftDown() ★

The `isShiftDown()` method checks to see if `SHIFT_MASK` is set. If so, the method `isShiftDown()` returns `true`; otherwise, it returns `false`.

public int getModifiers() ★

The `getModifiers()` method returns the current state of the modifier keys. For each modifier key pressed, a different flag is raised in the return argument. To check if a modifier is set, AND the return value with a flag and check for a nonzero value.

```
if ((ie.getModifiers() & MouseEvent.META_MASK) != 0) {
    System.out.println ("Meta is set");
}
```

public long getWhen() ★

The `getWhen()` method returns the time at which the event occurred. The return value is in milliseconds. Convert the `long` value to a `Date` to examine the contents. For example:

```
Date d = new Date (ie.getWhen());
```

public void consume() ★

This class overrides the `AWTEvent.consume()` method to make it public. Anyone, not just a subclass, can mark an `InputEvent` as consumed.

public boolean isConsumed() ★

This class overrides the `AWTEvent.isconsumed()` method to make it public. Anyone can find out if an `InputEvent` has been consumed.

KeyEvent

The `KeyEvent` class is a subclass of `InputEvent` for dealing with keyboard events. There are two fundamental key actions: key presses and key releases. These are represented by `KEY_PRESSED` and `KEY_RELEASED` events. Of course, it's inconvenient to think in terms of all these individual actions, so Java also keeps track of the "logical" keys you type. These are represented by `KEY_TYPED` events. For every keyboard key pressed, a `KeyEvent.KEY_PRESSED` event occurs; the key that was pressed is identified by one of the virtual keycodes from Table 4.4 and is available through the `getKeyCode()` method. For example, if you type an uppercase A, you will get two `KEY_PRESSED` events, one for shift (`VK_SHIFT`) and one for the "a" (`VK_A`). You will also get two `KeyEvent.KEY_RELEASED` events. However, there will only be one `KeyEvent.KEY_TYPED` event; if you call `getKeyChar()` for the `KEY_TYPED` event, the result will be the Unicode character "A" (type `char`). `KEY_TYPED` events do not happen for action-oriented keys like function keys. Constants

Like the `Event` class, numerous constants help you identify all the keyboard keys. Table 4.4 shows the constants that refer to these keyboard keys. The values are all declared `public static final int`. A few keys represent ASCII characters that have string equivalents like `\n`.

Table 4.4: Key Constants in Java 1.1

VK_ENTER	VK_0	VK_A	VK_F1	VK_ACCEPT
VK_BACK_SPACE	VK_1	VK_B	VK_F2	VK_CONVERT
VK_TAB	VK_2	VK_C	VK_F3	VK_FINAL
VK_CANCEL	VK_3	VK_D	VK_F4	VK_KANA
VK_CLEAR	VK_4	VK_E	VK_F5	VK_KANJI
VK_SHIFT	VK_5	VK_F	VK_F6	VK_MODECHANGE
VK_CONTROL	VK_6	VK_G	VK_F7	VK_NONCONVERT
VK_ALT	VK_7	VK_H	VK_F8	
VK_PAUSE	VK_8	VK_I	VK_F9	
VK_CAPS_LOCK	VK_9	VK_J	VK_F10	
VK_ESCAPE	VK_NUMPAD0	VK_K	VK_F11	
VK_SPACE	VK_NUMPAD1	VK_L	VK_F12	
VK_PAGE_UP	VK_NUMPAD2	VK_M	VK_DELETE	
VK_PAGE_DOWN	VK_NUMPAD3	VK_N	VK_NUM_LOCK	
VK_END	VK_NUMPAD4	VK_O	VK_SCROLL_LOCK	
VK_HOME	VK_NUMPAD5	VK_P	VK_PRINTSCREEN	
VK_LEFT	VK_NUMPAD6	VK_Q	VK_INSERT	
VK_UP	VK_NUMPAD7	VK_R	VK_HELP	
VK_RIGHT	VK_NUMPAD8	VK_S	VK_META	
VK_DOWN	VK_NUMPAD9	VK_T	VK_BACK_QUOTE	
VK_COMMA	VK_MULTIPLY	VK_U	VK_QUOTE	
VK_PERIOD	VK_ADD	VK_V	VK_OPEN_BRACKET	
VK_SLASH	VK_SEPARATER[1]	VK_W	VK_CLOSE_BRACKET	
VK_SEMICOLON	VK_SUBTRACT	VK_X		
VK_EQUALS	VK_DECIMAL	VK_Y		
VK_BACK_SLASH	VK_DIVIDE	VK_Z		

Footnotes:

[1] Expect VK_SEPARATOR to be added at some future point. This constant represents the numeric separator key on your keyboard.

public final static int VK_UNDEFINED ★

When a KEY_TYPED event happens, there is no keycode. If you ask for it, the getKeyCode() method returns VK_UNDEFINED.

public final static char CHAR_UNDEFINED ★

> For `KEY_PRESSED` and `KEY_RELEASED` events that do not have a corresponding Unicode character to display (like Shift), the `getKeyChar()` method returns `CHAR_UNDEFINED`.

Other constants identify what the user did with a key.

public final static int KEY_FIRST ★
public final static int KEY_LAST ★

> The `KEY_FIRST` and `KEY_LAST` constants hold the endpoints of the range of identifiers for `KeyEvent` types.

public final static int KEY_PRESSED ★

> The `KEY_PRESSED` constant identifies key events that occur because a keyboard key has been pressed. To differentiate between action and non-action keys, call the `isActionKey()` method described later. The `KeyListener.keyPressed()` interface method handles this event.

public final static int KEY_RELEASED ★

> The `KEY_RELEASED` constant identifies key events that occur because a keyboard key has been released. The `KeyListener.keyReleased()` interface method handles this event.

public final static int KEY_TYPED ★

> The `KEY_TYPED` constant identifies a combination of a key press followed by a key release for a non-action oriented key. The `KeyListener.keyTyped()` interface method handles this event.

Constructors

public KeyEvent(Component source, int id, long when, int modifiers, int keyCode, char keyChar) ★

> This constructor[2] creates a `KeyEvent` with the given `source`; the source is the object generating the event. The `id` field identifies the event type. If system-generated, the `id` will be one of the constants above. However, nothing stops you from creating your own `id` for your event types. The `when` parameter represents the time the event happened. The `modifiers` parameter holds the state of the various modifier keys; masks to represent these keys are defined in the `InputEvent` class. Finally, `keyCode` is the virtual key that triggered the event, and `keyChar` is the character that triggered it.
>
> > [2] Beta releases of Java 1.1 have an additional constructor that lacks the `keyChar` parameter. Comments in the code indicate that this constructor will be deleted prior to the 1.1.1 release.
>
> The `KeyEvent` constructor throws the `IllegalArgumentException` run-time exception in two situations. First, if the `id` is `KEY_TYPED` and `keyChar` is `CHAR_UNDEFINED`, it throws an exception because if a key has been typed, it must be associated with a character. Second, if the `id` is `KEY_TYPED` and `keyCode` is not `VK_UNDEFINED`, it throws an exception because typed keys frequently represent

combinations of key codes (for example, Shift struck with "a"). It is legal for a `KEY_PRESSED` or `KEY_RELEASED` event to contain both a `keyCode` and a `keyChar`, though it's not clear what such an event would represent.

Methods

public char getKeyChar() ★

The `getKeyChar()` method retrieves the Unicode character associated with the key in this `KeyEvent`. If there is no character, `CHAR_UNDEFINED` is returned.

public void setKeyChar(char KeyChar) ★

The `setKeyChar()` method allows you to change the character for the `KeyEvent`. You could use this method to convert characters to uppercase.

public int getKeyCode() ★

The `getKeyCode()` method retrieves the virtual keycode (i.e., one of the constants in Table 4.4) of this `KeyEvent`.

public void setKeyCode(int keyCode) ★

The `setKeyCode()` method allows you to change the keycode for the `KeyEvent`. Changes you make to the `KeyEvent` are seen by subsequent listeners and the component's peer.

public void setModifiers(int modifiers) ★

The `setModifiers()` method allows you to change the modifier keys associated with a `KeyEvent` to `modifiers`. The parent class `InputEvent` already has a `getModifiers()` method that is inherited. Since this is your own personal copy of the `KeyEvent`, no other listener can find out about the change.

public boolean isActionKey() ★

The `isActionKey()` method allows you to check whether the key associated with the `KeyEvent` is an action key (e.g., function, arrow, keypad) or not (e.g., an alphanumeric key). For action keys, this method returns `true`; otherwise, it returns `false`. For action keys, the `keyChar` field usually has the value `CHAR_UNDEFINED`.

public static String getKeyText (int keyCode) ★

The static `getKeyText()` method returns the localized textual string for `keyCode`. For each nonalphanumeric virtual key, there is a key name (the "key text"); these names can be changed using the AWT properties. Table 4.5 shows the properties used to redefine the key names and the default name for each key.

Table 4.5: Key Text Properties

Property	Default	Property	Default
AWT.accept	Accept	AWT.f8	F8
AWT.add	NumPad +	AWT.f9	F9
AWT.alt	Alt	AWT.help	Help
AWT.backQuote	Back Quote	AWT.home	Home
AWT.backSpace	Backspace	AWT.insert	Insert
AWT.cancel	Cancel	AWT.kana	Kana
AWT.capsLock	Caps Lock	AWT.kanji	Kanji
AWT.clear	Clear	AWT.left	Left
AWT.control	Control	AWT.meta	Meta
AWT.decimal	NumPad .	AWT.modechange	Mode Change
AWT.delete	Delete	AWT.multiply	NumPad *
AWT.divide	NumPad /	AWT.noconvert	No Convert
AWT.down	Down	AWT.numLock	Num Lock
AWT.end	End	AWT.numpad	NumPad
AWT.enter	Enter	AWT.pause	Pause
AWT.escape	Escape	AWT.pgdn	Page Down
AWT.final	Final	AWT.pgup	Page Up
AWT.f1	F1	AWT.printScreen	Print Screen
AWT.f10	F10	AWT.quote	Quote
AWT.f11	F11	AWT.right	Right
AWT.f12	F12	AWT.scrollLock	Scroll Lock
AWT.f2	F2	AWT.separator	NumPad ,
AWT.f3	F3	AWT.shift	Shift
AWT.f4	F4	AWT.space	Space
AWT.f5	F5	AWT.subtract	NumPad -
AWT.f6	F6	AWT.tab	Tab
AWT.f7	F7	AWT.unknown	Unknown keyCode
AWT.up	Up		

public static String getKeyModifiersText (int modifiers) ★

The static getKeyModifiersText() method returns the localized textual string for modifiers. The parameter modifiers is a combination of the key masks defined by the InputEvent class. As with the keys themselves, each modifier is associated with a textual name. If multiple modifiers are set, they are concatenated with a plus sign (+) separating them. Similar to getKeyText(), the strings are localized because for each modifier, an awt property is available to redefine the string. Table 4.6 lists the properties and the default modifier names.

Table 4.6: Key Modifiers Text Properties

Property	Default
`AWT.alt`	Alt
`AWT.control`	Ctrl
`AWT.meta`	Meta
`AWT.shift`	Shift

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `KeyEvent` level, `paramString()` adds a textual string for the `id` (if available), the text for the key (if available from `getKeyText()`), and modifiers (from `getKeyModifiersText()`). A key press event would result in something like the following:

```
java.awt.event.KeyEvent[KEY_PRESSED,keyCode=118,
F7,modifiers=Ctrl+Shift] on textfield0
```

MouseEvent

The `MouseEvent` class is a subclass of `InputEvent` for dealing with mouse events. Constants

public final static int MOUSE_FIRST ★
public final static int MOUSE_LAST ★

The `MOUSE_FIRST` and `MOUSE_LAST` constants hold the endpoints of the range of identifiers for `MouseEvent` types.

public final static int MOUSE_CLICKED ★

The `MOUSE_CLICKED` constant identifies mouse events that occur when a mouse button is clicked. A mouse click consists of a mouse press and a mouse release. The `MouseListener.mouseClicked()` interface method handles this event.

public final static int MOUSE_DRAGGED ★

The `MOUSE_DRAGGED` constant identifies mouse events that occur because the mouse is moved over a component with a mouse button pressed. The interface method `MouseMotionListener.mouseDragged()` handles this event.

public final static int MOUSE_ENTERED ★

The `MOUSE_ENTERED` constant identifies mouse events that occur when the mouse first enters a component. The `MouseListener.mouseEntered()` interface method handles this event.

public final static int MOUSE_EXITED ★

The `MOUSE_EXISTED` constant identifies mouse events that occur because the mouse leaves a component's space. The `MouseListener.mouseExited()` interface method handles this event.

public final static int MOUSE_MOVED ★

The `MOUSE_MOVED` constant identifies mouse events that occur because the mouse is moved without a mouse button down. The interface method `MouseMotionListener.mouseMoved()` handles this event.

public final static int MOUSE_PRESSED ★

The `MOUSE_PRESSED` constant identifies mouse events that occur because a mouse button has been pressed. The `MouseListener.mousePressed()` interface method handles this event.

public final static int MOUSE_RELEASED ★

The `MOUSE_RELEASED` constant identifies mouse events that occur because a mouse button has been released. The `MouseListener.mouseReleased()` interface method handles this event.

Constructors

public MouseEvent(Component source, int id, long when, int modifiers, int x, int y, int clickCount, boolean popupTrigger) ★

This constructor creates a `MouseEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. If system-generated, the `id` will be one of the constants described in the previous section. However, nothing stops you from creating your own `id` for your event types. The `when` parameter represents the time the event happened. The `modifiers` parameter holds the state of the various modifier keys, using the masks defined for the `InputEvent` class, and lets you determine which button was pressed. (`x`, `y`) represents the coordinates of the event relative to the origin of `source`, while `clickCount` designates the number of consecutive times the mouse button was pressed within an indeterminate time period. Finally, the `popupTrigger` parameter signifies whether this mouse event should trigger the display of a `PopupMenu`, if one is available. (The `PopupMenu` class is discussed in Chapter 10, *Would You Like to Choose from the Menu?*)

Methods

public int getX() ★

The `getX()` method returns the current x coordinate of the event relative to the source.

public int getY() ★

The `getY()` method returns the current y coordinate of the event relative to the source.

public synchronized Point getPoint() ★

The `getPoint()` method returns the current x and y coordinates of the event relative to the event source.

public synchronized void translatePoint(int x, int y) ★

The `translatePoint()` method translates the x and y coordinates of the `MouseEvent` instance by `x` and `y`. This method functions similarly to the `Event.translate()` method.

public int getClickCount() ★

The `getClickCount()` method retrieves the current `clickCount` setting for the event.

public boolean isPopupTrigger() ★

The `isPopupTrigger()` method retrieves the state of the `popupTrigger` setting for the event. If this method returns `true` and the source of the event has an associated `PopupMenu`, the event should be used to display the menu, as shown in the following code. Since the action the user performs to raise a pop-up menu is platform specific, this method lets you raise a pop-up menu without worrying about what kind of event took place. You only need to call `isPopupTrigger()` and show the menu if it returns `true`.

```
public void processMouseEvent(MouseEvent e) {
    if (e.isPopupTrigger())
        aPopup.show(e.getComponent(), e.getX(), e.getY());
    super.processMouseEvent(e);
}
```

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `MouseEvent` level, a textual string for the `id` (if available) is tacked on to the coordinates, modifiers, and click count. A mouse down event would result in something like the following:

```
java.awt.event.MouseEvent[MOUSE_PRESSED,(5,7),mods=0,clickCount=2] on textfield0
```

ActionEvent

The `ActionEvent` class is the first higher-level event class. It encapsulates events that signify that the user is doing something with a component. When the user selects a button, list item, or menu item, or presses the Return key in a text field, an `ActionEvent` passes through the event queue looking for listeners. Constants

public final static int ACTION_FIRST ★
public final static int ACTION_LAST ★

> The `ACTION_FIRST` and `ACTION_LAST` constants hold the endpoints of the range of identifiers for `ActionEvent` types.

public final static int ACTION_PERFORMED ★

> The `ACTION_PERFORMED` constant represents when a user activates a component. The `ActionListener.actionPerformed()` interface method handles this event.

public static final int ALT_MASK ★
public static final int CTRL_MASK ★
public static final int META_MASK ★
public static final int SHIFT_MASK ★

> Similar to the mouse events, action events have `modifiers`. However, they are not automatically set by the system, so they don't help you see what modifiers were pressed when the event occurred. You may be able to use these constants if you are generating your own action events. To see the value of an action event's modifiers, call `getModifiers()`.

Constructors

public ActionEvent(Object source, int id, String command) ★

> This constructor creates an `ActionEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. If system-generated, the `id` will be `ACTION_PERFORMED`. However, nothing stops you from creating your own `id` for your event types. The `command` parameter is the event's action command. Ideally, the action command should be some locale-independent string identifying the user's action. Most components that generate action events set this field to the selected item's label by default.

public ActionEvent(Object source, int id, String command, int modifiers) ★

> This constructor adds `modifiers` to the settings for an `ActionEvent`. This allows you to define action-oriented events that occur only if certain modifier keys are pressed.

Methods

public String getActionCommand() ★

> The `getActionCommand()` method retrieves the `command` field from the event. It represents the command associated with the object that triggered the event. The idea behind the action command is to differentiate the command associated with some event from the displayed content of the event source. For example, the action command for a button may be Help. However, what the user sees on the label of the button could be a string

localized for the environment of the user. Instead of having your event handler look for 20 or 30 possible labels, you can test whether an event has the action command Help.

public int getModifiers() ★

The `getModifiers()` method returns the state of the modifier keys. For each one set, a different flag is raised in the method's return value. To check if a modifier is set, AND the return value with a flag, and check for a nonzero value.

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `ActionEvent` level, `paramString()` adds a textual string for the event `id` (if available), along with the `command` from the constructor. When the user selects a `Button` with the action command Help, printing the resulting event yields:

```
java.awt.event.ActionEvent[ACTION_PERFORMED,cmd=Help] on button0
```

AdjustmentEvent

The `AdjustmentEvent` class is another higher-level event class. It encapsulates events that represent scrollbar motions. When the user moves the slider of a scrollbar or scroll pane, an `AdjustmentEvent` passes through the event queue looking for listeners. Although there is only one type of adjustment event, there are five subtypes represented by constants `UNIT_DECREMENT`, `UNIT_INCREMENT`, and so on. Constants

public final static int ADJUSTMENT_FIRST ★
public final static int ADJUSTMENT_LAST ★

The `ADJUSTMENT_FIRST` and `ADJUSTMENT_LAST` constants hold the endpoints of the range of identifiers for `AdjustmentEvent` types.

public final static int ADJUSTMENT_VALUE_CHANGED ★

The `ADJUSTMENT_VALUE_CHANGED` constant identifies adjustment events that occur because a user moves the slider of a `Scrollbar` or `ScrollPane`. The `AdjustmentListener.adjustmentValueChanged()` interface method handles this event.

public static final int UNIT_DECREMENT ★

`UNIT_DECREMENT` identifies adjustment events that occur because the user selects the increment arrow.

public static final int UNIT_INCREMENT ★

`UNIT_INCREMENT` identifies adjustment events that occur because the user selects the decrement arrow.

public static final int BLOCK_DECREMENT ★

> `BLOCK_DECREMENT` identifies adjustment events that occur because the user selects the block decrement area, between the decrement arrow and the slider.

public static final int BLOCK_INCREMENT ★

> `BLOCK_INCREMENT` identifies adjustment events that occur because the user selects the block increment area, between the increment arrow and the slider.

public static final int TRACK ★

> `TRACK` identifies adjustment events that occur because the user selects the slider and drags it. Multiple adjustment events of this subtype usually occur consecutively.

Constructors

public AdjustmentEvent(Adjustable source, int id, int type, int value) ★

> This constructor creates an `AdjustmentEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. If system-generated, the `id` of the `AdjustmentEvent` will be `ADJUSTMENT_VALUE_CHANGED`. However, nothing stops you from creating your own `id` for your event types. The `type` parameter is normally one of the five subtypes, with `value` being the current setting of the slider, but is not restricted to that.

Methods

public Adjustable getAdjustable() ★

> The `getAdjustable()` method retrieves the `Adjustable` object associated with this event--that is, the event's `source`.

public int getAdjustmentType() ★

> The `getAdjustmentType()` method retrieves the `type` parameter from the constructor. It represents the subtype of the current event and, if system-generated, is one of the following constants: `UNIT_DECREMENT`, `UNIT_INCREMENT`, `BLOCK_DECREMENT`, `BLOCK_INCREMENT`, or `TRACK`.

public int getValue() ★

> The `getValue()` method retrieves the `value` parameter from the constructor. It represents the current setting of the adjustable object.

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called to help build the string to display. At the `AdjustableEvent` level, `paramString()` adds a textual string for the event `id` (if available), along with a textual string of the `type` (if available), and `value`. For example:

```
java.awt.event.AdjustableEvent[ADJUSTMENT_VALUE_CHANGED,
adjType=TRACK,value=27] on scrollbar0
```

ItemEvent

The `ItemEvent` class is another higher-level event class. It encapsulates events that occur when the user selects a component, like `ActionEvent`. When the user selects a checkbox, choice, list item, or checkbox menu item, an `ItemEvent` passes through the event queue looking for listeners. Although there is only one type of `ItemEvent`, there are two subtypes represented by the constants `SELECTED` and `DESELECTED`. Constants

public final static int ITEM_FIRST ★
public final static int ITEM_LAST ★

The `ITEM_FIRST` and `ITEM_LAST` constants hold the endpoints of the range of identifiers for `ItemEvent` types.

public final static int ITEM_STATE_CHANGED ★

The `ITEM_STATE_CHANGED` constant identifies item events that occur because a user selects a component, thus changing its state. The interface method `ItemListener.itemStateChanged()` handles this event.

public static final int SELECTED ★

`SELECTED` indicates that the user selected the item.

public static final int DESELECTED ★

`DESELECTED` indicates that the user deselected the item.

Constructors

public ItemEvent(ItemSelectable source, int id, Object item, int stateChange) ★

This constructor creates a `ItemEvent` with the given `source`; the source is the object generating the event. The `id` field serves as the identifier of the event type. If system-generated, the `id` will be `ITEM_STATE_CHANGE`. However, nothing stops you from creating your own `id` for your event types. The `item` parameter represents the text of the item selected: for a `Checkbox`, this would be its label, for a `Choice` the current selection. For your own events, this parameter could be virtually anything, since its type is `Object`.

Methods

public ItemSelectable getItemSelectable() ★

The `getItemSelectable()` method retrieves the `ItemSelectable` object associated with this event--that is, the event's source.

public Object getItem() ★

The `getItem()` method returns the `item` that was selected. This usually represents some text to help identify the source but could be nearly anything for user-generated events.

public int getStateChange() ★

The `getStateChange()` method returns the `stateChange` parameter from the constructor and, if system generated, is either `SELECTED` or `DESELECTED`.

public String paramString() ★

When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `ItemEvent` level, `paramString()` adds a textual string for the event `id` (if available), along with a textual string indicating the value of `stateChange` (if available) and `item`. For example:

```
java.awt.event.ItemEvent[ITEM_STATE_CHANGED,item=Help,
stateChange=SELECTED] on checkbox1
```

TextEvent

The `TextEvent` class is yet another higher-level event class. It encapsulates events that occur when the contents of a `TextComponent` have changed, although is not required to have a `TextComponent` source. When the contents change, either programmatically by a call to `setText()` or because the user typed something, a `TextEvent` passes through the event queue looking for listeners. Constants

public final static int TEXT_FIRST ★
public final static int TEXT_LAST ★

The `TEXT_FIRST` and `TEXT_LAST` constants hold the endpoints of the range of identifiers for `TextEvent` types.

public final static int TEXT_VALUE_CHANGED ★

The `TEXT_VALUE_CHANGED` constant identifies text events that occur because a user changes the contents of a text component. The interface method `TextListener.textValueChanged()` handles this event.

Constructors

public TextEvent(Object source, int id) ★

> This constructor creates a `TextEvent` with the given `source`; the source is the object generating the event. The `id` field identifies the event type. If system-generated, the `id` will be `TEXT_VALUE_CHANGE`. However, nothing stops you from creating your own `id` for your event types.

Method

public String paramString() ★

> When you call the `toString()` method of an `AWTEvent`, the `paramString()` method is called in turn to build the string to display. At the `TextEvent` level, `paramString()` adds a textual string for the event `id` (if available).

Event Listener Interfaces and Adapters

Java 1.1 has 11 event listener interfaces, which specify the methods a class must implement to receive different kinds of events. For example, the `ActionListener` interface defines the single method that is called when an `ActionEvent` occurs. These interfaces replace the various event-handling methods of Java 1.0: `action()` is now the `actionPerformed()` method of the `ActionListener` interface, `mouseUp()` is now the `mouseReleased()` method of the `MouseListener` interface, and so on. Most of the listener interfaces have a corresponding adapter class, which is an abstract class that provides a null implementation of all the methods in the interface. (Although an adapter class has no abstract methods, it is declared `abstract` to remind you that it must be subclassed.) Rather than implementing a listener interface directly, you have the option of extending an adapter class and overriding only the methods you care about. (Much more complex adapters are possible, but the adapters supplied with AWT are very simple.) The adapters are available for the listener interfaces with multiple methods. (If there is only one method in the listener interface, there is no need for an adapter.)

This section describes Java 1.1's listener interfaces and adapter classes. It's worth noting here that Java 1.1 does not allow you to modify the original event when you're writing an event handler.

ActionListener

The `ActionListener` interface contains the one method that is called when an `ActionEvent` occurs. It has no adapter class. For an object to listen for action events, it is necessary to call the `addActionListener()` method with the class that implements the `ActionListener` interface as the parameter. The method `addActionListener()` is implemented by `Button`, `List`, `MenuItem`, and `TextField` components. Other components don't generate action events.

public abstract void actionPerformed(ActionEvent e) ★

> The `actionPerformed()` method is called when a component is selected or activated. Every component is activated differently; for a `List`, activation means that the user has double-clicked on an entry. See the appropriate section for a description of each component.
>
> `actionPerformed()` is the Java 1.1 equivalent of the `action()` method in the 1.0 event model.

AdjustmentListener

The `AdjustmentListener` interface contains the one method that is called when an `AdjustmentEvent` occurs. It has no adapter class. For an object to listen for adjustment events, it is necessary to call `addAdjustmentListener()` with the class that implements the `AdjustmentListener` interface as the parameter. The `addAdjustmentListener()` method is implemented by the `Scrollbar` component and the `Adjustable` interface. Other components don't generate adjustment events.

public abstract void adjustmentValueChanged(AdjustmentEvent e) ★

> The `adjustmentValueChanged()` method is called when a slider is moved. The `Scrollbar` and `ScrollPane` components have sliders, and generate adjustment events when the sliders are moved. (The `TextArea` and `List` components also have sliders, but do not generate adjustment events.) See the appropriate section for a description of each component.
>
> There is no real equivalent to `adjustmentValueChanged()` in Java 1.0; to work with scrolling events, you had to override the `handleEvent()` method.

ComponentListener and ComponentAdapter

The `ComponentListener` interface contains four methods that are called when a `ComponentEvent` occurs; component events are used for general actions on components, like moving or resizing a component. The adapter class corresponding to `ComponentListener` is `ComponentAdapter`. If you care only about one or two of the methods in `ComponentListener`, you can subclass the adapter and override only the methods that you are interested in. For an object to listen for component events, it is necessary to call `Component.addComponentListener()` with the class that implements the interface as the parameter.

public abstract void componentResized(ComponentEvent e) ★

> The `componentResized()` method is called when a component is resized (for example, by a call to `Component.setSize()`).

public abstract void componentMoved(ComponentEvent e) ★

> The `componentMoved()` method is called when a component is moved (for example, by a call to `Component.setLocation()`).

public abstract void componentShown(ComponentEvent e) ★

> The `componentShown()` method is called when a component is shown (for example, by a call to `Component.show()`).

public abstract void componentHidden(ComponentEvent e) ★

> The `componentHidden()` method is called when a component is hidden (for example, by a call to `Component.hide()`).

ContainerListener and ContainerAdapter

The `ContainerListener` interface contains two methods that are called when a `ContainerEvent` occurs; container events are generated when components are added to or removed from a container. The adapter class for `ContainerListener` is `ContainerAdapter`. If you care only about one of the two methods in `ContainerListener`, you can subclass the adapter and override only the method that you are interested in. For a container to listen for container events, it is necessary to call `Container.addContainerListener()` with the class that implements the interface as the parameter.

public abstract void componentAdded(ContainerEvent e) ★

> The `componentAdded()` method is called when a component is added to a container (for example, by a call to `Container.add()`).

public abstract void componentRemoved(ContainerEvent e) ★

> The `componentRemoved()` method is called when a component is removed from a container (for example, by a call to `Container.remove()`).

FocusListener and FocusAdapter

The `FocusListener` interface has two methods, which are called when a `FocusEvent` occurs. Its adapter class is `FocusAdapter`. If you care only about one of the methods, you can subclass the adapter and override the method you are interested in. For an object to listen for a `FocusEvent`, it is necessary to call the `Component.addFocusListener()` method with the class that implements the `FocusListener` interface as the parameter.

public abstract void focusGained(FocusEvent e) ★

> The `focusGained()` method is called when a component receives input focus, usually by the user clicking the mouse in the area of the component.
>
> This method is the Java 1.1 equivalent of `Component.gotFocus()` in the Java 1.0 event model.

public abstract void focusLost(FocusEvent e) ★

> The `focusLost()` method is called when a component loses the input focus.
>
> This method is the Java 1.1 equivalent of `Component.lostFocus()` in the Java 1.0 event model.

ItemListener

The `ItemListener` interface contains the one method that is called when an `ItemEvent` occurs. It has no adapter class. For an object to listen for an `ItemEvent`, it is necessary to call `addItemListener()` with the class that implements the `ItemListener` interface as the parameter. The `addItemListener()` method is implemented by the `Checkbox`, `CheckboxMenuItem`, `Choice`, and `List` components. Other components don't generate item events.

public abstract void itemStateChanged(ItemEvent e) ★

> The `itemStateChanged()` method is called when a component's state is modified. Every component is modified differently; for a `List`, modifying the component means single-clicking on an entry. See the appropriate section for a description of each component.

KeyListener and KeyAdapter

The `KeyListener` interface contains three methods that are called when a `KeyEvent` occurs; key events are generated when the user presses or releases keys. The adapter class for `KeyListener` is `KeyAdapter`. If you only care about one or two of the methods in `KeyListener`, you can subclass the adapter and only override the methods that you are interested in. For an object to listen for key events, it is necessary to call `Component.addKeyListener()` with the class that implements the interface as the parameter.

public abstract void keyPressed(KeyEvent e) ★

> The `keyPressed()` method is called when a user presses a key. A key press is, literally, just what it says. A key press event is called for every key that is pressed, including keys like Shift and Control. Therefore, a `KEY_PRESSED` event has a virtual key code identifying the physical key that was pressed; but that's not the same as a typed character, which usually consists of several key presses (for example, Shift+A to type an uppercase A). The `keyTyped()` method reports actual characters.
>
> This method is the Java 1.1 equivalent of `Component.keyDown()` in the Java 1.0 event model.

public abstract void keyReleased(KeyEvent e) ★

> The `keyReleased()` method is called when a user releases a key. Like the `keyPressed()` method, when dealing with `keyReleased()`, you must think of virtual key codes, not characters.
>
> This method is the Java 1.1 equivalent of `Component.keyUp()` in the Java 1.0 event model.

public abstract void keyTyped(KeyEvent e) ★

> The `keyTyped()` method is called when a user types a key. The method `keyTyped()` method reports the actual character typed. Action-oriented keys, like function keys, do not trigger this method being called.

MouseListener and MouseAdapter

The `MouseListener` interface contains five methods that are called when a nonmotion oriented `MouseEvent` occurs; mouse events are generated when the user presses or releases a mouse button. (Separate classes, `MouseMotionListener` and `MouseMotionAdapter`, are used to handle mouse motion events; this means that you can listen for mouse clicks only, without being bothered by thousands of mouse motion events.) The adapter class for `MouseListener` is `MouseAdapter`. If you care about only one or two of the methods in `MouseListener`, you can subclass the adapter and override only the methods that you are interested in. For an object to listen for mouse events, it is necessary to call the method `Window.addWindowListener()` with the class that implements the interface as the parameter.

public abstract void mouseEntered(MouseEvent e) ★

The `mouseEntered()` method is called when the mouse first enters the bounding area of the component.

This method is the Java 1.1 equivalent of `Component.mouseEnter()` in the Java 1.0 event model.

public abstract void mouseExited(MouseEvent e) ★

The `mouseExited()` method is called when the mouse leaves the bounding area of the component.

This method is the Java 1.1 equivalent of `Component.mouseExit()` in the Java 1.0 event model.

public abstract void mousePressed(MouseEvent e) ★

The `mousePressed()` method is called each time the user presses a mouse button within the component's space.

This method is the Java 1.1 equivalent of `Component.mouseDown()` in the Java 1.0 event model.

public abstract void mouseReleased(MouseEvent e) ★

The `mouseReleased()` method is called when the user releases the mouse button after a mouse press. The user does not have to be over the original component any more; the original component (i.e., the component in which the mouse was pressed) is the source of the event.

This method is the Java 1.1 equivalent of `Component.mouseUp()` in the Java 1.0 event model.

public abstract void mouseClicked(MouseEvent e) ★

The `mouseClicked()` method is called once each time the user clicks a mouse button; that is, once for each mouse press/mouse release combination.

MouseMotionListener and MouseMotionAdapter

The `MouseMotionListener` interface contains two methods that are called when a motion-oriented `MouseEvent` occurs; mouse motion events are generated when the user moves the mouse, whether or not a button is pressed. (Separate classes, `MouseListener` and `MouseAdapter`, are used to handle mouse clicks and entering/exiting components. This makes it easy to ignore mouse motion events, which are very frequent and can hurt performance. You should listen only for mouse motion events if you specifically need them.) `MouseMotionAdapter` is the adapter class for `MouseMotionListener`. If you care about only one of the methods in `MouseMotionListener`, you can subclass the adapter and override only the method that you are interested in. For an object to listen for mouse motion events, it is necessary to call `Component.addMouseMotionListener()` with the class that implements the interface as the parameter.

public abstract void mouseMoved(MouseEvent e) ★

The `mouseMoved()` method is called every time the mouse moves within the bounding area of the component, and no mouse button is pressed.

This method is the Java 1.1 equivalent of `Component.mouseMove()` in the Java 1.0 event model.

public abstract void mouseDragged(MouseEvent e) ★

The `mouseDragged()` method is called every time the mouse moves while a mouse button is pressed. The source of the `MouseEvent` is the component that was under the mouse when it was first pressed.

This method is the Java 1.1 equivalent of `Component.mouseDrag()` in the Java 1.0 event model.

TextListener

The `TextListener` interface contains the one method that is called when a `TextEvent` occurs. It has no adapter class. For an object to listen for a `TextEvent`, it is necessary to call `addTextListener()` with the class that implements the `TextListener` interface as the parameter. The `addTextListener()` method is implemented by the `TextComponent` class, and thus the `TextField` and `TextArea` components. Other components don't generate text events.

public abstract void textValueChanged(TextEvent e) ★

The `textValueChanged()` method is called when a text component's contents are modified, either by the user (by a keystroke) or programmatically (by the `setText()` method).

WindowListener and WindowAdapter

The `WindowListener` interface contains seven methods that are called when a `WindowEvent` occurs; window events are generated when something changes the visibility or status of a window. The adapter class for `WindowListener` is `WindowAdapter`. If you care about only one or two of the methods in `WindowListener`, you can subclass the adapter and override only the methods that you are interested in. For an object to listen for window events, it is necessary to call the method `Window.addWindowListener()` or `Dialog.addWindowListener()` with the class that implements the interface as the parameter.

public abstract void windowOpened(WindowEvent e) ★

The `windowOpened()` method is called when a `Window` is first opened.

public abstract void windowClosing(WindowEvent e) ★

The `windowClosing()` method is triggered whenever the user tries to close the `Window`.

public abstract void windowClosed(WindowEvent e) ★

The `windowClosed()` method is called after the `Window` has been closed.

public abstract void windowIconified(WindowEvent e) ★

The `windowIconified()` method is called whenever a user iconifies a `Window`.

public abstract void windowDeiconified(WindowEvent e) ★

The `windowDeiconified()` method is called when the user deiconifies the `Window`.

public abstract void windowActivated(WindowEvent e) ★

The `windowActivated()` method is called whenever a `Window` is brought to the front.

public abstract void windowDeactivated(WindowEvent e) ★

The `windowDeactivated()` method is called when the `Window` is sent away from the front, either through iconification, closing, or another window becoming active.

AWTEventMulticaster

The `AWTEventMulticaster` class is used by AWT to manage the listener queues for the different events, and for sending events to all interested listeners when they occur (multicasting). Ordinarily, you have no need to work with this class or know about its existence. However, if you wish to create your own components that have their own set of listeners, you can use the class instead of implementing your own event-delivery system. See "Constructor methods" in this section for more on how to use the `AWTEventMulticaster`.

`AWTEventMulticaster` looks like a strange beast, and to some extent, it is. It contains methods to add and remove every possible kind of listener and implements all of the listener interfaces (11 as of Java 1.1). Because it implements all the listener interfaces, you can pass an event multicaster as an argument wherever you expect any kind of listener. However, unlike a class you might implement to listen for a specific kind of event, the multicaster includes machinery for maintaining chains of listeners. This explains the rather odd signatures for the `add()` and `remove()` methods. Let's look at one in particular:

```
public static ActionListener add(ActionListener first, ActionListener second)
```

This method takes two `ActionListener`s and returns another `ActionListener`. The returned listener is actually an event multicaster that contains the two listeners given as arguments in a linked list. However, because it implements the `ActionListener` interface, it is just as much an `ActionListener` as any class you might write; the fact that it contains two (or more) listeners inside it is irrelevant. Furthermore, both arguments can also be event multicasters, containing arbitrarily long chains of action listeners; in this case, the returned listener combines the two chains. Most often, you will use add to add a single listener to a chain that you're building, like this:

```
actionListenerChain=AWTEventMulticaster.add(actionListenerChain,
                                            newActionListener);
```

`actionListenerChain` is an `ActionListener`--but it is also a multicaster holding a chain of action listeners. To start a chain, use `null` for the first argument. You rarely need to call the `AWTEventMulticaster` constructor. `add()` is a static method, so you can use it with either argument set to `null` to start the chain.

Now that you can maintain chains of listeners, how do you use them? Simple; just deliver your event to the appropriate method in the chain. The multicaster takes care of sending the event to all the listeners it contains:

```
actionListenerChain.actionPerformed(new ActionEvent(...));
```

Variables

protected EventListener a; ★
protected EventListener b; ★

> The `a` and `b` event listeners each consist of a chain of `EventListeners`.

Constructor methods

protected AWTEventMulticaster(EventListener a, EventListener b) ★

> The constructor is protected. It creates an `AWTEventMulticaster` instance from the two chains of listeners. An instance is automatically created for you when you add your second listener by calling an `add()` method.

Listener methods

These methods implement all of the listener interfaces. Rather than repeating all the descriptions, the methods are just listed.

public void actionPerformed(ActionEvent e) ★
public void adjustmentValueChanged(AdjustmentEvent e) ★
public void componentAdded(ContainerEvent e) ★
public void componentHidden(ComponentEvent e) ★
public void componentMoved(ComponentEvent e) ★
public void componentRemoved(ContainerEvent e) ★
public void componentResized(ComponentEvent e) ★
public void componentShown(ComponentEvent e) ★
public void focusGained(FocusEvent e) ★
public void focusLost(FocusEvent e) ★
public void itemStateChanged(ItemEvent e) ★
public void keyPressed(KeyEvent e) ★
public void keyReleased(KeyEvent e) ★
public void keyTyped(KeyEvent e) ★
public void mouseClicked(MouseEvent e) ★

public void mouseDragged(MouseEvent e) ★
public void mouseEntered(MouseEvent e) ★
public void mouseExited(MouseEvent e) ★
public void mouseMoved(MouseEvent e) ★
public void mousePressed(MouseEvent e) ★
public void mouseReleased(MouseEvent e) ★
public void textValueChanged(TextEvent e) ★
public void windowActivated(WindowEvent e) ★
public void windowClosed(WindowEvent e) ★
public void windowClosing(WindowEvent e) ★
public void windowDeactivated(WindowEvent e) ★
public void windowDeiconified(WindowEvent e) ★
public void windowIconified(WindowEvent e) ★
public void windowOpened(WindowEvent e) ★

> These methods broadcast the event given as an argument to all the listeners.

Support methods

There is an `add()` method for every listener interface. Again, I've listed them with a single description.

public static ActionListener add(ActionListener first, ActionListener second) ★
public static AdjustmentListener add(AdjustmentListener first, AdjustmentListener second) ★
public static ComponentListener add(ComponentListener first, ComponentListener second) ★
public static ContainerListener add(ContainerListener first, ContainerListener second) ★
public static FocusListener add(FocusListener first, FocusListener second) ★
public static ItemListener add(ItemListener first, ItemListener second) ★
public static KeyListener add(KeyListener first, KeyListener second)
public static MouseListener add(MouseListener first, MouseListener second) ★
public static MouseMotionListener add(MouseMotionListener first, MouseMotionListener second) ★
public static TextListener add(TextListener first, TextListener second) ★
public static WindowListener add(WindowListener first, WindowListener second) ★

> These methods combine the listener sets together; they are called by the "add listener" methods of the various components. Usually, the `first` parameter is the initial listener chain, and the `second` parameter is the listener to add. However, nothing forces that. The combined set of listeners is returned.

protected static EventListener addInternal(EventListener first, EventListener second) ★

> The `addInternal()` method is a support routine for the various `add()` methods. The combined set of listeners is returned.

Again, there are `remove()` methods for every listener type, and I've economized on the descriptions.

public static ComponentListener remove(ComponentListener list, ComponentListener oldListener) ★
public static ContainerListener remove(ContainerListener list, ContainerListener oldListener) ★
public static FocusListener remove(FocusListener list, FocusListener oldListener) ★
public static KeyListener remove(KeyListener list, KeyListener oldListener) ★
public static MouseMotionListener remove(MouseMotionListener list, MouseMotionListener oldListener) ★
public static MouseListener remove(MouseListener list, MouseListener oldListener) ★
public static WindowListener remove(WindowListener list, WindowListener oldListener) ★
public static ActionListener remove(ActionListener list, ActionListener oldListener) ★
public static ItemListener remove(ItemListener list, ItemListener oldListener) ★
public static AdjustmentListener remove(AdjustmentListener list, AdjustmentListener oldListener) ★
public static TextListener remove(TextListener list, TextListener oldListener) ★

> These methods remove `oldListener` from the list of listeners, `list`. They are called by the "remove listener" methods of the different components. If `oldListener` is not found in the `list`, nothing happens. All these methods return the new list of listeners.

protected static EventListener removeInternal(EventListener list, EventListener oldListener) ★

> The `removeInternal()` method is a support routine for the various `remove()` methods. It removes `oldListener` from the list of listeners, `list`. Nothing happens if `oldListener` is not found in the `list`. The new set of listeners is returned.

protected EventListener remove(EventListener oldListener) ★

> This `remove()` method removes `oldListener` from the `AWTEventMulticaster`. It is a support routine for `removeInternal()`.

protected void saveInternal(ObjectOutputStream s, String k) throws IOException ★

> The `saveInternal()` method is a support method for serialization.

Using an event multicaster

Example 4.4 shows how to use `AWTEventMulticaster` to create a component that generates `ItemEvents`. The `AWTEventMulticaster` is used in the `addItemListener()` and `removeItemListener()` methods. When it comes time to generate the event in `processEvent()`, the `itemStateChanged()` method is called to notify anyone who might be interested. The item event is generated when a mouse button is clicked; we just count the number of clicks to determine whether an item was selected or deselected. Since we do not have any mouse listeners, we need to enable mouse events with `enableEvents()` in the constructor, as shown in the following example.

Example 4.4: Using an AWTEventMulticaster

```
// Java 1.1 only
import java.awt.*;
import java.awt.event.*;
class ItemEventComponent extends Component implements ItemSelectable {
    boolean selected;
    int i = 0;
    ItemListener itemListener = null;
    ItemEventComponent () {
        enableEvents (AWTEvent.MOUSE_EVENT_MASK);
    }
    public Object[] getSelectedObjects() {
        Object o[] = new Object[1];
        o[0] = new Integer (i);
        return o;
    }
    public void addItemListener (ItemListener l) {
        itemListener = AWTEventMulticaster.add (itemListener, l);
    }
    public void removeItemListener (ItemListener l) {
        itemListener = AWTEventMulticaster.remove (itemListener, l);
    }
    public void processEvent (AWTEvent e) {
        if (e.getID() == MouseEvent.MOUSE_PRESSED) {
            if (itemListener != null) {
                selected = !selected;
                i++;
                itemListener.itemStateChanged (
                    new ItemEvent (this, ItemEvent.ITEM_STATE_CHANGED,
                        getSelectedObjects(),
                        (selected?ItemEvent.SELECTED:ItemEvent.DESELECTED)));
            }
        }
    }
}
public class ItemFrame extends Frame implements ItemListener {
    ItemFrame () {
        super ("Listening In");
        ItemEventComponent c = new ItemEventComponent ();
        add (c, "Center");
        c.addItemListener (this);
        c.setBackground (SystemColor.control);
        setSize (200, 200);
    }
    public void itemStateChanged (ItemEvent e) {
        Object[] o = e.getItemSelectable().getSelectedObjects();
        Integer i = (Integer)o[0];
        System.out.println (i);
    }
    public static void main (String args[]) {
        ItemFrame f = new ItemFrame();
        f.show();
    }
}
```

The `ItemFrame` displays just an `ItemEventComponent` and listens for its item events.

The `EventQueue` class lets you manage Java 1.1 events directly. You don't usually need to manage events yourself; the system takes care of event delivery behind the scene. However, should you need to, you can acquire the system's event queue by calling `Toolkit.getSystemEventQueue()`, peek into the event queue by calling `peekEvent()`, or post new events by calling `postEvent()`. All of these operations may be restricted by the `SecurityManager`. You should not remove the events from the queue (i.e., don't call `getNextEvent()`) unless you really mean to.Constructors

public EventQueue() ★

> This constructor creates an `EventQueue` for those rare times when you need to manage your own queue of events. More frequently, you just work with the system event queue acquired through the `Toolkit`.

Methods

public synchronized AWTEvent peekEvent() ★

> The `peekEvent()` method looks into the event queue and returns the first event, without removing that event. If you modify the event, your modifications are reflected in the event still on the queue. The returned object is an instance of `AWTEvent`. If the queue is empty, `peekEvent()` returns `null`.

public synchronized AWTEvent peekEvent(int id) ★

> This `peekEvent()` method looks into the event queue for the first event of the specified type. `id` is one of the integer constants from an `AWTEvent` subclass or an integer constant of your own. If there are no events of the appropriate type on the queue, `peekEvent()` returns `null`.
>
> Note that a few of the `AWTEvent` classes have both event types and subtypes; `peekEvent()` checks event types only and ignores the subtype. For example, to find an `ItemEvent`, you would call `peekEvent(ITEM_STATE_CHANGED)`. However, a call to `peekEvent(SELECTED)` would return `null`, since `SELECTED` identifies an `ItemEvent` subtype.

public synchronized void postEvent(AWTEvent theEvent) ★

> This version of `postEvent()` puts a new style (Java1.1) event on the event queue.

public synchronized AWTEvent getNextEvent() throws InterruptedException ★

> The `getNextEvent()` method removes an event from the queue. If the queue is empty, the call waits. The object returned is the item taken from the queue; it is either an `Event` or an `AWTEvent`. If the method call is

interrupted, the method getNextEvent() throws an InterruptedException.

5.4 A Simple Calculator

It is always helpful to see complete and somewhat useful examples after learning something new. Example 5.2 shows a working calculator that performs floating point addition, subtraction, multiplication, and division. Figure 5.4 shows the calculator in operation. The button in the lower left corner is a decimal point. This applet uses a number of classes that will be discussed later in the book (most notably, some layout managers and a `Panel`); try to ignore them for now. Focus on the `action()` and `compute()` methods; `action()` figures out which button was pressed, converting it to a digit (0-9 plus the decimal point) or an operator (=, +, -, *, /). As you build a number, it is displayed in the label `lab`, which conveniently serves to store the number in string form. The `compute()` method reads the label's text, converts it to a floating point number, does the computation, and displays the result in the label. The `addButtons()` method is a helper method to create a group of `Button` objects at one time.

Example 5.2: Calculator Source Code

```
import java.awt.*;
import java.applet.*;
public class JavaCalc extends Applet {
    Label lab;
    boolean firstDigit = true;
    float savedValue = 0.0f;     // Initial value
    String operator = "=";  // Initial operator
    public void addButtons (Panel p, String labels) {
        int count = labels.length();
        for (int i=0;i<count;i++)
            p.add (new Button (labels.substring(i,i+1)));
    }
    public void init () {
        setLayout (new BorderLayout());
        add ("North", lab = new Label ("0", Label.RIGHT));
        Panel p = new Panel();
        p.setLayout (new GridLayout (4, 4));
        addButtons (p, "789/");
        addButtons (p, "456*");
        addButtons (p, "123-");
        addButtons (p, ".0=+");
        add ("Center", p);
    }
    public boolean action (Event e, Object o) {
        if (e.target instanceof Button) {
            String s = (String)o;
            if ("0123456789.".indexOf (s) != -1) { // isDigit
                if (firstDigit) {
                    firstDigit = false;
                    lab.setText (s);
                } else {
                    lab.setText (lab.getText() + s);
                }
            } else { // isOperator
                if (!firstDigit) {
                    compute (lab.getText());
                    firstDigit = true;
                }
                operator = s;
            }
            return true;
        }
        return false;
    }
    public void compute (String s) {
        float sValue = new Float (s).floatValue();
        char c = operator.charAt (0);
        switch (c) {
            case '=':   savedValue  = sValue;
                        break;
            case '+':   savedValue += sValue;
                        break;
            case '-':   savedValue -= sValue;
                        break;
            case '*':   savedValue *= sValue;
                        break;
            case '/':   savedValue /= sValue;
                        break;
        }
        lab.setText (String.valueOf(savedValue));
    }
}
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.6 Creating Your Own Component

If you find that no AWT component satisfies your needs, you can create your own. This is usually done either by extending an existing component or by starting from scratch. When extending an existing component, you start with the base functionality of an existing object and add to it. The users will not see anything new or different about the object until they start to interact with it, since it is not a new component. For example, a `TextField` could be subclassed to convert all letters input to uppercase. On the other hand, if you create a new component from scratch, it will appear the same on all platforms (regardless of what the platform's native components look like), and you have to make sure the user can fairly easily figure out how to work with it. Example 5.3 shows how to create your own `Component` by creating a `Label` that displays vertically, as opposed to the standard `Label` `Component` that displays horizontally. The whole process is fairly easy.

The third possibility for creating your own components involves adding functionality to containers. This is fairly easy to do and can be useful if you are constantly grouping components together. For example, if you are always adding a `TextField` or `Label` to go with a `Scrollbar` to display the value, do it once, and call it something meaningful like `LabeledScrollbarPanel`. Then whenever you need it again, reuse your `LabeledScrollbarPanel`. Think about reusability whenever you can.

With Java 1.1, the colors for these new components should be set to color values consistent to the user's platform. This is done through color constants provided in the `SystemColor` class introduced in Chapter 2, *Simple Graphics*.

VerticalLabel

When you create new components, they must meet three requirements:

- In Java 1.0, you must extend a subclass of `Component`, usually `Canvas`. In Java 1.1, you can extend `Component` itself, creating a lightweight component. In many cases, this alternative is more efficient.
- You must provide a constructor for the new component so that you can create new instances of it; if you really don't need a constructor, you can use the default constructor that you inherit from `Canvas` or `Component`.
- You must provide a way to draw the object on the screen by overriding the `paint()` method.

If initializing the component requires information about display characteristics (for example, you need to know the default `Font`), you must wait until the object is displayed on the screen before you initialize it. This is done by overriding the `addNotify()` method. First, call `super.addNotify()` to create the peer; you can now ask for platform-dependent information and initialize your component accordingly. Remember to override `getPreferredSize()` and `getMinimumSize()` (the Java 1.0 names are `preferredSize()` and `minimumSize()`) to return the proper dimensions for the new component, so that layout management works properly. There can be other support methods, depending upon the requirements of the object. For example, it is helpful, but not required, to provide a `toString()` or `paramString()` method.

Creating a new component sounds a lot harder than it is. Example 5.3 contains the source for a new component called `VerticalLabel`. It displays a label that reads from top to bottom, instead of from left to right, and can be configured to display its text right or left justified or centered. Figure 5.5 displays the new component `VerticalLabel` in action.

Example 5.3: Source for VerticalLabel Component

```
import java.awt.*;
public class VerticalLabel extends Canvas {
   public static final int LEFT = 0;
   public static final int CENTER = 1;
   public static final int RIGHT = 2;
   private String text;
   private int    vgap;
   private int    alignment;
   Dimension      mySize;
   int            textLength;
   char           chars[];
   // constructors
   public VerticalLabel () {
        this (null, 0, CENTER);
   }
   public VerticalLabel (String text) {
        this (text, 0, CENTER);
   }
   public VerticalLabel (String text, int vgap, int alignment) {
      this.text = text;
      this.vgap = vgap;
      this.alignment = alignment;
   }
   void init () {
      textLength = text.length();
      chars = new char[textLength];
      text.getChars (0, textLength, chars, 0);
      Font f = getFont();
      FontMetrics fm = getFontMetrics (f);
      mySize = new Dimension(0,0);
      mySize.height = (fm.getHeight() * textLength) + (vgap * 2);
      for (int i=0; i < textLength; i++) {
          mySize.width = Math.max (mySize.width, fm.charsWidth(chars, i, 1));
      }
   }
   public int getAlignment () {
      return alignment;
   }
   public void addNotify () {
       super.addNotify();
       init();  // Component must be visible for init to work
   }
   public void setText (String text)    {this.text = text; init();}
   public String getText ()             {return text; }
   public void setVgap (int vgap)       {this.vgap = vgap; init();}
   public int getVgap ()                {return vgap; }
   public Dimension preferredSize ()    {return mySize; }
   public Dimension minimumSize ()      {return mySize; }
   public void paint (Graphics g) {
      int x,y;
      int xPositions[];
      int yPositions[];
// Must redo this each time since font/screen area might change
// Use actual width for alignment
      Font f = getFont();
      FontMetrics fm = getFontMetrics (f);
      xPositions = new int[textLength];
      for (int i=0; i < textLength; i++) {
         if (alignment == RIGHT) {
            xPositions[i] = size().width - fm.charWidth (chars[i]);
         } else if (alignment == LEFT) {
            xPositions[i] = 0;
         } else {// CENTER
            xPositions[i] = (size().width - fm.charWidth (chars[i])) / 2;
         }
      }
      yPositions = new int[textLength];
      for (int i=0; i < textLength; i++) {
         yPositions[i] = (fm.getHeight() * (i+1)) + vgap;
      }
      for (int i = 0; i < textLength; i++) {
         x = xPositions[i];
         y = yPositions[i];
         g.drawChars (chars, i, 1, x, y);
      }
   }
   protected String paramString () {
      String str=",align=";
      switch (alignment) {
         case LEFT:    str += "left"; break;
         case CENTER:  str += "center"; break;
         case RIGHT:   str += "right"; break;
      }
      if (vgap!=0) str+= ",vgap=" + vgap;
      return super.paramString() + str + ",label=" + text;
   }
}
```

Figure 5.5: Using VerticalLabel

[Graphic: Figure 5-5]

The following code is a simple applet using the `VerticalLabel`. It creates five instances of `VerticalLabel` within a `BorderLayout` panel, with gaps (see Chapter 7, *Layouts* for more on `BorderLayout`). The top and bottom labels are justified to the left and right, respectively, to demonstrate justification.

```
import java.awt.*;
import java.applet.*;
public class vlabels extends Applet {
   public void init () {
        setLayout (new BorderLayout (10, 10));
        setFont (new Font ("TimesRoman", Font.BOLD, 12));
        add ("North",  new VerticalLabel ("One", 10, VerticalLabel.LEFT));
        add ("South",  new VerticalLabel ("Two", 10, VerticalLabel.RIGHT));
        add ("West",   new VerticalLabel ("Three"));
        add ("East",   new VerticalLabel ("Four"));
        add ("Center", new VerticalLabel ("Five"));
        resize (preferredSize());
   }
}
```

Lightweight VerticalLabel

The `VerticalLabel` in Example 5.3 works in both Java 1.0 and 1.1 but is relatively inefficient. When you create one, the system must create a `Canvas` and the peer of the `Canvas`. This work doesn't gain you anything; since this is a new component, it doesn't have to match the native appearance of any other component.

In Java 1.1, there's a way to avoid the overhead if you are creating a component that doesn't have to match a native object. This is called a *lightweight component*. To create one, you just subclass `Component` itself. To make a lightweight version of our `VerticalLabel`, we have to change only one line of code.

```
// Java 1.1 only
public class VerticalLabel extends Component
```

Everything else remains unchanged.

5.7 Cursor

Introduced in Java 1.1, the `Cursor` class provides the different cursors that can be associated with a `Component`. Previously, cursors could only be associated with a whole `Frame`. Now any component can use fancy cursors when the user is interacting with the system.

To change the cursor, a component calls its `setCursor()` method; its argument is a `Cursor` object, which is defined by this class.

NOTE:

There is still no way to assign a user-defined cursor to a `Component`. You are restricted to the 14 predefined cursors.

Cursor Constants

The following is a list of `Cursor` constants. The cursors corresponding to the constants are shown in Figure 5.6.

public final static int DEFAULT_CURSOR
public final static int CROSSHAIR_CURSOR
public final static int TEXT_CURSOR
public final static int WAIT_CURSOR
public final static int HAND_CURSOR
public final static int MOVE_CURSOR
public final static int N_RESIZE_CURSOR
public final static int S_RESIZE_CURSOR
public final static int E_RESIZE_CURSOR
public final static int W_RESIZE_CURSOR
public final static int NE_RESIZE_CURSOR
public final static int NW_RESIZE_CURSOR

public final static int SE_RESIZE_CURSOR
public final static int SW_RESIZE_CURSOR

Figure 5.6: Standard Java cursors

[Graphic: Figure 5-6]

Cursor Methods

public Cursor (int type) ★

The sole constructor creates a `Cursor` of the specified `type`. `type` must be one of the `Cursor` class constants. If `type` is not one of the class constants, the constructor throws the run-time exception `IllegalArgumentException`.

This constructor exists primarily to support object serialization; you don't need to call it in your code. It is more efficient to call `getPredefinedCursor()`, discussed later in this section.

Miscellaneous methods

public int getType() ★

The `getType()` method returns the cursor type. The value returned is one of the class constants.

static public Cursor getPredefinedCursor(int type) ★

The `getPredefinedCursor()` method returns the predefined `Cursor` of the given `type`. If `type` is not one of the class constants, this method throws the run-time exception `IllegalArgumentException`. This method checks what `Cursor` objects already exist and gives you a reference to a preexisting `Cursor` if it can find one with the appropriate type. Otherwise, it creates a new `Cursor` for you. This is more efficient than calling the `Cursor` constructor whenever you need one.

static public Cursor getDefaultCursor() ★

The `getDefaultCursor()` method returns the predefined `Cursor` for the `DEFAULT_CURSOR` type.

PREVIOUS | HOME | NEXT

Creating Your Own Component | BOOK INDEX | Containers

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

6.2 Panel

The `Panel` class provides a generic container within an existing display area. It is the simplest of all the containers. When you load an applet into Netscape Navigator or an *appletviewer*, you have a `Panel` to work with at the highest level.

A `Panel` has no physical appearance. It is just a rectangular display area. The default `LayoutManager` of `Panel` is `FlowLayout`; `FlowLayout` is described in FlowLayout.

Panel Methods

Constructors

public Panel ()

> The first constructor creates a `Panel` with a `LayoutManager` of `FlowLayout`.

public Panel (LayoutManager layout) ★

> This constructor allows you to set the initial `LayoutManager` of the new `Panel` to `layout`. If `layout` is `null`, there is no `LayoutManager`, and you must shape and position the components within the `Panel` yourself.

Miscellaneous methods

public void addNotify ()

> The `addNotify()` method creates the `Panel` peer. If you override this method, first call `super.addNotify()`, then add your customizations for the new class. Then you can do everything you need with the information about the newly created peer.

Panel Events

In Java 1.0, a `Panel` peer generates all the events that are generated by the `Component` class; it does not generate events that are specific to a particular type of component. That is, it generates key events, mouse events, and focus events; it doesn't generate action events or list events. If an event happens within a child component of a `Panel`, the target of the event is the child component, not the `Panel`. There's one exception to this rule: if a component uses the `LightweightPeer` (new to Java 1.1), it cannot be the target of an event.

With Java 1.1, events are delivered to whatever listener is associated with a contained component. The fact that the component is within a `Panel` has no relevance.

PREVIOUS Container | HOME BOOK INDEX | NEXT Insets

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

6.3 Insets

The `Insets` class provides a way to encapsulate the layout margins of the four different sides of a container. The class helps in laying out containers. The `Container` can retrieve their values through the `getInsets()` method, then analyze the settings to position components. The different inset values are measured in pixels. The space reserved by insets can still be used for drawing directly within `paint()`. Also, if the `LayoutManager` associated with the container does not look at the insets, the request will be completely ignored.

Insets Methods

Variables

There are four variables for insets, one for each border.

public int top

> This variable contains the border width in pixels for the top of a container.

public int bottom

> This variable contains the border width in pixels for the bottom of a container.

public int left

> This variable contains the border width in pixels for the left edge of a container.

public int right

> This variable contains the border width in pixels for the right edge of a container.

Constructors

public Insets (int top, int left, int bottom, int right)

> The constructor creates an `Insets` object with `top`, `left`, `bottom`, and `right` being the size of the insets in pixels. If this object was the return object from the `getInsets()` method of a container, these values represent the size of a border inside that container.

Miscellaneous methods

public Object clone ()

> The `clone()` method creates a clone of the `Insets` so the same `Insets` object can be associated with multiple containers.

public boolean equals(Object object) ★

> The `equals()` method defines equality for insets. Two `Insets` objects are equal if the four settings for the different values are equal.

public String toString ()

> The `toString()` method of `Insets` returns the current settings. Using the `new Insets (10, 20, 30, 40)` constructor, the results would be:

```
java.awt.Insets[top=10,left=20,bottom=30,right=40]
```

Insets Example

The following source code demonstrates the use of insets within an applet's `Panel`. The applet displays a button that takes up the entire area of the `Panel`, less the insets, then draws a rectangle around that area. This is shown visually in Figure 6.1. The example demonstrates that if you add components to a container, the `LayoutManager` deals with the insets for you in positioning them. But if you are drawing directly to the `Panel`, you must look at the insets if you want to avoid the requested area within the container.

```
import java.awt.*;
import java.applet.*;
public class myInsets extends Applet {
    public Insets insets () {
        return new Insets (50, 50, 50, 50);
    }
    public void init () {
        setLayout (new BorderLayout ());
        add ("Center", new Button ("Insets"));
    }
    public void paint (Graphics g) {
        Insets i = insets();
        int width  = size().width - i.left - i.right;
        int height = size().height - i.top - i.bottom;
        g.drawRect (i.left-2, i.top-2, width+4, height+4);
        g.drawString ("Insets Example", 25, size().height - 25);
    }
}
```

Figure 6.1: Insets

[Graphic: Figure 6-1]

To change the applet's insets from the default, we override the `insets()` method to return a new `Insets` object, with the new values.

Window

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

6.4 Window

A `Window` is a top-level display area that exists outside the browser or applet area you are working in. It has no adornments, such as the borders, window title, or menu bar that a typical window manager might provide. A `Frame` is a subclass of `Window` that adds these parts (borders, window title). Normally you will work with the children of `Window` and not `Window` directly. However, you might use a `Window` to create your own pop-up menu or some other GUI component that requires its own window and isn't provided by AWT. This technique isn't as necessary in Java 1.1, which has a `PopupMenu` component.

The default `LayoutManager` for `Window` is `BorderLayout`, which is described in BorderLayout.

Window Methods

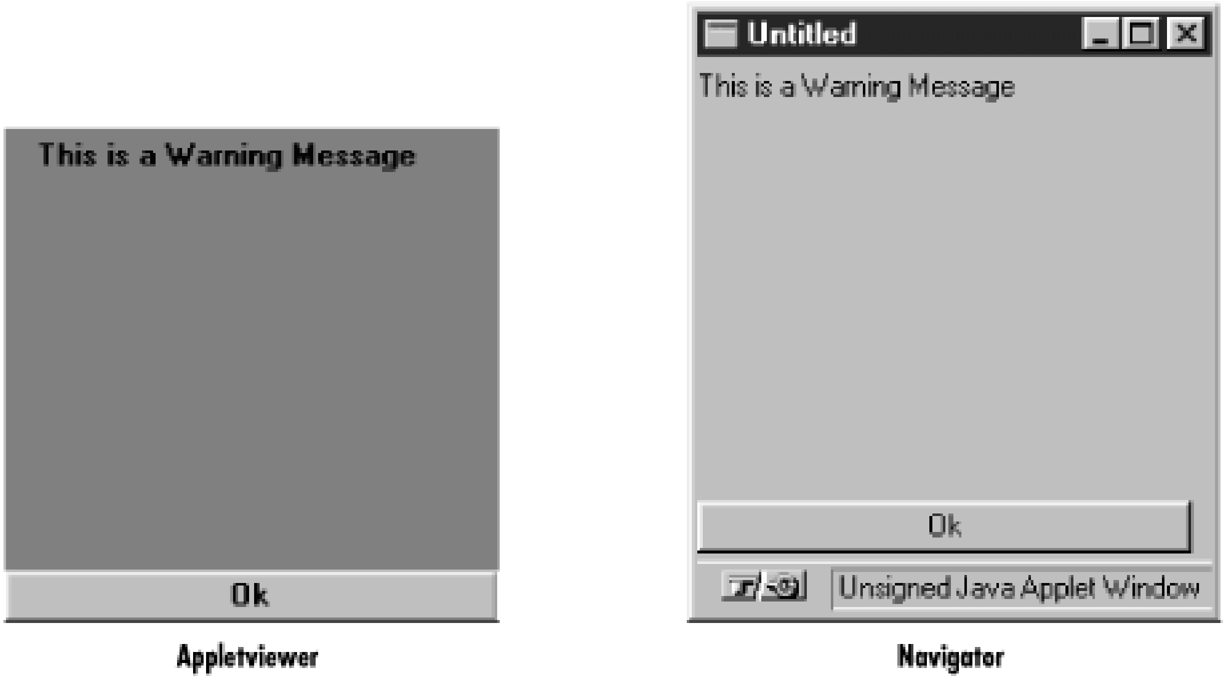
Constructors

public Window (Frame parent)

> There is one public constructor for `Window`. It has one parameter, which specifies the `parent` of the `Window`. When the `parent` is minimized, so is the `Window`. In an application, you must therefore create a `Frame` before you can create a `Window`; this isn't much of an inconvenience since you usually need a `Frame` in which to build your user interface. In an applet, you often do not have access to a `Frame` to use as the parent, so you can pass `null` as the argument.
>
> Figure 6.2 shows a simple `Window` on the left. Notice that there are no borders or window management adornments present. The `Window` on the right was created by an applet loaded over the network. Notice the warning message you get in the status bar at the bottom of the screen. This is to warn users that the `Window` was created by an applet that comes from an untrusted source, and you can't necessarily trust it to do what it says. The warning is particularly appropriate for windows, since a user can't necessarily tell whether a window was created by an applet or any other application. It is therefore possible to write applets that mimic windows from well-known applications, to trick the user into giving away passwords, credit card numbers, or other sensitive

information.

Figure 6.2: Two windows



This is a Warning Message

Appletviewer

Navigator

In some environments, you can get the browser's `Frame` to use with the `Window`'s constructor. This is one way to create a `Dialog`, as we shall see. By repeatedly calling `getParent()` until there are no more parents, you can discover an applet's top-level parent, which should be the browser's `Frame`. Example 6.1 contains the code you would write to do this. You should then check the return value to see if you got a `Frame` or `null`. This code is completely nonportable, but you may happen to be in an environment where it works.

Example 6.1: Finding a Parent Frame

```
import java.awt.*;
public class ComponentUtilities {
    public static Frame getTopLevelParent (Component component) {
        Component c = component;
        while (c.getParent() != null)
            c = c.getParent();
        if (c instanceof Frame)
            return (Frame)c;
        else
            return null;
    }
}
```

Appearance methods

A handful of methods assist with the appearance of the `Window`.

public void pack ()

The `pack()` method resizes the `Window` to the preferred size of the components it contains and validates the `Window`.

public void show ()

The `show()` method displays the `Window`. When a `Window` is initially created it is hidden. If the window is already showing when this method is called, it calls `toFront()` to bring the window to the foreground. To hide the window, just call the `hide()` method of `Component`. After you `show()` a window, it is validated for you.

The first call to `show()` for any `Window` generates a `WindowEvent` with the ID `WINDOW_OPENED`.

public void dispose ()

The `dispose()` method releases the resources of the `Window` by hiding it and removing its peer. Calling this method generates a `WindowEvent` with the ID `WINDOW_CLOSED`.

public void toFront ()

The `toFront()` method brings the `Window` to the foreground of the display. This is automatically called if you call `show()` and the `Window` is already shown.

public void toBack ()

The `toBack()` method puts the `Window` in the background of the display.

public boolean isShowing() ★

The `isShowing()` method returns `true` if the `Window` is visible on the screen.

Miscellaneous methods

public Toolkit getToolkit ()

The `getToolkit()` method returns the current `Toolkit` of the window. The `Toolkit` provides you with information about the native platform. This will allow you to size the `Window` based upon the current screen resolution and get images for an application. See Building a New Component from a Window for a usage example.

public Locale getLocale () ★

The `getLocale()` method retrieves the current `Locale` of the window, if it has one. Using a `Locale` allows you to write programs that can adapt themselves to different languages and different regional variants. If no `Locale` has been set, `getLocale()` returns the default `Locale`. The default `Locale` has a user language of English and no region. To change the default `Locale`, set the system properties `user.language` and `user.region` or call `Locale.setDefault()` (`setDefault()` verifies access rights with the security manager).[1]

[1] For more on the `Locale` class, see the *Java Fundamental Classes Reference* from O'Reilly & Associates.

public final String getWarningString ()

The `getWarningString()` method returns `null` or a string that is displayed on the bottom of insecure `Window` instances. If the `SecurityManager` says that top-level windows do not get a warning message, this method returns `null`. If a message is required, the default text is "Warning: Applet Window". However, Java allows the user to change the warning by setting the system property `awt.appletWarning`. (Netscape Navigator and Internet Explorer do not allow the warning message to be changed. Netscape Navigator's current (V3.0) warning string is "Unsigned Java Applet Window.") The purpose of this string is to warn users that the `Window` was created by an untrusted source, as opposed to a standard application, and should be used with caution.

public Component getFocusOwner () ★

The `getFocusOwner()` method allows you to ask the `Window` which of its components currently has the input focus. This is useful if you are cutting and pasting from the system clipboard; asking who has the input focus tells you where to put the data you get from the clipboard. The system clipboard is covered in Chapter 16, *Data Transfer*. If no component in the `Window` has the focus, `getFocusOwner()` returns `null`.

public synchronized void addNotify ()

The `addNotify()` method creates the `Window` peer. This is automatically done when you call the `show()` method of the `Window`. If you override this method, first call `super.addNotify()`, then add your customizations for the new class. Then you can do everything you need to with the information about the newly created peer.

Window Events

In Java 1.0, a `Window` peer generates all the events that are generated by the `Component` class; it does not generate events that are specific to a particular type of component. That is, it generates key events, mouse events, and focus events; it doesn't generate action events or list events. If an event occurs within a child component of a `Window`, the target of the event is the child component, not the `Window`.

In addition to the `Component` events, five events are specific to windows, none of which are passed on by the window's peer. These events happen at the `Frame` and `Dialog` level. The events are `WINDOW_DESTROY`, `WINDOW_EXPOSE`, `WINDOW_ICONIFY`, `WINDOW_DEICONIFY`, and `WINDOW_MOVED`. The default event handler, `handleEvent()`, doesn't call a convenience method to handle any of these events. If you want to work with them, you must override `handleEvent()`. See Frame Events for an example that catches the `WINDOW_DESTROY` event.

public boolean postEvent (Event e) ☆

The `postEvent()` method tells the `Window` to deal with `Event e`. It calls the `handleEvent()` method, which returns `true` if somebody handled `e` and `false` if no one handles it. This method, which overrides `Component.postEvent()`, is necessary because a `Window` is, by definition, an outermost container, and therefore does not need to post the event to its parent.

Listeners and 1.1 event handling

With the 1.1 event model, you register listeners for different event types; the listeners are told when the event happens. These methods register listeners and let the `Window` component inspect its own events.

public void addWindowListener(WindowListener listener) ★

The `addWindowListener()` method registers `listener` as an object interested in being notified when an `WindowEvent` passes through the `EventQueue` with this `Window` as its target. When such an event occurs, one of the methods in the `WindowListener` interface is called. Multiple listeners can be registered.

public void removeWindowListener(WindowListener listener) ★

The `removeWindowListener()` method removes `listener` as an interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives every `AWTEvent` with this `Window` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `Window`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processWindowEvent(WindowEvent e) ★

The `processWindowEvent()` method receives every `WindowEvent` with this `Window` as its target. `processWindowEvent()` then passes them along to any listeners for processing. When you subclass `Window`, overriding `processWindowEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processWindowEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processWindowEvent()`, you must remember to call `super.processWindowEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

6.5 Frames

The `Frame` is a special type of `Window` that looks like other high level programs in your windowing environment. It adds a `MenuBar`, window title, and window gadgets (like resize, maximize, minimize, window menu) to the basic `Window` object. All the menu-related pieces are discussed in Chapter 10, *Would You Like to Choose from the Menu?*

The default layout manager for a `Frame` is `BorderLayout`.

Frame Constants

The `Frame` class includes a number of constants used to specify cursors. These constants are left over from Java 1.0 and maintained for compatibility. In Java 1.1, you should use the new `Cursor` class, introduced in the previous chapter, and the `Component.setCursor()` method to change the cursor over a frame. Avoid using the `Frame` constants for new code. To see these cursors, refer to Figure 5.6.

public final static int DEFAULT_CURSOR
public final static int CROSSHAIR_CURSOR
public final static int TEXT_CURSOR
public final static int WAIT_CURSOR
public final static int SW_RESIZE_CURSOR
public final static int SE_RESIZE_CURSOR
public final static int NW_RESIZE_CURSOR
public final static int NE_RESIZE_CURSOR
public final static int N_RESIZE_CURSOR
public final static int S_RESIZE_CURSOR
public final static int W_RESIZE_CURSOR
public final static int E_RESIZE_CURSOR
public final static int HAND_CURSOR
public final static int MOVE_CURSOR

NOTE:

HAND_CURSOR and MOVE_CURSOR are not available on Windows platforms with Java 1.0. If you ask to use these and they are not available, you get DEFAULT_CURSOR.

Frame Constructors

public Frame ()

The constructor for Frame creates a hidden window with a window title of "Untitled" (Java1.0) or an empty string (Java1.1). Like Window, the default LayoutManager of a Frame is BorderLayout. DEFAULT_CURSOR is the initial cursor. To position the Frame on the screen, call Component.move(). Since the Frame is initially hidden, you need to call the show() method before the user sees the Frame.

public Frame (String title)

This version of Frame's constructor is identical to the first but sets the window title to title. Figure 6.3 shows the results of a call to new Frame("My Frame") followed by resize() and show().

Figure 6.3: A typical Frame

[Graphic: Figure 6-3]

Frame Methods

public String getTitle ()

The getTitle() method returns the current title for the Frame. If there is no title, this method returns null.

public void setTitle (String title)

The setTitle() method changes the Frame's title to title.

public Image getIconImage ()

The `getIconImage()` method returns the image used as the icon. Initially, this returns `null`. For some platforms, the method should not be used because the platform does not support the concept.

public void setIconImage (Image image)

The `setIconImage()` method changes the image to display when the `Frame` is iconified to `image`. Not all platforms utilize this resource.

public MenuBar getMenuBar ()

The `getMenuBar()` method retrieves the `Frame`'s current menu bar.

public synchronized void setMenuBar (MenuBar bar)

The `setMenuBar()` method changes the menu bar of the `Frame` to `bar`. If `bar` is `null`, it removes the menu bar so that none is available. It is possible to have multiple menu bars based upon the context of the application. However, the same menu bar cannot appear on multiple frames and only one can appear at a time. The `MenuBar` class, and everything to do with menus, is covered in Chapter 10, *Would You Like to Choose from the Menu?*.

public synchronized void remove (MenuComponent component)

The `remove()` method removes `component` from `Frame` if `component` is the frame's menu bar. This is equivalent to calling `setMenuBar()` with a parameter of `null` and in actuality is what `remove()` calls.

public synchronized void dispose ()

The `dispose()` method frees up the system resources used by the `Frame`. If any `Dialogs` or `Windows` are associated with this `Frame`, their resources are freed, too. Some people like to call `Component.hide()` before calling the `dispose()` method so users do not see the frame decomposing.

public boolean isResizable ()

The `isResizable()` method will tell you if the current `Frame` is resizable.

public void setResizable (boolean resizable)

The `setResizable()` method changes the resize state of the `Frame`. A `resizable` value of `true` means the user can resize the `Frame`, `false` means the user cannot. This must be set before the `Frame` is shown or the peer created.

public void setCursor (int cursorType)

The `setCursor()` method changes the cursor of the `Frame` to `cursorType`. `cursorType` must be one of the cursor constants provided with the `Frame` class. You cannot create your own cursor image yet. When changing from the `DEFAULT_CURSOR` to another cursor, the mouse must be moved for the cursor icon to change to the new cursor. If `cursorType` is not one of the predefined cursor types, `setCursor()` throws the `IllegalArgumentException` run-time exception.

This method has been replaced by the `Component.setCursor()` method. Both function equivalently, but this method is being phased out.

public int getCursorType ()

The `getCursorType()` method retrieves the current cursor.

This method has been replaced by the `Component.getCursor()` method. Both function equivalently, but this method is being phased out.

Miscellaneous methods

public synchronized void addNotify ()

The `addNotify()` method creates the `Frame` peer. This is automatically done when you call the `show()` method of the `Frame`. If you override this method, first call `super.addNotify()`, then add your customizations for the new class. Then you can do everything you need to do with the information about the newly created peer.

protected String paramString ()

When you call the `toString()` method of `Frame`, the default `toString()` method of `Component` is called. This in turn calls `paramString()`, which builds up the string to display. At the `Frame` level, `paramString()` appends `resizable` (if `true`) and the `title` (if present). Using the default `Frame` constructor, the results would be:

```
java.awt.Frame[0,0,0x0,invalid,hidden,layout=java.awt.BorderLayout,
resizable,title=]
```

Until the `Frame` is shown, via `show()`, the position and size are not known and therefore appear as zeros. After showing the `Frame`, you might see:

```
java.awt.Frame[44,44,300x300,layout=java.awt.BorderLayout,
resizable,title=]
```

Frame Events

In Java 1.0, a `Frame` peer generates all the events that are generated by the `Component` class; it does not generate events that are specific to a particular type of component. That is, it generates key events, mouse events, and focus events; it doesn't generate action events or list events. If an event happens within a child component of a `Frame`, the target of the event is the child component, not the `Frame`.Window

In addition to the `Component` events, `Frame` generates the `WINDOW` events. These events are `WINDOW_DESTROY`, `WINDOW_EXPOSE`, `WINDOW_ICONIFY`, `WINDOW_DEICONIFY`, and `WINDOW_MOVED`.

One common event, `WINDOW_DESTROY`, is generated when the user tries to close the `Frame` by selecting Quit, Close, or Exit (depending on your windowing environment) from the window manager's menu. By default, this event does nothing. You must provide an event handler that explicitly closes the `Frame`. If you do not, your `Frame` will close only when the Java Virtual Machine exits--for example, when you quit Netscape Navigator. The `handleEvent()` method in the following example, or one like it, should therefore be included in all classes that extend `Frame`. If a `WINDOW_DESTROY` event occurs, it gets rid of the `Frame` and exits the program. Make sure your method calls `super.handleEvent()` to process the other events.

```
public boolean handleEvent (Event e) {
    if (e.id == Event.WINDOW_DESTROY) {
        hide();
        dispose();
        System.exit(0);
        return true;          // boolean method, must return something
    } else {
                              // handle other events we find interesting
    }
                              // make sure normal event processing happens
    return super.handleEvent (e);
}
```

Listeners and 1.1 event handling

With the 1.1 event model, you register listeners for different event types; the listeners are told when the event happens. The `Frame` class inherits all its listener handling from `Window`.

Here's the Java 1.1 code necessary to handle `WINDOW_CLOSING` events; it is equivalent to the `handleEvent()` method in the previous example. First, you must add the following line to the `Frame`'s constructor:

```
enableEvents (AWTEvent.WINDOW_EVENT_MASK);
```

This line guarantees that we will receive window events, even if there is no listener. The `processWindowEvent()` method in the following code does the actual work of closing things down:

```
// Java 1.1 only
protected void processWindowEvent(WindowEvent e) {
    if (e.getID() == WindowEvent.WINDOW_CLOSING) {
        // Notify others we are closing
        if (windowListener != null)
            windowListener.windowClosing(e);
        System.exit(0);
    } else {
        super.processEvent(e);
    }
}
```

If you forget to enable events, `processWindowEvent()` may never be called, and your windows will not shut down until the Java Virtual Machine exits. All subclasses of `Frame` should include code like this to make sure they terminate gracefully.

Building a New Component from a Window

Now that we have discussed the `Frame` and `Window` objects, we can briefly investigate some ways to use them together. Previously I said that you can use a `Window` to build your own pop-up menu. That's no longer necessary in Java 1.1, but the same techniques apply to plenty of other objects. In the following example, we build a set of pop-up buttons; it also uses the `Toolkit` of a `Frame` to load images within an application. The pop-up button set appears when the user presses the right mouse button over the image. It is positioned at the coordinates of the `mouseDown()` event; to do so, we add the current `location()` of the `Frame` to the mouse's `x` and `y` coordinates. Figure 6.4 shows what this application looks like when the pop-up button set is on the screen.

```
import java.awt.*;
public class PopupButtonFrame extends Frame {
    Image im;
    Window w = new PopupWindow (this);
    PopupButtonFrame () {
        super ("PopupButton Example");
        resize (250, 100);
        show();
        im = getToolkit().getImage ("rosey.jpg");
        MediaTracker mt = new MediaTracker (this);
        mt.addImage (im, 0);
        try {
            mt.waitForAll();
        } catch (Exception e) {e.printStackTrace(); }
    }
    public static void main (String args[]) {
        Frame f = new PopupMenuFrame ();
    }
    public void paint (Graphics g) {
        if (im != null)
            g.drawImage (im, 20, 20, this);
    }
    public boolean mouseDown (Event e, int x, int y) {
        if (e.modifiers == Event.META_MASK) {
            w.move (location().x+x, location().y+y);
            w.show();
            return true;
        }
        return false;
    }
}
class PopupWindow extends Window {
    PopupWindow (Frame f) {
        super (f);
        Panel p = new Panel ();
        p.add (new Button ("About"));
        p.add (new Button ("Save"));
        p.add (new Button ("Quit"));
        add ("North", p);
        setBackground (Color.gray);
        pack();
    }
    public boolean action (Event e, Object o) {
        if ("About".equals (o))
            System.out.println ("About");
        else if ("Save".equals (o))
            System.out.println ("Save Me");
        else if ("Quit".equals (o))
            System.exit (0);
        hide();
        return true;
    }
}
```

Figure 6.4: Pop-up buttons

[Graphic: Figure 6-4]

The most interesting method in this application is `mouseDown()`. When the user clicks on the mouse, `mouseDown()` checks whether the `META_MASK` is set in the event modifiers; this indicates that the user pressed the right mouse button, or pressed the left button while pressing the Meta key. If this is `true`, `mouseDown()` moves the window to the location of the mouse click, calls `show()` to display the window, and returns `true` to indicate that the event was handled completely. If `mouseDown` were called with any other kind of mouse event, we return `false` to let the event propagate to any other object that might be interested. Remember that the coordinates passed with the mouse event are the coordinates of the mouse click relative to the `Frame`; to find out where to position the pop-up window, we need an absolute location and therefore ask the `Frame` for its location.

`PopupWindow` itself is a simple class. Its constructor simply creates a display with three buttons. The call to `pack()` sizes the window so that it provides a nice border around the buttons but isn't excessively large; you can change the border by playing with the window's insets if you want, but that usually isn't necessary. The class `PopupWindow` has an `action()` method that is called when the user clicks one of the buttons. When the user clicks on a button, `action()` prints a message and hides the window.

6.6 Dialogs

The `Dialog` class provides a special type of display window that is normally used for pop-up messages or input from the user. It should be associated with a `Frame` (a required parameter for the constructor), and whenever anything happens to this `Frame`, the same thing will happen to the `Dialog`. For instance, if the parent `Frame` is iconified, the `Dialog` disappears until the `Frame` is de-iconified. If the `Frame` is destroyed, so are all the associated dialogs. Figure 6.5 and Figure 6.6 show typical dialog boxes.

In addition to being associated with a `Frame`, `Dialog` is either modeless or modal. A modeless `Dialog` means a user can interact with both the `Frame` and the `Dialog` at the same time. A modal `Dialog` is one that blocks input to the remainder of the application, including the `Frame`, until the `Dialog` box is acted upon. Note that the parent `Frame` is still executing; unlike some windowing systems, Java does not suspend the entire application for a modal `Dialog`. Normally, blocking access would be done to get input from the user or to show a warning message. Example 6.2 shows how to create and use a modal `Dialog` box, as we will see later in the chapter.

Since `Dialog` subclasses `Window`, its default `LayoutManager` is `BorderLayout`.

In applets, when you create a `Dialog`, you need to provide a reference to the browser's `Frame`, not the applet. In order to get this, you can try to go up the container hierarchy of the `Applet` with `getParent()` until it returns `null`. (You cannot specify a null parent as you can with a `Window`.) See Example 6.1 for a utility method to do this. Simple include a line like the following in your applet:

```
Frame top = ComponentUtilities.getTopLevelParent (this);
```

Then pass `top` to the `Dialog` constructor. Another alternative is to create a new `Frame` to associate with your dialog.

Dialog Constructors and Methods

Constructors

If any constructor is passed a `null` parent, the constructor throws the run-time exception `IllegalArgumentException`.

public Dialog (Frame parent) ★

> This constructor creates an instance of `Dialog` with no title and with `parent` as the `Frame` owning it. It is not modal and is initially resizable.

public Dialog (Frame parent, boolean modal) ☆

> This constructor creates an instance of `Dialog` with no title and with `parent` as the `Frame` owning it. If `modal` is `true`, the `Dialog` grabs all the user input of the program until it is closed. If `modal` is `false`, there is no special behavior associated with the `Dialog`. Initially, the `Dialog` will be resizable. This constructor is comment-flagged as deprecated.

public Dialog (Frame parent, String title) ★

> This version of the constructor creates an instance of `Dialog` with `parent` as the `Frame` owning it and a window title of `title`. It is not modal and is initially resizable.

public Dialog (Frame parent, String title, boolean modal)

> This version of the constructor creates an instance of `Dialog` with `parent` as the `Frame` owning it and a window title of `title`. If `mode` is `true`, the `Dialog` grabs all the user input of the program until it is closed. If `modal` is `false`, there is no special behavior associated with the `Dialog`. Initially, the `Dialog` will be resizable.

> **NOTE:**

In some 1.0 versions of Java, modal dialogs were not supported properly. You needed to create some multithreaded contraption that simulated modality. Modal dialogs work properly in 1.1.

Figure 6.5: A Dialog in an application or local applet

[Graphic: Figure 6-5]

Figure 6.6: The same Dialog in an applet that came across the network

[Graphic: Figure 6-6]

Appearance methods

public String getTitle ()

> The `getTitle()` method returns the current title for the `Dialog`. If there is no title for the `Dialog`, `getTitle()` returns `null`.

public void setTitle (String title)

> The `setTitle()` method changes the current title of the `Dialog` to `title`. To turn off any title for the `Dialog`, use `null` for `title`.

public boolean isResizable ()

> The `isResizable()` method tells you if the current `Dialog` is resizable.

public void setResizable (boolean resizable)

The `setResizable()` method changes the resize state of the `Dialog`. A `resizable` value of `true` means the user can resize the `Dialog`, while `false` means the user cannot. This must be set before the `Dialog` is shown or the peer created.

Modal methods

public boolean isModal ()

The `isModal()` method returns the current mode of the `Dialog`. `true` indicates the dialog traps all user input.

public void setModal (boolean mode) ★

The `setModal()` method changes the current mode of the `Dialog` to `mode`. The next time the dialog is displayed via `show()`, it will be modal. If the dialog is currently displayed, `setModal()` has no immediate effect. The change will take place the next time `show()` is called.

public void show () ★

The `show()` method brings the `Dialog` to the front and displays it. If the dialog is modal, `show()` takes care of blocking events so that they don't reach the parent `Frame`.

Miscellaneous methods

public synchronized void addNotify ()

The `addNotify()` method creates the `Dialog` peer. The peer is created automatically when you call the dialog's `show()` method. If you override the method `addNotify()`, first call `super.addNotify()`, then add your customizations for the new class. You will then be able to do everything you need with the information about the newly created peer.

protected String paramString ()

When you call the `toString()` method of `Dialog`, the default `toString()` method of `Component` is called. This in turn calls `paramString()` which builds up the string to display. At the `Dialog` level, `paramString()` appends the current mode (modal/modeless) and title (if present). Using the constructor ``Dialog (top, `Help`, true)``, the results would be as follows:

```
java.awt.Dialog[0,0,0x0,invalid,hidden,layout=java.awt.BorderLayout,
    modal,title=Help]
```

Dialog Events

In Java 1.0, a Dialog peer generates all the events that are generated by the Component class; it does not generate events that are specific to a particular type of component. That is, it generates key events, mouse events, and focus events; it doesn't generate action events or list events. If an event happens within a child component of a Dialog, the target of the event is the child component, not the Dialog.Window

In addition to the Component events, Dialog generates the WINDOW events. These events are WINDOW_DESTROY, WINDOW_EXPOSE, WINDOW_ICONIFY, WINDOW_DEICONIFY, and WINDOW_MOVED. Listeners and 1.1 event handling

With the 1.1 event model, you register listeners for different event types; the listeners are told when the event happens. The Dialog class inherits all its listener handling from Window.

Dialog Example

Example 6.2 demonstrates how a modal Dialog tries to work in Java 1.0. In some windowing systems, "modal" means that the calling application, and sometimes the entire system stops, and input to anything other than the Dialog is blocked. With Java 1.0, a modal Dialog acts only on the parent frame and simply prevents it from getting screen-oriented input by disabling all components within the frame. The Java program as a whole continues to execute.

Example 6.2 displays a Dialog window with username and password fields, and an Okay button. When the user selects the Okay button, a realistic application would validate the username and password; in this case, they are just displayed on a Frame. Since the Frame must wait for the Dialog to finish before looking at the values of the two fields, the Dialog must tell the Frame when it can look. This is done through a custom interface implemented by the parent Frame and invoked by the Dialog in its action method.

Figure 6.7 is the initial Dialog; Figure 6.8 shows the result after you click Okay. Example 6.2 contains the source code.

Figure 6.7: Username and password Dialog

[Graphic: Figure 6-7]

Notice the use of the newly created `DialogHandler` interface when the user selects the Okay button. Also, see how the pre- and post-event-handling methods are separated. All the pre-event processing takes place before the `Dialog` is shown. The post-event processing is called by the `Dialog` through the new `DialogHandler` interface method, `dialogDoer()`. The interface provides a common method name for all your `Dialog` boxes to call.

Figure 6.8: Resulting Frame

[Graphic: Figure 6-8]

Example 6.2: Modal Dialog Usage

```
import java.awt.*;
interface DialogHandler {
    void dialogDoer (Object o);
}
class modeTest extends Dialog {
    TextField user;
    TextField pass;
    modeTest (DialogHandler parent) {
        super ((Frame)parent, "Mode Test", true);
        add ("North", new Label ("Please enter username/password"));
        Panel left = new Panel ();
        left.setLayout (new BorderLayout ());
        left.add ("North", new Label ("Username"));
        left.add ("South", new Label ("Password"));
        add ("West", left);
        Panel right = new Panel ();
        right.setLayout (new BorderLayout ());
        user = new TextField (15);
        pass = new TextField (15);
        pass.setEchoCharacter ('*');
        right.add ("North", user);
        right.add ("South", pass);
        add ("East", right);
        add ("South", new Button ("Okay"));
        resize (250, 125);
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            dispose();
            return true;
        } else if ((e.target instanceof Button) &&
             (e.id == Event.ACTION_EVENT)) {
            ((DialogHandler)getParent ()).dialogDoer(e.arg);
        }
        return super.handleEvent (e);
    }
}
public class modeFrame extends Frame implements DialogHandler {
    modeTest d;
    modeFrame (String s) {
        super (s);
        resize (100, 100);
        d = new modeTest (this);
        d.show ();
    }
    public static void main (String []args) {
        Frame f = new modeFrame ("Frame");
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            hide();
            dispose();
            System.exit (0);
        }
        return super.handleEvent (e);
    }
    public void dialogDoer(Object o) {
        d.dispose();
        add ("North", new Label (d.user.getText()));
        add ("South", new Label (d.pass.getText()));
        show ();
    }
}
```

Since the Java 1.1 modal `Dialog` blocks the calling `Frame` appropriately, the overhead of the `DialogHandler` interface is not necessary and all the work can be combined into the `main()` method, as shown in the following:

```
// only reliable in Java 1.1
import java.awt.*;
class modeTest11 extends Dialog {
    TextField user;
    TextField pass;
    modeTest11 (Frame parent) {
        super (parent, "Mode Test", true);
        add ("North", new Label ("Please enter username/password"));
        Panel left = new Panel ();
        left.setLayout (new BorderLayout ());
        left.add ("North", new Label ("Username"));
        left.add ("South", new Label ("Password"));
        add ("West", left);
        Panel right = new Panel ();
        right.setLayout (new BorderLayout ());
        user = new TextField (15);
        pass = new TextField (15);
        pass.setEchoCharacter ('*');
        right.add ("North", user);
        right.add ("South", pass);
        add ("East", right);
        add ("South", new Button ("Okay"));
        resize (250, 125);
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            dispose();
            return true;
        } else if ((e.target instanceof Button) &&
             (e.id == Event.ACTION_EVENT)) {
            hide();
        }
        return super.handleEvent (e);
    }
}
public class modeFrame11 extends Frame {
    modeFrame11 (String s) {
        super (s);
        resize (100, 100);
    }
    public static void main (String []args) {
        Frame f = new modeFrame11 ("Frame");
        modeTest11 d;
        d = new modeTest11 (f);
        d.show ();
        d.dispose();
        f.add ("North", new Label (d.user.getText()));
        f.add ("South", new Label (d.pass.getText()));
        f.show ();
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            hide();
            dispose();
            System.exit (0);
        }
        return super.handleEvent (e);
    }
}
```

The remainder of the code is virtually identical. The most significant difference is that the dialog's `handleEvent()`method just hides the dialog, rather than calling `DialogHandler.dialogDoer()`.

Frames BOOK INDEX FileDialog

6.7 FileDialog

`FileDialog` is a subclass of `Dialog` that lets the user select files for opening or saving. You must load or save any files yourself. If used in an application or *appletviewer*, the `FileDialog` always looks like the local system's file dialog. The `FileDialog` is always a modal `Dialog`, meaning that the calling program is blocked from continuing (and cannot accept input) until the user responds to the `FileDialog`. Figure 6.9 shows the `FileDialog` component in Motif, Windows NT/95, and the Macintosh.

Unlike the other `Window` subclasses, there is no `LayoutManager` for `FileDialog`, since you are creating the environment's actual file dialog. This means you cannot subclass `FileDialog` to alter its behavior or appearance. However, the class is not "final."

> **NOTE:**

Netscape Navigator throws an `AWTError` when you try to create a `FileDialog` because Navigator does not permit local file system access.

FileDialog Methods

Constants

A `FileDialog` has two modes: one for loading a file (input) and one for saving (output). The following variables provide the mode to the constructor. The `FileDialog` functions the same way in both modes. The only visible difference is whether a button on the screen is labeled Load or Save. You must load or save the requested file yourself. On certain platforms there may be functional differences: in `SAVE` mode, the `FileDialog` may ask if you want to replace a file if it already exists; in `LOAD` mode, the `FileDialog` may not accept a filename that does not exist.

public final static int LOAD

> `LOAD` is the constant for load mode. It is the default mode.

public final static int SAVE

> `SAVE` is the constant for save mode.

Constructors

public FileDialog (Frame parent) ★

The first constructor creates a `FileDialog` for loading with a parent `Frame` of `parent`. The window title is initially empty.

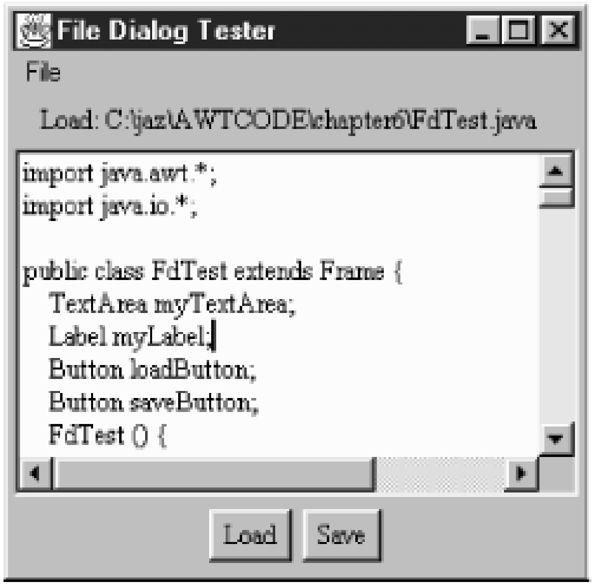
public FileDialog (Frame parent, String title)

This constructor creates a `FileDialog` for loading with a parent `Frame` of `parent`. The window title is `title`.

public FileDialog (Frame parent, String title, int mode)

The final constructor creates a `FileDialog` with an initial mode of `mode`. If `mode` is neither `LOAD` nor `SAVE`, the `FileDialog` is in `SAVE` mode.

Figure 6.9: FileDialogs for Motif, Windows NT/95, and the Macintosh



Load: C:\jaz\AWTCODE\chapter6\FdTest.java

```
import java.awt.*;
import java.io.*;

public class FdTest extends Frame {
    TextArea myTextArea;
    Label myLabel;
    Button loadButton;
    Button saveButton;
    FdTest () {
```

Appearance methods

public String getDirectory ()

`getDirectory()` returns the current directory for the `FileDialog`. Normally, you check this when `FileDialog` returns after a `show()` and a call to `getFile()` returns something other than `null`.

public void setDirectory (String directory)

The `setDirectory()` method changes the initial directory displayed in the `FileDialog` to `directory`. You must call `setDirectory()` prior to displaying the `FileDialog`.

public String getFile ()

The `getFile()` method returns the current file selection from the `FileDialog`. If the user pressed the Cancel button on the `FileDialog`, `getFile()` returns `null`. This is the only way to determine if the user pressed Cancel.

NOTE:

On some platforms in Java 1.0 `getFile()` returns a string that ends in `.*.*` (two periods and two asterisks) if the file does not exist. You need to remove the extra characters before you can create the file.

public void setFile (String file)

The `setFile()` method changes the default file for the `FileDialog` to `file`. Because the `FileDialog` is modal, this must be done before you call `show()`. The string may contain a filename filter like **.java* to show a preliminary list of files to select. This has nothing to do with the use of the `FilenameFilter` class.

public FilenameFilter getFilenameFilter ()

The `getFilenameFilter()` method returns the current `FilenameFilter`. The `FilenameFilter` class is part of the `java.io` package. `FilenameFilter` is an interface that allows you to restrict choices to certain directory and filename combinations. For example, it can be used to limit the user to selecting *.jpg*, *.gif*, and *.xbm* files. The class implementing `FilenameFilter` would not return other possibilities as choices.

public void setFilenameFilter (FilenameFilter filter)

The `setFilenameFilter()` method changes the current filename filter to `filter`. This needs to be done before you `show()` the `FileDialog`.

NOTE:

The JDK does not support the `FilenameFilter` with `FileDialog` boxes. `FilenameFilter` works but can't be used with `FileDialog`.

Miscellaneous methods

public int getMode ()

The `getMode()` method returns the current mode of the `FileDialog`. If an invalid mode was used in the constructor, this method returns an invalid mode here. No error checking is performed.

public void setMode (int mode) ★

The `setMode()` method changes the current mode of the `FileDialog` to `mode`. If `mode` is not one of the class constants `LOAD` or `SAVE`, `setMode()` throws the run-time exception `IllegalArgumentException`.

public synchronized void addNotify ()

The `addNotify()` method creates the `FileDialog` peer. This is automatically done when you call the `show()` method of the `FileDialog`. If you override this method, first call `super.addNotify()`, then add your customizations for the new class. Then you can do everything you need with the information about the newly created peer.

protected String paramString ()

When you call the `toString()` method of `FileDialog`, the default `toString()` method of `Component` is called. This in turn calls `paramString()`, which builds up the string to display. At the `FileDialog` level, `paramString()` appends the directory (if not `null`) and current mode to the return value. Using the constructor `FileDialog(top, `Load Me`)`, the results would be as follows:

```
java.awt.FileDialog[0,0,0x0,invalid,hidden,modal,title=Load Me,load]
```

A FileDialog Example

To get a better grasp of how the `FileDialog` works, the following application uses a `FileDialog` to select a file for display in a `TextArea`. You can also use `FileDialog` to save the file back to disk. Figure 6.10 shows the application, with a file displayed in the text area; the `FileDialog` itself looks like any other file dialog on the run-time system. Example 6.3 shows the code.

CAUTION:

This example can overwrite an existing file.

            if ((curFile = file.getFile()) != null) {
                String filename = file.getDirectory() + curFile;
                // curFile ends in .*.* if file does not exist
                byte[] data;
                setCursor (Frame.WAIT_CURSOR);
                if (state == FileDialog.LOAD) {
                    File f = new File (filename);
                    try {
                        FileInputStream fin = new FileInputStream (f);
                        int filesize = (int)f.length();
                        data = new byte[filesize];
                        fin.read (data, 0, filesize);
                    } catch (FileNotFoundException exc) {
                        String errorString = "File Not Found: " + filename;
                        data = new byte[errorString.length()];
                        errorString.getBytes (0, errorString.length(), data, 0);
                    } catch (IOException exc) {
                        String errorString = "IOException: " + filename;
                        data = new byte[errorString.length()];
                        errorString.getBytes (0, errorString.length(), data, 0);
                    }
                    myLabel.setText ("Load: " + filename);
                } else {
// Remove trailing ".*.*" if present - signifies file does not exist
                    if (filename.indexOf (".*.*") != -1) {
                        filename = filename.substring (0, filename.length()-4);
                    }
                    File f = new File (filename);
                    try {
                        FileOutputStream fon = new FileOutputStream (f);
                        String text = myTextArea.getText();
                        int textsize = text.length();
                        data = new byte[textsize];
                        text.getBytes (0, textsize, data, 0);
                        fon.write (data);
                        fon.close ();
                    } catch (IOException exc) {
                        String errorString = "IOException: " + filename;
                        data = new byte[errorString.length()];
                        errorString.getBytes (0, errorString.length(), data, 0);
                    }
                    myLabel.setText ("Save: " + filename);
                }
                // Note - on successful save, text is redisplayed
                myTextArea.setText (new String (data, 0));
                setCursor (Frame.DEFAULT_CURSOR);
            }
            return true;
        }
        return false;
    }
}
```

Most of this application is one long `action()` method that handles all the action events that take place within the `Frame`. The constructor doesn't do much besides arrange the display; it includes code to create a File menu with one item, Quit. This menu is visible in the upper left corner of the `Frame`; we'll see more about working with menus in Chapter 10, *Would You Like to Choose from the Menu?* We provide a `main()` method to display the `Frame` and a `handleEvent()` method to shut the application down if the event `WINDOW_DESTROY` occurs.

But the heart of this program is clearly its `action()` method. `action()` starts by checking whether the user selected a menu item; if so, it shuts down the application because the only item on our menu is Quit. It then checks whether the user clicked on one of the buttons and sets the `FileDialog` mode to `LOAD` or `SAVE` accordingly. It then sets a default filename, **.java*, which limits the display to filenames ending in *.java*. Next, `action()` shows the dialog. Because file dialogs are modal, `show()` blocks until the user selects a file or clicks Cancel.

The next line detects whether or not `getFile()` returns `null`. A `null` return indicates that the user selected Cancel; in this case, the dialog disappears, but nothing else happens. We then build a complete filename from the directory name and the name the user selected. If the dialog's state is `LOAD`, we read the file and display it in the text area. Otherwise, the dialog's state must be `SAVE`, so we save the contents of the text area under the given filename. Note that we first check for the string `*.*` and remove it if it is present. In Java 1.1, these two lines are unnecessary, but they don't hurt, either.

7.2 FlowLayout

`FlowLayout` is the default `LayoutManager` for a `Panel`. A `FlowLayout` adds components to the container in rows, working from left to right. When it can't fit any more components in a row, it starts a new row--not unlike a word processor with word wrap enabled. When the container gets resized, the components within it get repositioned based on the container's new size. If sufficient space is available, components within `FlowLayout` containers are given their preferred size. If there is insufficient space, you do not see the components in their entirety.

FlowLayout Methods

Constants

`FlowLayout` defines three constants, all of which are used to specify alignment. The alignment tells `FlowLayout` where to start positioning the components on each row. Each component is still added from left to right, no matter what the alignment setting is.

public final static int LEFT

> `LEFT` is the constant for left alignment.

public final static int CENTER

> `CENTER` is the constant for center alignment and is the default.

public final static int RIGHT

> `RIGHT` is the constant for right alignment.

Constructors

public FlowLayout ()

This constructor creates a `FlowLayout` using default settings: center alignment with a horizontal and vertical gap of five pixels. The gap is the space between the different components in the different directions. By default, there will be five pixels between components. The constructor is usually called within a call to `setLayout()`: `setLayout (new FlowLayout())`. Figure 7.1 shows how the default `FlowLayout` behaves with different screen sizes. As the screen C shows, if the screen is too small, the components will *not* be shrunk so that they can fit better.

Figure 7.1: FlowLayout with six buttons and three different screen sizes

[Graphic: Figure 7-1]

public FlowLayout (int alignment)

This version of the constructor creates a `FlowLayout` using the specified `alignment` and a horizontal and vertical gap of five pixels. Valid alignments are the `FlowLayout` constants, although there is no verification. Figure 7.2 shows the effect of different alignments: `FlowLayout.LEFT` (screen A), `FlowLayout.CENTER` (B), and `FlowLayout.RIGHT` (C).

Figure 7.2: FlowLayout with three different alignments

[Graphic: Figure 7-2]

public FlowLayout (int alignment, int hgap, int vgap)

> The final version of the constructor is called by the other two. It requires you to explicitly specify the alignment, horizontal gap (`hgap`), and vertical gap (`vgap`). This creates a `FlowLayout` with an alignment of `alignment`, horizontal gap of `hgap`, and vertical gap of `vgap`. The units for gaps are pixels. It is possible to have negative gaps if you want components to be placed on top of one another. Figure 7.3 shows the effect of changing the gap sizes.

Figure 7.3: FlowLayout with hgap of 0 and vgap of 20

[Graphic: Figure 7-3]

Informational methods

public int getAlignment () ★

> The `getAlignment()` method retrieves the current alignment of the `FlowLayout`. The return value should equal one of the class constants `LEFT`, `CENTER`, or `RIGHT`.

public void setAlignment (int alignment) ★

The `setAlignment()` method changes the `FlowLayout` alignment to `alignment`. The alignment value should equal one of the class constants `LEFT`, `CENTER`, or `RIGHT`, but this method does not check. After changing the alignment, you must `validate()` the `Container`.

public int getHgap () ★

The `getHgap()` method retrieves the current horizontal gap setting.

public void setHgap (int hgap) ★

The `setHgap()` method changes the current horizontal gap setting to `hgap`. After changing the gaps, you must `validate()` the `Container`.

public int getVgap () ★

The `getVgap()` method retrieves the current vertical gap setting.

public void setVgap (int hgap) ★

The `setVgap()` method changes the current vertical gap setting to `vgap`. After changing the gaps, you must `validate()` the `Container`.

LayoutManager methods

public void addLayoutComponent (String name, Component component)

The `addLayoutComponent()` method of `FlowLayout` does nothing.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `FlowLayout` does nothing.

public Dimension preferredLayoutSize (Container target)

The `preferredLayoutSize()` method of `FlowLayout` calculates the preferred dimensions for the `target` container. The `FlowLayout` computes the preferred size by placing all the components in one row and adding their individual preferred sizes along with gaps and insets.

public Dimension minimumLayoutSize (Container target)

The `minimumLayoutSize()` method of `FlowLayout` calculates the minimum dimensions for the container by adding up the sizes of the components. The `FlowLayout` computes the minimum size by placing all the components in one row and adding their individual minimum sizes along with gaps and insets.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s components on the screen, starting with the first row of the display, going left to right across the screen, based on the current alignment setting. When it reaches the right margin of the container, it skips down to the next row, and continues drawing additional components.

Miscellaneous methods

public String toString ()

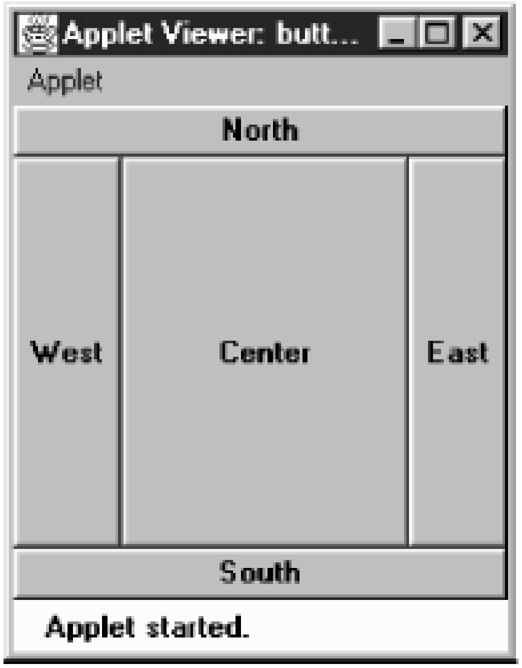
The `toString()` method of `FlowLayout` returns the current horizontal and vertical gap settings along with the alignment (left, center, right). For a `FlowLayout` that uses all the defaults, `toString()` produces:

```
java.awt.FlowLayout[hgap=5,vgap=5,align=center]
```

7.3 BorderLayout

`BorderLayout` is the default `LayoutManager` for a `Window`. It provides a very flexible way of positioning components along the edges of the window. The following call to `setLayout()` changes the `LayoutManager` of the current container to the default `BorderLayout`: `setLayout(new BorderLayout())`. Figure 7.4 shows a typical `BorderLayout`.

Figure 7.4: BorderLayout



Applet started.

`BorderLayout` is the only layout provided that requires you to name components when you add them to the layout; if you're using a `BorderLayout`, you must use `add(String name, Component component)` in Java 1.0 or `add(Component component, String name)` in Java 1.1 (parameter order switched). (The `CardLayout` can use these versions of `add()`, but does not require it.) The `name` parameter of `add()` specifies the region to which the component should be added. The five different regions are "North", "South", "East", and "West" for the edges of the window, and "Center" for any remaining interior space. These names are case sensitive. It is not necessary that a container use all five regions. If a region is not used, it relinquishes its space to the regions around it. If you `add()` multiple objects to a single region, the layout manager only displays the last one. If you want to display multiple objects within a region, group them within a `Panel` first, then `add()` the `Panel`.

NOTE:

In Java 1.1, if you do not provide a name, the component is placed in the "Center" region.

BorderLayout Methods

Constants

Prior to Java 1.1, you had to use string constants to specify the constraints when adding a component to a container whose layout is `BorderLayout`. With Java 1.1, you can use class constants, instead of a literal string, in the following list.

public static final String CENTER ★

The `CENTER` constant represents the "Center" string and indicates that a component should be added to the center region.

public static final String EAST ★

The `EAST` constant represents the "East" string and indicates that a component should be added to the east region.

public static final String NORTH ★

The `NORTH` constant represents the "North" string and indicates that a component should be added to the north region.

public static final String SOUTH ★

The `SOUTH` constant represents the "South" string and indicates that a component should be added to the south region.

public static final String WEST ★

The `WEST` constant represents the "West" string and indicates that a component should be added to the west region.

Constructors

public BorderLayout ()

This constructor creates a `BorderLayout` using a default setting of zero pixels for the horizontal and vertical gaps. The gap specifies the space between adjacent components. With horizontal and vertical gaps of zero, components in adjacent regions will touch each other. As Figure 7.4 shows, each component within a `BorderLayout` will be resized to fill an entire region.

public BorderLayout (int hgap, int vgap)

This version of the constructor allows you to create a `BorderLayout` with a horizontal gap of `hgap` and vertical gap of `vgap`, putting some space between the different components. The units for gaps are pixels. It is possible to have negative gaps if you want components to overlap.

Informational methods

public int getHgap () ★

The `getHgap()` method retrieves the current horizontal gap setting.

public void setHgap (int hgap) ★

The `setHgap()` method changes the current horizontal gap setting to `hgap`. After changing the gaps, you must `validate()` the `Container`.

public int getVgap () ★

The `getVgap()` method retrieves the current vertical gap setting.

public void setVgap (int hgap) ★

The `setVgap()` method changes the current vertical gap setting to `vgap`. After changing the gaps, you must `validate()` the `Container`.

LayoutManager methods

public void addLayoutComponent (String name, Component component) ☆

This version of `addLayoutComponent()` has been deprecated and replaced by the `addLayoutComponent(Component, Object)` method of the `LayoutManager2` interface.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `BorderLayout` removes `component` from the container, if it is in one of the five regions. If `component` is not in the container already, nothing happens.

public Dimension preferredLayoutSize (Container target)

The `preferredLayoutSize()` method of `BorderLayout` calculates the preferred dimensions for the components in `target`. To compute the preferred height, a `BorderLayout` adds the height of the `getPreferredSize()` of the north and south components to the maximum `getPreferredSize()` height of the east, west, and center components. The vertical gaps are added in for the north and south components, if present. The top and bottom insets are also added into the height. To compute the preferred width, a `BorderLayout` adds the width of the `getPreferredSize()` of east, west, and center components, along with the horizontal gap for the east and west regions. It compares this value to the preferred widths of the north and south components. The `BorderLayout` takes the maximum of these three and then adds the left and right insets, plus twice the horizontal gap. The result is the preferred width for the container.

public Dimension minimumLayoutSize (Container target)

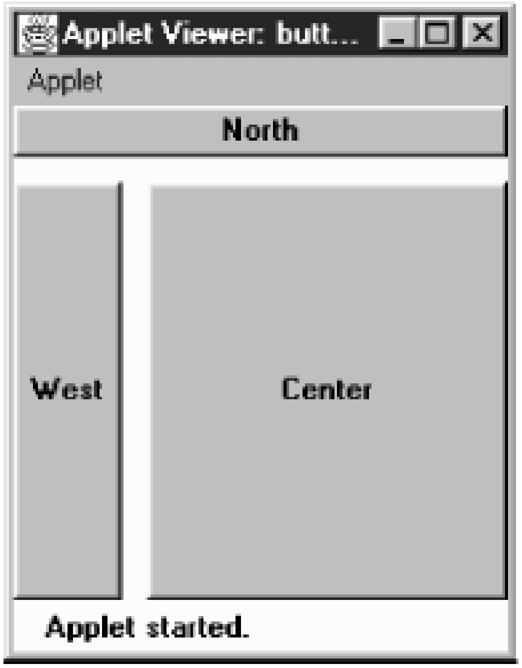
The `minimumLayoutSize()` method of `BorderLayout` calculates the minimum dimensions for the components in `target`. To compute the minimum height, a `BorderLayout` adds the height of the `getMinimumSize()` of the north and south components to the maximum of the minimum heights of the east, west, and center components. The vertical gaps are added in for the north and south components, if present, along with the container's top and bottom insets. To compute the minimum width, a `BorderLayout` adds the width of the `getMinimumSize()` of east, west, and center components, along with the horizontal gap for the east and west regions. The `BorderLayout` takes the maximum of these three and then adds the left and right insets, plus twice the horizontal gap. The result is the minimum width for the container.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s components on the screen in the appropriate regions. The north region takes up the entire width of the container along the top.

South does the same along the bottom. The heights of north and south will be the heights of the components they contain. The east and west regions are given the widths of the components they contain. For height, east and west are given whatever is left in the container after satisfying north's and south's height requirements. If there is any extra vertical space, the east and west components are resized accordingly. Any space left in the middle of the screen is assigned to the center region. If there is insufficient space for all the components, space is allocated according to the following priority: north, south, west, east, and center. Unlike `FlowLayout`, `BorderLayout` reshapes the internal components of the container to fit within their region. Figure 7.5 shows what happens if the east and south regions are not present and the gaps are nonzero.

Figure 7.5: BorderLayout with missing regions



LayoutManager2 methods

public void addLayoutComponent (Component component, Object name) ★

This `addLayoutComponent()` method puts `component` in the `name` region of the container. In Java 1.1, if `name` is null, `component` is added to the center. If the name is not "North", "South", "East", "West", or "Center", the component is added to the container but won't be displayed. Otherwise, it is displayed in the appropriate region.

There can only be one component in any region, so any component already in the named region is removed. To get multiple components in one region of a `BorderLayout`, group the components in another container, and add the container as a whole to the layout.

If `name` is not a `String`, `addLayoutComponent()` throws the run-time exception

`IllegalArgumentException`.

public abstract Dimension maximumLayoutSize(Container target) ★

The `maximumLayoutSize()` method returns a `Dimension` object with a width and height of `Integer.MAX_VALUE`. In effect, this means that `BorderLayout` does not support the concept of maximum size.

public abstract float getLayoutAlignmentX(Container target) ★

The `getLayoutAlignmentX()` method says that `BorderLayout` containers should be centered horizontally within the area available.

public abstract float getLayoutAlignmentY(Container target) ★

The `getLayoutAlignmentY()` method says that `BorderLayout` containers should centered vertically within the area available.

public abstract void invalidateLayout(Container target) ★

The `invalidateLayout()` method of `BorderLayout` does nothing.

Miscellaneous methods

public String toString ()

The `toString()` method of `BorderLayout` returns a string showing the current horizontal and vertical gap settings. If both gaps are zero, the result will be:

```
java.awt.BorderLayout[hgap=0,vgap=0]
```

7.4 GridLayout

The `GridLayout` layout manager is ideal for laying out objects in rows and columns, where each cell in the layout has the same size. Components are added to the layout from left to right, top to bottom. `setLayout(new GridLayout(2,3))` changes the `LayoutManager` of the current container to a 2 row by 3 column `GridLayout`. Figure 7.6 shows an applet using this layout.

Figure 7.6: Applet using GridLayout

[Graphic: Figure 7-6]

GridLayout Methods

Constructors

public GridLayout () ★

> This constructor creates a `GridLayout` initially configured to have one row, an infinite number of columns, and no gaps. A gap is the space between adjacent components in the horizontal or vertical direction. With a gap of zero, components in adjacent cells will have no space between them.

public GridLayout (int rows, int columns)

This constructor creates a `GridLayout` initially configured to be `rows` x `columns` in size. The default setting for horizontal and vertical gaps is zero pixels. The gap is the space between adjacent components in the horizontal and vertical directions. With a gap of zero, components in adjacent cells will have no space between them.

You can set the number of rows or columns to zero; this means that the layout will grow without bounds in that direction. If both `rows` and `columns` are zero, the run-time exception `IllegalArgumentException` will be thrown.

NOTE:

The rows and columns passed to the `GridLayout` constructor are only recommended values. It is possible that the system will pick other values if the number of objects you add to the layout is sufficiently different from the size you requested; for example, you placed nine objects in a six-element grid.

public GridLayout (int rows, int columns, int hgap, int vgap)

This version of the constructor is called by the previous one. It creates a `GridLayout` with an initial configuration of `rows` x `columns`, with a horizontal gap of `hgap` and vertical gap of `vgap`. The gap is the space between the different components in the different directions, measured in pixels. It is possible to have negative gaps if you want components to overlap.

You can set the number of rows or columns to zero; this means that the layout will grow without bounds in that direction. If both `rows` and `columns` are zero, the run-time exception `IllegalArgumentException` will be thrown.

Informational methods

public int getColumns () ★

The `getColumns()` method retrieves the current column setting, which may differ from the number of columns displayed.

public void setColumns (int columns) ★

The `setColumns()` method changes the current column setting to `columns`. After changing the setting, you must `validate()` the `Container`. If you try to set the number of rows and the number of columns to zero, this method throws the run-time exception

`IllegalArgumentException`.

public int getRows () ★

The `getRows()` method retrieves the current row setting; this may differ from the number of rows displayed.

public void setRows (int rows) ★

The `setRows()` method changes the current row setting to `rows`. After changing the setting, you must `validate()` the `Container`. If you try to set the number of rows and the number of columns to zero, this method throws the run-time exception `IllegalArgumentException`.

public int getHgap () ★

The `getHgap()` method retrieves the current horizontal gap setting.

public void setHgap (int hgap) ★

The `setHgap()` method changes the current horizontal gap setting to `hgap`. After changing the gaps, you must `validate()` the `Container`.

public int getVgap () ★

The `getVgap()` method retrieves the current vertical gap setting.

public void setVgap (int hgap) ★

The `setVgap()` method changes the current vertical gap setting to `vgap`. After changing the gaps, you must `validate()` the `Container`.

LayoutManager methods

public void addLayoutComponent (String name, Component component)

The `addLayoutComponent()` method of `GridLayout` does nothing.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `GridLayout` does nothing.

public Dimension preferredLayoutSize (Container target)

The `preferredLayoutSize()` method of `GridLayout` calculates the preferred dimensions for the components in `target`. The preferred size depends on the size of the grid, which may not be the size requested by the constructor; the `GridLayout` treats the constructor's arguments as recommendations and may ignore them if appropriate.

The actual number of rows and columns is based upon the number of components within the `Container`. The `GridLayout` tries to observe the number of rows requested first, calculating the number of columns. If the requested number of rows is nonzero, the number of columns is determined by (# components + rows - 1) / rows. If request is for zero rows, the number of rows to use is determined by a similar formula: (# components + columns - 1) / columns. Table 7.1 demonstrates this calculation. The last entry in this table is of special interest: if you request a 3x3 grid but only place four components in the layout, you get a 2x2 layout as a result. If you do not want to be surprised, size the `GridLayout` based on the number of objects you plan to put into the display.

Table 7.1: GridLayout Row/Column Calculation

Rows	Columns	# Components	Display Rows	Display Columns
0	1	10	10	1
0	2	10	5	2
1	0	10	1	10
2	0	10	2	5
2	3	10	2	5
2	3	20	2	10
3	2	10	3	4
3	3	3	3	1
3	3	4	2	2

Once we know the dimensions of the grid, it's easy to compute the preferred size for the layout. The `GridLayout` takes the maximum height and maximum width of the preferred sizes for all the components in the layout. (Note that the maximum width and maximum height aren't necessarily from the same component.) This becomes the preferred size of each cell within the layout. The preferred size of the layout as a whole is computed using the preferred size of a cell and adding gaps and insets as appropriate.

public Dimension minimumLayoutSize (Container target)

The `minimumLayoutSize()` method of `GridLayout` calculates the minimum dimensions for the components in `target`. First it determines the actual number of rows and columns in the final layout, using the method described previously. The `minimumLayoutSize()` method then determines the widest and tallest `getMinimumSize()` of a component, and this becomes the minimum size of a cell within the layout. The minimum size of the layout as a whole is computed using the minimum size of a cell and adding gaps and insets as appropriate.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s components on the screen in a series of rows and columns. Each component within a `GridLayout` will be the same size, if it is possible. If there is insufficient space for all the components, the size of each is reduced proportionally.

Miscellaneous methods

public String toString ()

The `toString()` method of `GridLayout` returns a string including the current horizontal and vertical gap settings, along with the rows and columns settings. For a `GridLayout` created with 2 rows and 3 columns, the result would be:

```
java.awt.GridLayout[hgap=0,vgap=0,rows=2,cols=3]
```

BorderLayout BOOK INDEX CardLayout

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.5 CardLayout

The CardLayout layout manager is significantly different from the other layouts. Whereas the other layout managers attempt to display all the components within the container at once, a CardLayout displays only one component at a time. (That component could be a Component or another Container.) The result is similar to Netscape Navigator's Property sheets or a tabbed Dialog, without the tabs. You can flip through the cards (components) in the layout in order or jump to a specific card if you know its name. The following call to setLayout() changes the LayoutManager of the current container to CardLayout:

```
lm = new CardLayout();
setLayout (lm);
```

Unlike most other layout managers, CardLayout has a number of instance methods that programs have to call. Therefore, you usually have to retain a reference to the layout manager. In addition, you usually have some other component to control the CardLayout (i.e., select which card to view). Most simply, you could put some buttons in a panel and stick this panel in the north region of a BorderLayout; then make another panel with a CardLayout, and place that in the center. A more complex task would be to build a set of tabs to control the CardLayout.

A CardLayout allows you to assign names to the components it manages. You can use the name to jump to an arbitrary component by calling the manager's show() method. In Java 1.0, naming was optional; you could call add(Component) to put a component in the layout with a null name. A null name meant only that you couldn't flip to the component at will; you could only display the component by calling next() or previous() (or first() or last()), which cycle through all the components in order. In Java 1.1, all components added to a CardLayout must be named.

CardLayout Methods

Constructors

public CardLayout ()

This constructor creates a `CardLayout` using a horizontal and vertical gap of zero pixels. With `CardLayout`, there is no space between components because only one component is visible at a time; think of the gaps as insets.

public CardLayout (int hgap, int vgap)

This version of the constructor allows you to create a `CardLayout` with a horizontal gap of `hgap` and vertical gap of `vgap` to add some space around the outside of the component that is displayed. The units for gaps are pixels. Using negative gaps chops off components at the edges of the container.

Informational methods

public int getHgap () ★

The `getHgap()` method retrieves the current horizontal gap setting.

public void setHgap (int hgap) ★

The `setHgap()` method changes the current horizontal gap setting to `hgap`. After changing the gaps, you must `validate()` the `Container`.

public int getVgap () ★

The `getVgap()` method retrieves the current vertical gap setting.

public void setVgap (int hgap) ★

The `setVgap()` method changes the current vertical gap setting to `vgap`. After changing the gaps, you must `validate()` the `Container`.

LayoutManager methods

public void addLayoutComponent (String name, Component component) ☆

This version of `addLayoutComponent()` has been deprecated and replaced by the `addLayoutComponent(Component, Object)` method of the `LayoutManager2` interface.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `CardLayout` removes `component` from the container. If `component` is not in the container already, nothing happens.

public Dimension preferredLayoutSize (Container target)

The `preferredLayoutSize()` method of `CardLayout` retrieves the preferred size for all the components within it. The `preferredLayoutSize()` method then determines the widest and tallest size of all components (not necessarily from the same one), adds the appropriate insets and gaps, and uses that as the preferred size for the layout.

public Dimension minimumLayoutSize (Container target)

The `minimumLayoutSize()` method of `CardLayout` calculates the minimum size for all the components within it. The `minimumLayoutSize()` method then determines the widest and tallest minimum size of all components (not necessarily from the same one), adds the appropriate insets and gaps, and uses that as the minimum size for the layout.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s visible components one on top of another. Initially, all components are visible. Components do not become invisible until you select one for display, by calling the `first()`, `last()`, `next()`, `previous()`, or `show()` methods. Where possible, `CardLayout` reshapes all components to fit the target container.

LayoutManager2 methods

public void addLayoutComponent (Component component, Object name) ★

This `addLayoutComponent()` method of `CardLayout` puts `component` into an internal table with a key of `name`. The `name` comes from the version of `add()` that has a constraints object as a parameter. The name allows you to refer to the component when you call other card layout methods, like `show()`. If you call the version of `add()` that only takes a `Component` parameter, you cannot call the `show()` method to flip to the specific component.

If `name` is not a `String`, the run-time exception `IllegalArgumentException` is thrown.

public abstract Dimension maximumLayoutSize(Container target) ★

The `maximumLayoutSize()` method returns a `Dimension` object with a width and height of `Integer.MAX_VALUE`. In practice, this means that `CardLayout` doesn't support the concept of maximum size.

public abstract float getLayoutAlignmentX(Container target) ★

The `getLayoutAlignmentX()` method says that `CardLayout` containers should be centered horizontally within the area available.

public abstract float getLayoutAlignmentY(Container target) ★

The `getLayoutAlignmentY()` method says that `CardLayout` containers should be centered vertically within the area available.

public abstract void invalidateLayout(Container target) ★

The `invalidateLayout()` method of `CardLayout` does nothing.

CardLayout methods

This group of methods controls which component the `CardLayout` displays. The `show()` is only usable if you assigned components names when adding them to the container. The others can be used even if the components are unnamed; they cycle through the components in the order in which they were added. All of these methods require the parent `Container` (i.e., the container being managed by this layout manager) as an argument. If the layout manager of the `parent` parameter is anything other than the container using this instance of the `CardLayout`, the method throws the run-time exception `IllegalArgumentException`.

public void first (Container parent)

The `first()` method flips to the initial component in `parent`.

public void next (Container parent)

The `next()` method flips to the following component in `parent`, wrapping back to the beginning if the current component is the last.

public void previous (Container parent)

The `previous()` method flips to the prior component in `parent`, wrapping to the end if the current component is the first.

public void last (Container parent)

The `last()` method flips to the final component in `parent`.

public void show (Container parent, String name)

The `show()` method displays the component in parent that was assigned the given `name` when it was added to the container. If there is no component with `name` contained within `parent`, nothing happens.

Miscellaneous methods

public String toString ()

The `toString()` method of `CardLayout` returns the a string showing the current horizontal and vertical gap settings. The result for a typical `CardLayout` would be:

```
java.awt.CardLayout[hgap=0,vgap=0]
```

CardLayout Example

Figure 7.7 shows a simple `CardLayout`. This layout has three cards that cycle when you make a selection. The first card (A) contains some `Checkbox` items within a `Panel`, the second card (B) contains a single `Button`, and the third (C) contains a `List` and a `Choice` within another `Panel`.

Figure 7.7: Different views of CardLayout

[Graphic: Figure 7-7]

Example 7.1 is the code that generated Figure 7.7.

Example 7.1: The CardExample Class

```
import java.awt.*;
import java.applet.*;
public class CardExample extends Applet {
    CardLayout cl = new CardLayout();
    public void init () {
        String fonts[] = Toolkit.getDefaultToolkit().getFontList();
        setLayout (cl);
        Panel pA = new Panel();
        Panel pC = new Panel ();
        p1.setLayout (new GridLayout (3, 2));
        List l = new List(4, false);
        Choice c = new Choice ();
        for (int i=0;i<fonts.length;i++) {
            pA.add (new Checkbox (fonts[i]));
            l.addItem (fonts[i]);
            c.addItem (fonts[i]);
        }
        pC.add (l);
        pC.add (c);
        add ("One", pA);
        add ("Two", new Button ("Click Here"));
        add ("Three", pC);
    }
    public boolean action (Event e, Object o) {
        cl.next(this);
        return true;
    }
}
```

Each panel within the `CardLayout` has its own layout manager. `Panel` A uses a `GridLayout`; panel C uses its default layout manager, which is a `FlowLayout`. When the user takes any action (i.e., clicking on a checkbox or button, or selecting an item from the `List` or `Choice` components), the system generates a call to `action()`, which calls the `CardLayout`'s `next()` method, thus displaying the next card in the sequence.

PREVIOUS HOME NEXT

GridLayout BOOK INDEX GridBagLayout

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.6 GridBagLayout

The `GridBagLayout` is the most complex and flexible of the standard layout managers. Although it sounds like it should be a subclass of `GridLayout`, it's a different animal entirely. With `GridLayout`, elements are arranged in a rectangular grid, and each element in the container is sized identically (where possible). With `GridBagLayout`, elements can have different sizes and can occupy multiple rows or columns. The position and behavior of each element is specified by an instance of the `GridBagConstraints` class. By properly constraining the elements, you can specify the number of rows and columns an element occupies, which element grows when additional screen real estate is available, and various other restrictions. The actual grid size is based upon the number of components within the `GridBagLayout` and the `GridBagConstraints` of those objects. For example, Figure 7.8 shows a `GridBagLayout` with seven components, arranged on a 3x3 grid. The maximum capacity of a screen using `GridBagLayout` in Java 1.0 is 128 x 128 cells; in Java 1.1, the maximum size is 512 x 512 cells.

Figure 7.8: GridBagLayout with seven components on a 3x3 grid

[Graphic: Figure 7-8]

With the other layout managers, adding a component to the container requires only a call to `add()`. In Java 1.0, the `GridBagLayout` also requires you to call `setConstraints()` to tell the layout manager how to position the component. With Java 1.1, you use the new `add()` method that permits you to pass the component and its constraints in a single method call (`add(Component, Object)`). If no components are added with constraints (thus all using the defaults), the `GridBagLayout` places the components in a single row at the center of the screen and sizes them to their `getPreferredSize()`. This is a nice way to place a single object in the center of the screen without stretching it to take up the available space, as `BorderLayout` does. Figure 7.9 compares the default `GridBagLayout` with a `BorderLayout` displaying the same object in the center region.

Figure 7.9: Centering a component: GridBagLayout vs. BorderLayout

[Graphic: Figure 7-9]

When designing a container that will use `GridBagLayout`, it is easiest to plan what you want on graph paper, and then determine how the constraints should be set. The alternative, adding the components to the layout and then tweaking the constraints until you have something you like, could lead to premature baldness. Seriously, a trial-and-error approach to getting the constraints right will certainly be frustrating and will probably fail. Figure 7.10, using the same `GridBagLayout` used in Figure 7.8, indicates how the layout manager counts cells. The partial code used to create the screen follows in Example 7.2.

Example 7.2: Creating a GridBagLayout

```
public void init() {
    Button b;
    GridBagLayout gb = new GridBagLayout();
    GridBagConstraints gbc = new GridBagConstraints();
    setLayout(gb);
    try {
/* Row One - Three button */
        b = new Button ("One");
        addComponent (this, b, 0, 0, 1, 1,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
        b = new Button ("Two");
        addComponent (this, b, 1, 0, 1, 1,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
        b = new Button ("Three");
        addComponent (this, b, 2, 0, 1, 1,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
/* Row Two - Two buttons */
        b = new Button ("Four");
        addComponent (this, b, 0, 1, 2, 1,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
        b = new Button ("Five");
        addComponent (this, b, 2, 1, 1, 2,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
/* Row Three - Two buttons */
```

```
        b = new Button ("Six");
        addComponent (this, b, 0, 2, 1, 1,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
        b = new Button ("Seven");
        addComponent (this, b, 1, 2, 1, 1,
                GridBagConstraints.NONE, GridBagConstraints.CENTER);
    } catch (Exception e) {
        e.printStackTrace();
    }
}
```

Figure 7.10: How GridBagLayout counts rows and columns

[Graphic: Figure 7-10]

Most of the work in Example 7.2 is done by the helper method `addComponent()`, which creates a set of constraints, applies them to a component, and adds the component to a container. The code for `addComponent()` appears in GridBagConstraints; its signature is:

```
public static void addComponent (Container container, Component component,
        int gridx, int gridy, int gridwidth, int gridheight, int fill,
        int anchor) throws AWTException ;
```

The top left cell in the layout has location (`0,0`). There's nothing very surprising about buttons one, two, three, six, and seven. They occupy a 1x1 area on the layout's 3x3 grid. Button four occupies a 2x1 area; it is placed at location (0,1), and thus occupies this cell plus the cell at (`1,1`). Likewise, button five occupies a 1x2 area, and takes up the cells at (`2,1`) and (`2,2`). The total size of the layout is determined entirely by the components that are placed in it and their constraints.

GridBagLayout Methods

Variables

There are a handful of instance variables for `GridBagLayout`. They are not initialized until the container whose layout is `GridBagLayout` has been validated.

public int columnWidths[]

> The `columnWidths[]` array contains the widths of the components in the row with the most elements. The values of this array are returned by the `getLayoutDimensions()` method. You can access the array directly, but it is not recommended.

public int rowHeights[]

> The `rowHeights[]` array contains the heights of the components in the column with the most elements. The values of this array are returned by the `getLayoutDimensions()` method. You can access the array directly, but it is not recommended.

public double columnWeights[]

> The `columnWeights[]` array contains the `weightx` values of the components in the row with the most elements. The values of this array are returned by the `getLayoutWeights()` method. You can access the array directly, but it is not recommended.

public double rowWeights[]

> The `row Weights[]` array contains the `weighty` values of the components in the column with the most elements. The values of this array are returned by the `getLayoutWeights()` method. You can access the array directly, but it is not recommended.

Constructors

public GridBagLayout ()

> The constructor for `GridBagLayout` creates an instance of `GridBagLayout` with default `GridBagConstraints` behavior. An internal table is used to keep track of the components added to the layout.

LayoutManager methods

public void addLayoutComponent (String name, Component component)

> The `addLayoutComponent()` method of `GridBagLayout` does nothing. This method is not deprecated, unlike the similarly named methods in the other layout managers that implement `LayoutManager2`.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `GridBagLayout` does nothing.

public Dimension preferredLayoutSize (Container target)

The `preferredLayoutSize()` method calculates the preferred dimensions of the components of `target`. Sizing is based on the constraints of the various components. This task is definitely better off left to the computer.

public Dimension minimumLayoutSize (Container target)

The `minimumLayoutSize()` method calculates the minimum dimensions required to position the components of `target`. Sizing is based on the constraints of the various components.

public void layoutContainer (Container target)

The `layoutContainer()` method positions the components within `target` based upon the constraints of each component. If a component's anchor constraints are invalid, `layoutContainer()` throws the run-time exception `IllegalArgumentException`. The process of arranging the components is very complicated and beyond the scope of this book.

LayoutManager2 methods

public void addLayoutComponent (Component component, Object constraints) ★

This `addLayoutComponent()` method of `GridBagLayout` associates the `component` with the given `constraints` object. It calls the `setConstaints()` method.

If `name` is not a `GridBagConstraints`, `addLayoutComponent()` throws the run-time exception `IllegalArgumentException`.

public abstract Dimension maximumLayoutSize(Container target) ★

The `maximumLayoutSize()` method returns a `Dimension` object with a width and height of `Integer.MAX_VALUE`. In practice, this means that `GridBagLayout` doesn't support the concept of maximum size.

public abstract float getLayoutAlignmentX(Container target) ★

The `getLayoutAlignmentX()` method says that `GridBagLayout` containers should be centered horizontally within the area available.

public abstract float getLayoutAlignmentY(Container target) ★

The `getLayoutAlignmentY()` method says that `GridBagLayout` containers should be centered vertically within the area available.

public abstract void invalidateLayout(Container target) ★

The `invalidateLayout()` method of `GridBagLayout` does nothing.

Constraints

public GridBagConstraints getConstraints (Component component)

The `getConstraints()` method returns a clone of the current constraints for `component`. This makes it easier to generate constraints for a component based on another component.

public void setConstraints (Component component, GridBagConstraints constraints)

The `setConstraints()` method changes the `constraints` on `component` to a clone of `constraints`. The system creates a `clone()` of `constraints` so you can change the original constraints without affecting `component`.

Layout

public Point getLayoutOrigin ()

The `getLayoutOrigin()` method returns the origin for the `GridBagLayout`. The origin is the top left point within the container at which the components are drawn. Before the container is validated, `getLayoutOrigin()` returns the `Point` (`0,0`). After validation, `getLayoutOrigin()` returns the actual origin of the layout. The space used by the components within a `GridBagLayout` may not fill the entire container. You can use the results of `getLayoutOrigin()` and `getLayoutDimensions()` to find the layout's actual size and draw a `Rectangle` around the objects.

public int[][] getLayoutDimensions ()

The `getLayoutDimensions()` method returns two one-dimensional arrays as a single two-dimensional array. Index 0 is an array of widths (`columnWidths` instance variable), while index 1 is an array of heights (`rowHeights` instance variable). Until the layout is validated, these will be empty. After validation, the first array contains the widths of the components in the row with the most elements. The second contains the heights of the components in the column with the most elements. For Figure 7.10, the results would be (38, 51, 48) for widths since the first row has three elements and (21, 21, 21) for the heights since the first (and second) column has three elements in it.

public double[][] getLayoutWeights ()

The `getLayoutWeights()` method returns two one-dimensional arrays as a single two-dimensional array. Index 0 is an array of column weights (`columnWeights` instance variable), while index 1 is an array of row weights (`rowWeights` instance variable). Until the layout is validated, these will be empty. After validation, the first dimension contains all the `weightx` values of the components in the row with the most elements. The second dimension contains all the `weighty` values of the components in the column with the most elements. For Figure 7.10, the results would be (0, 0, 0) for `weightx` since the first row has three elements and (0, 0, 0) for `weighty` since the first column has three elements in it.

Miscellaneous methods

public Point location (int x, int y)

The `location()` method returns the `Point` (`0,0`) until the container is validated. After validation, this method returns the grid element under the location (`x`, `y`), where `x` and `y` are in pixels. The results could be used as the `gridx` and `gridy` constraints when adding another component.

public String toString ()

The `toString()` method of `GridBagLayout` returns the name of the class:

```
java.awt.GridBagLayout
```

GridBagConstraints

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.7 GridBagConstraints

GridBagConstraints are the meat behind the GridBagLayout; they specify how to display components. Unlike other layout managers, which have a built-in idea about what to do with their display, the GridBagLayout is a blank slate. The constraints attached to each component tell the layout manager how to build its display.

Every Component added to a GridBagLayout has a GridBagConstraints object associated with it. When an object is first added to the layout, it is given a default set of constraints (described later in this section). Calling setConstraints() (or add(Component, GridBagConstraints)) applies a new set of constraints to the object. Most people create a helper method to make the setConstraints() calls, passing constraint information as parameters. The helper method used in Example 7.2 follows:

```
public static void addComponent (Container container, Component component,
    int gridx, int gridy, int gridwidth, int gridheight, int fill,
    int anchor) throws AWTException {
    LayoutManager lm = container.getLayout();
    if (!(lm instanceof GridBagLayout)) {
        throw new AWTException ("Invalid layout" + lm);
    } else {
        GridBagConstraints gbc = new GridBagConstraints ();
        gbc.gridx = gridx;
        gbc.gridy = gridy;
        gbc.gridwidth = gridwidth;
        gbc.gridheight = gridheight;
        gbc.fill = fill;
        gbc.anchor = anchor;
        ((GridBagLayout)lm).setConstraints(component, gbc);
        container.add (component);
    }
}
```

In Java 1.1, you can make this method slightly cleaner by adding the component and applying the constraints in the same call to add(). To do so, replace the lines calling setConstraints() and add() with this line:

```
        // Java 1.1 only
        container.add(component, gbc);
```

GridBagConstraints Methods

Constants and variables

public int anchor

> The `anchor` specifies the direction in which the component will drift in the event that it is smaller than the space available for it. `CENTER` is the default. Others available are `NORTH`, `SOUTH`, `EAST`, `WEST`, `NORTHEAST`, `NORTHWEST`, `SOUTHEAST`, and `SOUTHWEST`.

public final static int CENTER
public final static int EAST
public final static int NORTH
public final static int NORTHEAST
public final static int NORTHWEST
public final static int SOUTH
public final static int SOUTHEAST
public final static int SOUTHWEST
public final static int WEST

> Constants used to set the `anchor`.

public int fill

> The value of `fill` controls the component's resize policy. If `fill` is `NONE` (the default), the layout manager tries to give the component its preferred size. If `fill` is `VERTICAL`, it resizes in height if additional space is available. If fill is `HORIZONTAL`, it resizes in width. If fill is `BOTH`, the layout manager takes advantage of all the space available in either direction. Figure 7.11 demonstrates `VERTICAL` (A), `HORIZONTAL` (B), and `NONE` (C) values; Figure 7.8 demonstrated the use of `BOTH`.

public final static int NONE
public final static int BOTH
public final static int HORIZONTAL
public final static int VERTICAL

> Constants used to set `fill`.

Figure 7.11: GridBagLayout with fill values of VERTICAL, HORIZONTAL, and NONE

[Graphic: Figure 7-11]

public int gridx
public int gridy

The `gridx` and `gridy` variables specify the grid position where this component will be placed. (`0,0`) specifies the cell at the origin of the screen. Table 7.2 shows the `gridx` and `gridy` values for the screen in Figure 7.8.

It isn't necessary to set `gridx` and `gridy` to a specific location; if you set these fields to `RELATIVE` (the default), the system calculates the location for you. According to the comments in the source code, if `gridx` is `RELATIVE`, the component appears to the right of the last component added to the layout. If `gridy` is `RELATIVE`, the component appears below the last component added to the layout. However, this is misleadingly simple. `RELATIVE` placement works best if you are adding components along a row or a column. In this case, there are four possibilities to consider:

- `gridx` and `gridy` `RELATIVE`: components are placed in one row.
- `gridx` `RELATIVE`, `gridy` constant: components are placed in one row, each to the right of the previous component.
- `gridx` constant, `gridy` `RELATIVE`: components are placed in one column, each below the previous component.
- Varying `gridx` or `gridy` while setting the other field to `RELATIVE` appears to start a new row, placing the component as the first element in the row.

public int gridwidth
public int gridheight

`gridwidth` and `gridheight` set the number of rows (`gridwidth`) and columns (`gridheight`) a particular component occupies. If `gridwidth` or `gridheight` is set to `REMAINDER`, the component will be the last element of the row or column occupying any space that's remaining. Table 7.2 shows the `gridwidth` and `gridheight` values for the screen in Figure 7.8. For the components in the last column, the `gridwidth` values could be `REMAINDER`. Likewise, `gridheight` could be set to `REMAINDER` for the components in the last row.

gridwidth and gridheight may also have the value RELATIVE, which forces the component to be the next to last component in the row or column. Looking back to Figure 7.8: if button six has a gridwidth of RELATIVE, button seven won't appear because button five is the last item in the row, and six is already next to last. If button five has a gridheight of RELATIVE, the layout manager will reserve space below it, so the button can be the next to last item in the column.

public final static int RELATIVE

Constant used for gridx and gridy to request relative placement, and by gridheight and gridwidth to specify the next to last component in a column or row. The behavior of RELATIVE placement can be very counter intuitive; in most cases, you will be better off specifying gridx, gridy, gridheight, and gridwidth explicitly.

public final static int REMAINDER

Constant used for gridwidth and gridheight, to specify that a component should fill the rest of the row or column.

Table 7.2: Demonstrating gridx/gridy/gridwidth/gridheight

Component	**gridx**	**gridy**	**gridwidth**	**gridheight**
One	0	0	1	1
Two	1	0	1	1
Three	2	0	1	1
Four	0	1	2	1
Five	2	1	1	2
Six	0	2	1	1
Seven	1	2	1	3

public Insets insets

The insets field specifies the external padding in pixels around the component (i.e., between the component and the edge of the cell, or cells, allotted to it). An Insets object can specify different padding for the top, bottom, left, and right sides of the component.

public int ipadx
public int ipady

ipadx and ipady specify the internal padding within the component. ipadx specifies the extra space to the right and left of the component (so the minimum width increases by `2*ipadx` pixels). `ipady` specifies the extra space above and below the component (so the minimum height increases by `2*ipady` pixels).

The difference between insets (external padding) and the `ipadx`, `ipady` variables (internal padding) is confusing. The insets don't add space to the component itself; they are external to the component. `ipadx` and `ipady` change the component's minimum size, so they do add space to the component itself.

public double weightx
public double weighty

The `weightx` and `weighty` variables describe how to distribute any additional space within the container. They allow you to control how components grow (or shrink) when the user resizes the container. If `weightx` is 0, the component won't get any additional space available in its row. If one or more components in a row have `weightx` values greater than 0, any extra space is distributed proportionally between them. For example, if one component has a `weightx` value of 1 and the others are all 0, that one component will get all the additional space. If four components in a row each have `weightx` values of 1 and the other components have `weightx` values of 0, the four components each get one quarter of the additional space. `weighty` behaves similarly. Because `weightx` and `weighty` control the distribution of extra space in any row or column, setting either for one component may affect the position of other components.

Constructors

public GridBagConstraints ()

The constructor creates a `GridBagConstraints` object in which all the fields have their default values. These defaults are shown in the Table 7.3.

Table 7.3: GridBagConstraints Defaults.

Variable	**Value**	**Description**
`anchor`	`CENTER`	If the component is smaller than the space available, it will be centered within its region.
`fill`	`NONE`	The component should not resize itself if extra space is available within its region.
`gridx`	`RELATIVE`	The component associated with this constraint will be positioned relative to the last item added. If all components have `gridx` and `gridy` `RELATIVE`, they will be placed in a single row.
`gridy`	`RELATIVE`	The component associated with this constraint will be positioned relative to the last item added.
`gridwidth`	`1`	The component will occupy a single cell within the layout.

`gridheight`	`1`	The component will occupy a single cell within the layout.
`insets`	`0x0x0x0`	No extra space is added around the edges of the component.
`ipadx`	`0`	There is no internal padding for the component.
`ipady`	`0`	There is no internal padding for the component.
`weightx`	`0`	The component will not get any extra space, if it is available.
`weighty`	`0`	The component will not get any extra space, if it is available.

Miscellaneous methods

public Object clone ()

> The `clone()` method creates a clone of the `GridBagConstraints` so the same `GridBagConstraints` object can be associated with multiple components.

GridBagLayout BOOK INDEX Combining Layouts

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

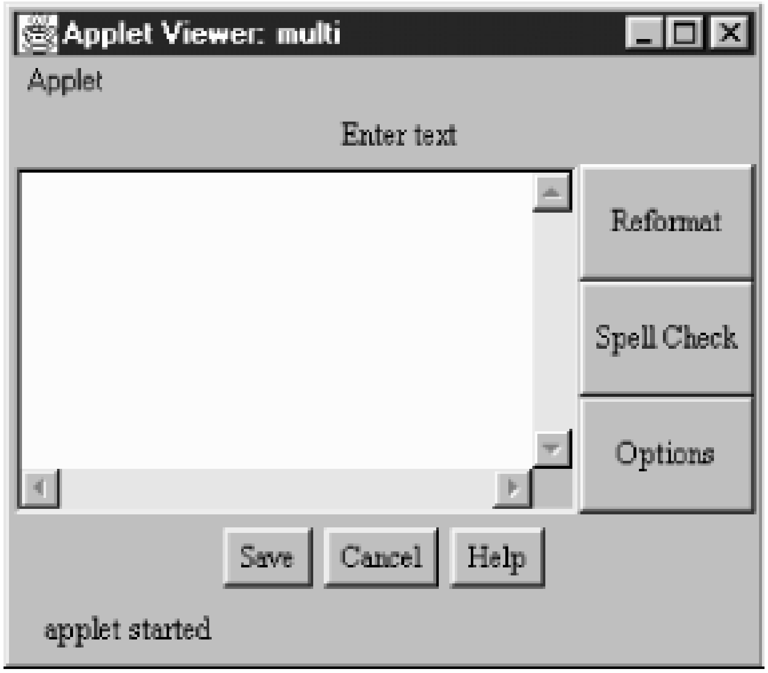
7.8 Combining Layouts

If you can't create the display you want with any of the standard layout managers, or you are unable to figure out `GridBagLayout`, you may want to try combining several different layouts. This technique can often help you build the display you want. Figure 7.12 shows a display that uses three panels and three different layouts.

Here's the source code to generate the display in Figure 7.12:

```
import java.awt.*;
public class multi extends java.applet.Applet {
    public void init() {
        Panel s = new Panel();
        Panel e = new Panel();
        setLayout (new BorderLayout ());
        add ("North", new Label ("Enter text", Label.CENTER));
        add ("Center", new TextArea ());
        e.setLayout (new GridLayout (0,1));
        e.add (new Button ("Reformat"));
        e.add (new Button ("Spell Check"));
        e.add (new Button ("Options"));
        add ("East", e);
        s.setLayout (new FlowLayout ());
        s.add (new Button ("Save"));
        s.add (new Button ("Cancel"));
        s.add (new Button ("Help"));
        add ("South", s);
    }
}
```

Figure 7.12: Multipanel screen using several layouts



The display in Figure 7.12 is created by adding four sections to a single `BorderLayout`. The north region contains a panel with a single `Label` in it. The panel uses its default `LayoutManager`, which is a `FlowLayout`. Why bother with this panel? Why not just add a label at the north position in the `BorderLayout`? Our strategy gives the label the position and size we want: the label is centered and displayed at its preferred size. If we had added the label directly to the `BorderLayout`, it would have been left justified and resized to fill the region.

The `TextArea` has no special requirements, so we added it directly to the center of the `BorderLayout`.

The three buttons on the right of the screen were arranged in a panel with a `GridLayout`; then this panel was placed in the east region of the `BorderLayout`.

To create the buttons at the bottom of the screen, we used another `Panel` with a `FlowLayout`. It centers the three buttons and displays them at their preferred size, with a gap between them.

With a little work, we could have created this display using a single `Panel` with a `GridBagLayout`. The result would have been more efficient; placing panels within panels has performance implications. Each container in the display has its own peer object, which uses up system resources. Furthermore, in the 1.0 version of AWT, nesting containers complicates event handling. However, using a `GridBagLayout` would have required much more work: figuring out the right `GridBagConstraints` for each component would be time consuming and result in code that is harder to understand. Sometimes, it's best to settle for the easy solution: a hybrid layout composed of several simple panels, rather than a single very complex panel.

In Java 1.1, you can make this program even more efficient in its resource usage by using a lightweight component instead of panels. This is particularly easy because the panels in the multipanel screen exist strictly to help with layout and not for partitioning event handling. Therefore, you can define a `LightweightPanel` that extends `Container`, with no methods. Use this class instead of `Panel`. The `LightweightPanel` allows you to lay out areas without creating unnecessary peers. Here's all the code for the `LightweightPanel`:

```
// Java 1.1 only
import java.awt.*;
public class LightweightPanel extends Container {
}
```

7.9 Disabling the LayoutManager

To create a container with no layout manager, use `null` as the argument to `setLayout()`. If you do this, you must size and position every component individually. In most cases, disabling the `LayoutManager` is a bad idea because what might look great on one platform could look really bad on another, due to differences in fonts, native components, and other display characteristics. Figure 7.13 displays a container with a disabled `LayoutManager`; both buttons were positioned by specifying their size and location explicitly.

Figure 7.13: Applet with disabled layout manager

[Graphic: Figure 7-13]

Here's the code that produces Figure 7.13:

```
import java.awt.Button;
import java.applet.Applet;
```

```
public class noLayout extends Applet {
    public void init () {
        setLayout (null);
        Button x = new Button ("Hello");
        add (x);
        x.reshape (50, 60, 50, 70);
        Button y = new Button ("World");
        add (y);
        y.reshape (100, 120, 50, 70);
    }
}
```

Combining Layouts BOOK INDEX Designing Your Own LayoutManager

7.10 Designing Your Own LayoutManager

What if you can't find a `LayoutManager` that fits your requirements, or you find yourself repeatedly building the same multipanel display? In cases like these, you can build your own layout manager. It's really not that difficult; you only need to implement the five methods of the `LayoutManager` interface, plus a constructor and any additional methods your design requires. In this section, we'll review the `LayoutManager` interface and then construct a custom `LayoutManager` called `CornerLayout`.

LayoutManager Methods

A custom `LayoutManager` must implement the following five methods (ten methods if you implement `LayoutManager2`). For many layout managers, several of these methods can be stubs that don't do anything.

public void addLayoutComponent (String name, Component component)

> The `addLayoutComponent()` method is called by the `add(name, component)` method of `Container`. If your new `LayoutManager` does not have named component areas or does not pass generic positioning information via `name`, this method will be a stub with no code; you can let the container keep track of the components for you. Otherwise, this method must keep track of the component added, along with the information in name.
>
> How would you implement this method? For layouts that have named component areas (like `BorderLayout`), you could use a private instance variable to hold the component for each area. For layouts like `CardLayout`, which lets you refer to individual components by name, you might want to store the components and their names in an internal `Hashtable`.

public void removeLayoutComponent (Component component)

> This method is called by the `remove()` and `removeAll()` methods of `Container`. If you are storing information in internal instance variables or tables, you can remove the information about the given `Component` from the tables at this point. If you're not keeping track of the components yourself, this method can be a stub that does nothing.

public Dimension preferredLayoutSize (Container target)

> This method is called by `preferredSize()` to calculate the desired size of `target`.[1] Obviously, the preferred size of the container depends on the layout strategy that you implement. To compute the preferred size,

you usually need to call the `preferredSize()` method of every component in the container.

> [1] This is still true in Java 1.1; the new method, `getPreferredSize()`, just calls the deprecated method, `preferredSize()`.

Computing the preferred size can be messy. However, some layout strategies let you take a shortcut. If your layout policy is "I'm going to cram all the components into the space given to me, whether they fit or not," you can compute the preferred size of your layout simply by calling `target.size()` or (in Java 1.1) `target.getSize()`.

public Dimension minimumLayoutSize (Container target)

This method is called by `minimumSize()` to calculate the minimum size of `target`. The minimum size of the container depends on the layout strategy that you implement. To compute the minimum size, you usually need to call the `minimumSize()` method of every component in the container.

As with `preferredLayoutSize()`, you can sometimes save a lot of work by returning `target.size()`.

public void layoutContainer (Container target)

This method is called when target is first displayed and whenever it is resized. It is responsible for arranging the components within the container. Depending upon the type of `LayoutManager` you are creating, you will either loop through all the components in the container with the `getComponent()` method or use the named components that you saved in the `addLayoutComponent()` method. To position and size the components, call their `reshape()` or `setBounds()` methods.

A New LayoutManager: CornerLayout

`CornerLayout` is a simple but useful layout manager that is similar in many respects to `BorderLayout`. Like `BorderLayout`, it positions components in five named regions: "Northeast", "Northwest", "Southeast", "Southwest", and "Center". These regions correspond to the four corners of the container, plus the center. The "Center" region has three modes. `NORMAL`, the default mode, places the "Center" component in the center of the container, with its corners at the inner corner of the other four regions. `FULL_WIDTH` lets the center region occupy the full width of the container. `FULL_HEIGHT` lets the center region occupy the full height of the container. You cannot specify both `FULL_HEIGHT` and `FULL_WIDTH`; if you did, the "Center" component would overlap the corner components and take over the container. Figure 7.14 shows a `CornerLayout` in each of these modes.

Not all regions are required. If a complete side is missing, the required space for the container decreases. Ordinarily, the other components would grow to fill this vacated space. However, if the container is sized to its preferred size, so are the components. Figure 7.15 shows this behavior.

Figure 7.14: CornerLayout

[Graphic: Figure 7-14]

Figure 7.15: CornerLayout with missing regions

[Graphic: Figure 7-15]

Example 7.3 is the code for the `CornerLayout`. It shows the Java 1.0 version of the layout manager. At the end of this section, I show the simple change needed to adapt this manager to Java 1.1.

Example 7.3: The CornerLayout LayoutManager

```
import java.awt.*;
/**
 * An 'educational' layout. CornerLayout will layout a container
 * using members named "Northeast", "Northwest", "Southeast",
 * "Southwest", and "Center".
 *
 * The "Northeast", "Northwest", "Southeast" and "Southwest" components
 * get sized relative to the adjacent corner's components and
 * the constraints of the container's size. The "Center" component will
 * get any space left over.
 */
public class CornerLayout implements LayoutManager {
    int hgap;
    int vgap;
    int mode;
    public final static int NORMAL = 0;
    public final static int FULL_WIDTH = 1;
    public final static int FULL_HEIGHT = 2;
    Component northwest;
    Component southwest;
    Component northeast;
    Component southeast;
    Component center;
```

The CornerLayout class starts by defining instance variables to hold the gaps and mode and the components for each corner of the screen. It also defines three constants that control the behavior of the center region: NORMAL, FULL_WIDTH, and FULL_HEIGHT.

```
    /**
     * Constructs a new CornerLayout.
     */
    public CornerLayout() {
        this (0, 0, CornerLayout.NORMAL);
    }
    public CornerLayout(int mode) {
        this (0, 0, mode);
    }
    public CornerLayout(int hgap, int vgap) {
        this (hgap, vgap, CornerLayout.NORMAL);
    }
    public CornerLayout(int hgap, int vgap, int mode) {
        this.hgap = hgap;
        this.vgap = vgap;
        this.mode = mode;
    }
```

The constructors for CornerLayout are simple. The default (no arguments) constructor creates a CornerLayout with no gaps; the "Center" region is NORMAL mode. The last constructor, which is called by the other three, stores the gaps and the mode in instance variables.

```
    public void addLayoutComponent (String name, Component comp) {
        if ("Center".equals(name)) {
            center = comp;
        } else if ("Northwest".equals(name)) {
            northwest = comp;
        } else if ("Southeast".equals(name)) {
            southeast = comp;
        } else if ("Northeast".equals(name)) {
            northeast = comp;
        } else if ("Southwest".equals(name)) {
            southwest = comp;
        }
    }
```

addLayoutComponent() figures out which region a component has been assigned to, and saves the component in the corresponding instance variable. If the name of the component isn't "Northeast", "Northwest", Southeast", "Southwest", or "Center", the component is ignored.

```
    public void removeLayoutComponent (Component comp) {
        if (comp == center) {
            center = null;
        } else if (comp == northwest) {
            northwest = null;
        } else if (comp == southeast) {
            southeast = null;
        } else if (comp == northeast) {
            northeast = null;
        } else if (comp == southwest) {
            southwest = null;
        }
    }
```

`removeLayoutComponent()` searches for a given component in each region; if it finds the component, `removeLayoutComponent()` discards it by setting the instance variable to null.

```
    public Dimension minimumLayoutSize (Container target) {
        Dimension dim = new Dimension(0, 0);
        Dimension northeastDim = new Dimension (0,0);
        Dimension northwestDim = new Dimension (0,0);
        Dimension southeastDim = new Dimension (0,0);
        Dimension southwestDim = new Dimension (0,0);
        Dimension centerDim    = new Dimension (0,0);
        if ((northeast != null) && northeast.isVisible ()) {
            northeastDim = northeast.minimumSize ();
        }
        if ((southwest != null) && southwest.isVisible ()) {
            southwestDim = southwest.minimumSize ();
        }
        if ((center != null) && center.isVisible ()) {
            centerDim = center.minimumSize ();
        }
        if ((northwest != null) && northwest.isVisible ()) {
            northwestDim = northwest.minimumSize ();
        }
        if ((southeast != null) && southeast.isVisible ()) {
            southeastDim = southeast.minimumSize ();
        }
        dim.width = Math.max (northwestDim.width, southwestDim.width) +
                        hgap + centerDim.width + hgap +
                        Math.max (northeastDim.width, southeastDim.width);
        dim.height = Math.max (northwestDim.height, northeastDim.height) +
                        + vgap + centerDim.height + vgap +
                        Math.max (southeastDim.height, southwestDim.height);
        Insets insets = target.insets();
        dim.width += insets.left + insets.right;
        dim.height += insets.top + insets.bottom;
        return dim;
    }
```

`minimumLayoutSize()` computes the minimum size of the layout by finding the minimum sizes of all components. To compute the minimum width, `minimumLayoutSize()` adds the width of the center, plus the greater of the widths of the western regions (northwest and southwest), plus the greater of the widths of the eastern regions (northeast and southeast), then adds the appropriate gaps and insets. The minimum height is computed similarly; the method takes the greater of the minimum heights of the northern regions, the greater of the minimum heights of the southern regions, and adds them to the minimum height of the center region, together with the appropriate gaps and insets.

```
    public Dimension preferredLayoutSize (Container target) {
        Dimension dim = new Dimension(0, 0);
        Dimension northeastDim = new Dimension (0,0);
        Dimension northwestDim = new Dimension (0,0);
        Dimension southeastDim = new Dimension (0,0);
        Dimension southwestDim = new Dimension (0,0);
        Dimension centerDim    = new Dimension (0,0);
        if ((northeast != null) && northeast.isVisible ()) {
            northeastDim = northeast.preferredSize ();
        }
        if ((southwest != null) && southwest.isVisible ()) {
            southwestDim = southwest.preferredSize ();
        }
        if ((center != null) && center.isVisible ()) {
            centerDim = center.preferredSize ();
        }
        if ((northwest != null) && northwest.isVisible ()) {
            northwestDim = northwest.preferredSize ();
        }
        if ((southeast != null) && southeast.isVisible ()) {
            southeastDim = southeast.preferredSize ();
        }
        dim.width = Math.max (northwestDim.width, southwestDim.width) +
                        hgap + centerDim.width + hgap +
                        Math.max (northeastDim.width, southeastDim.width);
        dim.height = Math.max (northwestDim.height, northeastDim.height) +
                        + vgap + centerDim.height + vgap +
                        Math.max (southeastDim.height, southwestDim.height);
        Insets insets = target.insets();
        dim.width += insets.left + insets.right;
        dim.height += insets.top + insets.bottom;
        return dim;
    }
```

`preferredLayoutSize()` computes the preferred size of the layout. The method is almost identical to `minimumLayoutSize()`, except that it uses the preferred dimensions of each component.

```
    public void layoutContainer (Container target) {
        Insets insets = target.insets();
        int top = insets.top;
        int bottom = target.size ().height - insets.bottom;
        int left = insets.left;
        int right = target.size ().width - insets.right;
        Dimension northeastDim = new Dimension (0,0);
        Dimension northwestDim = new Dimension (0,0);
        Dimension southeastDim = new Dimension (0,0);
        Dimension southwestDim = new Dimension (0,0);
        Dimension centerDim    = new Dimension (0,0);
        Point topLeftCorner, topRightCorner, bottomLeftCorner,
                        bottomRightCorner;
        if ((northeast != null) && northeast.isVisible ()) {
            northeastDim = northeast.preferredSize ();
        }
        if ((southwest != null) && southwest.isVisible ()) {
            southwestDim = southwest.preferredSize ();
        }
        if ((center != null) && center.isVisible ()) {
            centerDim = center.preferredSize ();
        }
        if ((northwest != null) && northwest.isVisible ()) {
            northwestDim = northwest.preferredSize ();
        }
        if ((southeast != null) && southeast.isVisible ()) {
            southeastDim = southeast.preferredSize ();
        }
        topLeftCorner = new Point (left +
                          Math.max (northwestDim.width, southwestDim.width),
                          top +
                          Math.max (northwestDim.height, northeastDim.height));
        topRightCorner = new Point (right -
                          Math.max (northeastDim.width, southeastDim.width),
                          top +
                          Math.max (northwestDim.height, northeastDim.height));
        bottomLeftCorner = new Point (left +
                          Math.max (northwestDim.width, southwestDim.width),
                          bottom -
                          Math.max (southwestDim.height, southeastDim.height));
        bottomRightCorner = new Point (right  -
                          Math.max (northeastDim.width, southeastDim.width),
                          bottom -
                          Math.max (southwestDim.height, southeastDim.height));
        if ((northwest != null) && northwest.isVisible ()) {
            northwest.reshape (left, top,
                                left + topLeftCorner.x,
                                top + topLeftCorner.y);
        }
        if ((southwest != null) && southwest.isVisible ()) {
            southwest.reshape (left, bottomLeftCorner.y,
                                bottomLeftCorner.x - left,
                                bottom - bottomLeftCorner.y);
       }
```

```
        if ((southeast != null) && southeast.isVisible ()) {
            southeast.reshape (bottomRightCorner.x,
                        bottomRightCorner.y,
                        right - bottomRightCorner.x,
                        bottom - bottomRightCorner.y);
        }
        if ((northeast != null) && northeast.isVisible ()) {
            northeast.reshape (topRightCorner.x, top,
                                right - topRightCorner.x,
                                topRightCorner.y);
        }
        if ((center != null) && center.isVisible ()) {
            int x = topLeftCorner.x + hgap;
            int y = topLeftCorner.y + vgap;
            int width = bottomRightCorner.x - topLeftCorner.x - hgap * 2;
            int height = bottomRightCorner.y - topLeftCorner.y - vgap * 2;
            if (mode == CornerLayout.FULL_WIDTH) {
                x = left;
                width = right - left;
            } else if (mode == CornerLayout.FULL_HEIGHT) {
                y = top;
                height = bottom - top;
            }
            center.reshape (x, y, width, height);
        }
    }
```

`layoutContainer()` does the real work: it positions and sizes the components in our layout. It starts by computing the region of the target container that we have to work with, which is essentially the size of the container minus the insets. The boundaries of the working area are stored in the variables `top`, `bottom`, `left`, and `right`. Next, we get the preferred sizes of all visible components and use them to compute the corners of the "Center" region; these are stored in the variables `topLeftCorner`, `topRightCorner`, `bottomLeftCorner`, and `bottomRightCorner`.

Once we've computed the location of the "Center" region, we can start placing the components in their respective corners. To do so, we simply check whether the component is visible; if it is, we call its `reshape()` method. After dealing with the corner components, we place the "Center" component, taking into account any gaps (`hgap` and `vgap`) and the layout's mode. If the mode is `NORMAL`, the center component occupies the region between the inner corners of the other components. If the mode is `FULL_HEIGHT`, it occupies the full height of the screen. If it is `FULL_WIDTH`, it occupies the full width of the screen.

```
    public String toString() {
        Sting str;
        switch (mode) {
            case FULL_HEIGHT: str = "tall"; break;
            case FULL_WIDTH: str = "wide"; break;
            default: str = "normal"; break;
        }
        return getClass().getName () + "[hgap=" + hgap + ",vgap=" + vgap +
            ",mode="+str+"]";
    }
```

```
}
```

`toString()` simply returns a string describing the layout.

Strictly speaking, there's no reason to update the `CornerLayout` for Java 1.1. Nothing about Java 1.1 says that new layout managers have to implement the `LayoutManager2` interface. However, implementing `LayoutManager2` isn't a bad idea, particularly since `CornerLayout` works with constraints; like `BorderLayout`, it has named regions. To extend `CornerLayout` so that it implements `LayoutManager2`, add the following code; we'll create a new `CornerLayout2`:

```
// Java 1.1 only
import java.awt.*;
public class CornerLayout2 extends CornerLayout implements LayoutManager2 {
    public void addLayoutComponent(Component comp, Object constraints) {
        if ((constraints == null) || (constraints instanceof String)) {
            addLayoutComponent((String)constraints, comp);
        } else {
            throw new IllegalArgumentException(
                  "cannot add to layout: constraint must be a string (or null)");
        }
    }
    public Dimension maximumLayoutSize(Container target) {
        return new Dimension(Integer.MAX_VALUE, Integer.MAX_VALUE);
    }
    public float getLayoutAlignmentX(Container parent) {
        return Component.CENTER_ALIGNMENT;
    }
    public float getLayoutAlignmentY(Container parent) {
        return Component.CENTER_ALIGNMENT;
    }
    public void invalidateLayout(Container target) {
    }
}
```

The sun.awt Layout Collection

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

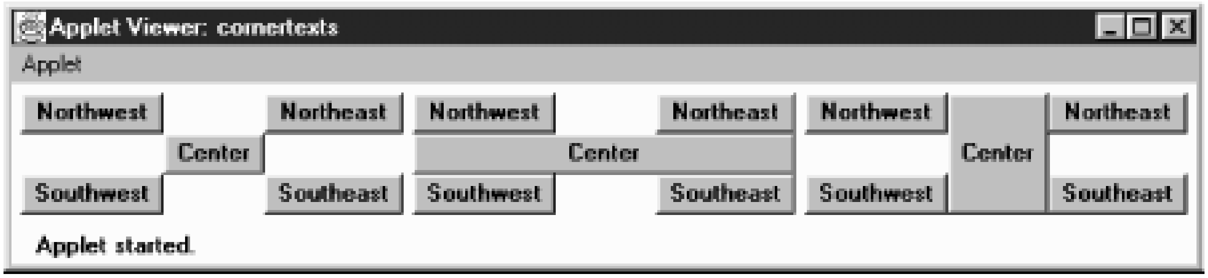
7.11 The sun.awt Layout Collection

The `sun.awt` package defines four additional layouts. The first two, `HorizBagLayout` and `VerticalBagLayout`, are available only when used with Sun's JDK or Internet Explorer, since they are not provided with Netscape Navigator and may not be available from other vendors. Therefore, these layout managers should be used selectively within applets. The third layout manager, `VariableGridLayout`, is available with Netscape Navigator 2.0 or 3.0 and Internet Explorer. Usage of this layout manager is safer within applets but is still at your own risk. The final layout manager is introduced in Java 1.1, `OrientableFlowLayout`. Only time will tell where that one will be available. Any of these layout managers could be moved into a future version of `java.awt` if there is enough interest.

HorizBagLayout

In a `HorizBagLayout`, the components are all arranged in a single row, from left to right. The height of each component is the height of the container; the width of each component is its preferred width. Figure 7.16 shows `HorizBagLayout` in use.

Figure 7.16: HorizBagLayout



Applet started.

Constructors

public HorizBagLayout ()

This constructor creates a `HorizBagLayout` with a horizontal gap of zero pixels. The gap is the space between the different components in the horizontal direction.

public HorizBagLayout (int hgap)

This constructor creates a `HorizBagLayout` using a horizontal gap of `hgap` pixels.

LayoutManager methods

public void addLayoutComponent (String name, Component component)

The `addLayoutComponent()` method of `HorizBagLayout` does nothing.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `HorizBagLayout` does nothing.

public Dimension preferredLayoutSize (Container target)

The `preferredLayoutSize()` method of `HorizBagLayout` sums up the preferred widths of all the components in `target`, along with the `hgap` and right and left insets to get the width of the `target`. The height returned will be the preferred height of the tallest component.

public Dimension minimumLayoutSize (Container target)

The `minimumLayoutSize()` method of `HorizBagLayout` sums up the minimum widths of all the components in `target`, along with the `hgap` and right and left insets to get the width of the `target`. The height returned will be the minimum height of the tallest component.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s components on the screen in one row. The height of each component is the height of the container. Each component's width is its preferred width, if enough space is available.

Miscellaneous methods

public String toString ()

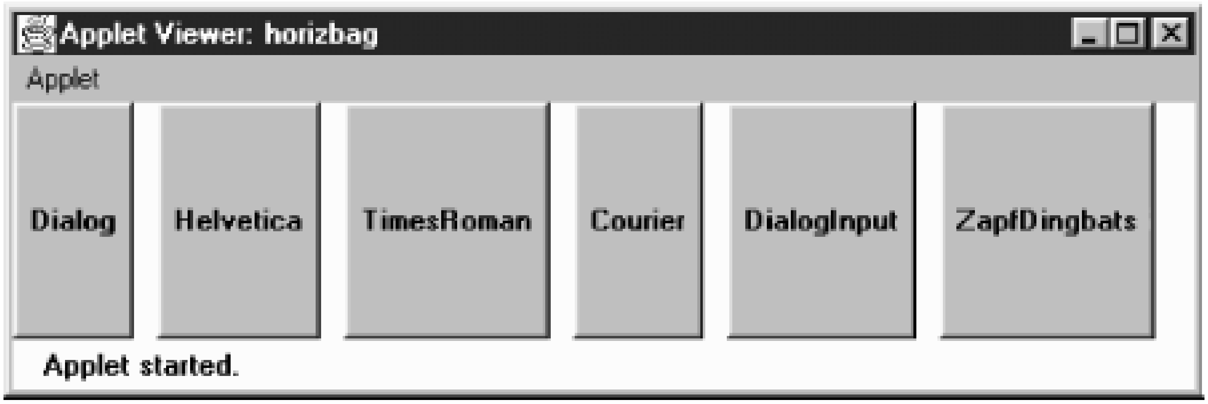
The `toString()` method of `HorizBagLayout` returns a string with the current horizontal gap setting--for example:

```
sun.awt.HorizBagLayout[hgap=0]
```

VerticalBagLayout

The `VerticalBagLayout` places all the components in a single column. The width of each component is the width of the container; each component is given its preferred height. Figure 7.17 shows `VerticalBagLayout` in use.

Figure 7.17: VerticalBagLayout



Constructors

public VerticalBagLayout ()

> This constructor creates a `VerticalBagLayout` with a vertical gap of zero pixels. The gap is the space between components in the vertical direction. With a gap of 0, adjacent components will touch each other.

public VerticalBagLayout (int vgap)

> This constructor creates a `VerticalBagLayout` with a vertical gap of `vgap` pixels.

LayoutManager methods

public void addLayoutComponent (String name, Component component)

> The `addLayoutComponent()` method of `VerticalBagLayout` does nothing.

public void removeLayoutComponent (Component component)

The `removeLayoutComponent()` method of `VerticalBagLayout` does nothing.

public Dimension preferredLayoutSize (Container target)

To get the preferred height of the layout, the `preferredLayoutSize()` method sums up the preferred height of all the components in `target` along with the `vgap` and top and bottom insets. For the preferred width, `preferredLayoutSize()` returns the preferred width of the widest component.

public Dimension minimumLayoutSize (Container target)

To get the minimum height of the layout, the `minimumLayoutSize()` method sums up the minimum height of all the components in `target` along with the `vgap` and top and bottom insets. For the minimum width, `minimumLayoutSize()` returns the minimum width of the widest component.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s components on the screen in one column. The width of each component is the width of the container. Each component's height is its `preferredSize()` height, if available.

Miscellaneous methods

public String toString ()

The `toString()` method of `VerticalBagLayout` returns a string with the current vertical gap setting. For example:

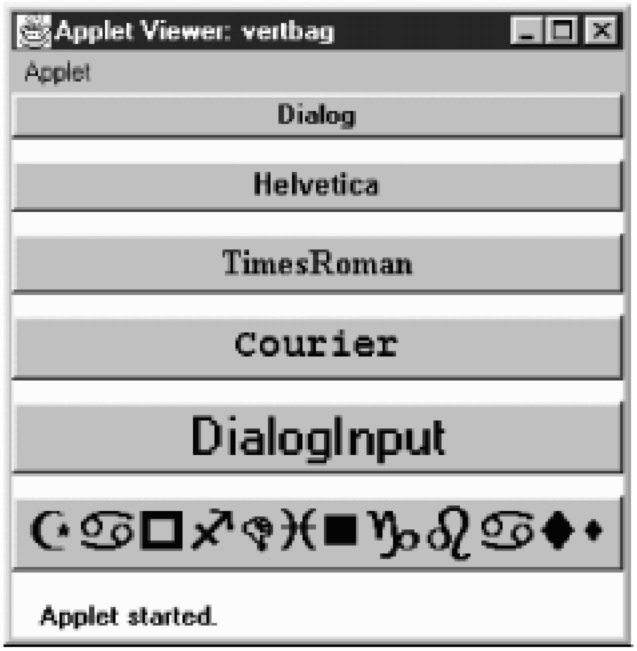
```
sun.awt.VerticalBagLayout[vgap=0]
```

VariableGridLayout

The `VariableGridLayout` builds upon the `GridLayout`. It arranges components on a grid of rows and columns. However, instead of giving all components the same size, the `VariableGridLayout` allows you to size rows and columns fractionally. Another difference between `VariableGridLayout` and `GridBagLayout` is that a `VariableGridLayout` has a fixed size. If you ask for a 3x3 grid, you will get exactly that. The layout manager throws the `ArrayIndexOutOfBoundsException` run-time exception if you try to add too many components.

Figure 7.18 shows a `VariableGridLayout` in which row one takes up 50 percent of the screen, and rows two and three take up 25 percent of the screen each. Column one takes up 50 percent of the screen; columns two and three take 25 percent each.

Figure 7.18: VariableGridLayout in Netscape Navigator



Here is the code that creates Figure 7.18:

```
import java.awt.*;
java.applet.Applet;
import sun.awt.VariableGridLayout;
public class vargrid extends Applet {
    public void init () {
        VariableGridLayout vgl;
        setLayout (vgl = new VariableGridLayout (3,3));
        vgl.setRowFraction (0, 1.0/2.0);
        vgl.setRowFraction (1, 1.0/4.0);
        vgl.setRowFraction (2, 1.0/4.0);
        vgl.setColFraction (0, 1.0/2.0);
        vgl.setColFraction (1, 1.0/4.0);
        vgl.setColFraction (2, 1.0/4.0);
        add (new Button ("One"));
        add (new Button ("Two"));
        add (new Button ("Three"));
        add (new Button ("Four"));
        add (new Button ("Five"));
        add (new Button ("Six"));
        add (new Button ("Seven"));
        add (new Button ("Eight"));
        add (new Button ("Nine"));
    }
}
```

Constructors

public VariableGridLayout (int rows, int columns)

> This constructor creates a `VariableGridLayout` with the specified number of `rows` and `columns`. You cannot specify zero for one dimension. If either `rows` or `columns` is zero, the constructor throws the `NullPointerException` run-time exception. This constructor uses the default values for horizontal and vertical gaps (zero pixels), which means that components in adjacent cells will touch each other.

public VariableGridLayout (int rows, int columns, int hgap, int vgap)

> This version of the constructor is called by the previous one. It creates a `VariableGridLayout` with the specified number of `rows` and `columns`, a horizontal gap of `hgap`, and a vertical gap of `vgap`. The gaps specify in pixels the space between adjacent components in the horizontal and vertical directions. It is possible to have negative gaps if you want components to overlap. You cannot specify zero for the number of rows or columns. If either `rows` or `columns` is zero, the constructor throws the run-time exception `NullPointerException`.

Support methods

The distinguishing feature of a `VariableGridLayout` is that you can tell a particular row or column to take up a certain fraction of the display. By default, the horizontal space available is split evenly among the grid's columns; vertical space is split evenly among the rows. This group of methods lets you find out how much space is allotted to each row or column and lets you change that allocation. The sum of the fractional amounts for each direction should add up to one. If greater than one, part of the display will be drawn offscreen. If less than one, additional screen real estate will be unused.

public void setRowFraction (int rowNumber, double fraction)

> This method sets the percentage of space available for row `rowNumber` to `fraction`.

public void setColFraction (int colNumber, double fraction)

> This method sets the percentage of space available for column `colNumber` to `fraction`.

public double getRowFraction (int rowNumber)

This method returns the current fractional setting for row `rowNumber`.

public double getColFraction (int colNumber)

This method returns the current fractional setting for column `colNumber`.

LayoutManager methods

The only method from `GridLayout` that is overridden is the `layoutContainer()` method.

public void layoutContainer (Container target)

The `layoutContainer()` method draws `target`'s components on the screen in a series of rows and columns. The size of each component within a `VariableGridLayout` is determined by the `RowFraction` and `ColFraction` settings for its row and column.

Miscellaneous methods

public String toString ()

The `toString()` method of `VariableGridLayout` returns a string with the current horizontal and vertical gap settings, the number of rows and columns, and the row and column fractional amounts. For example, the string produced by Figure 7.19 would be:

```
sun.awt.VariableGridLayout[hgap=0,vgap=0,rows=3,cols=3,
    rowFracs=[3]<0.50><0.25><0.25>,colFracs=[3]<0.50><0.25><0.25>]
```

OrientableFlowLayout

The `OrientableFlowLayout` is available for those who want something like a `FlowLayout` that lets you arrange components from top to bottom. Figure 7.19 shows `OrientableFlowLayout` in use.

Constants

Since `OrientableFlowLayout` subclasses `FlowLayout`, the `FlowLayout` constants of `LEFT`, `RIGHT`, and `CENTER` are still available.

public static final int HORIZONTAL ★

> The `HORIZONTAL` constant tells the layout manager to arrange components from left to right, like the `FlowLayout` manager.

public static final int VERTICAL ★

> The `VERTICAL` constant tells the layout manager to arrange components from top to bottom.

public static final int TOP ★

> The `TOP` constant tells the layout manager to align the first component at the top of the screen (top justification).

public static final int BOTTOM ★

> The `BOTTOM` constant tells the layout manager to align the first component at the bottom of the screen (bottom justification).

Constructors

public OrientableFlowLayout () ★

This constructor creates a `OrientableFlowLayout` that acts like the default `FlowLayout`. The objects flow from left to right and have an `hgap` and `vgap` of 5.

public OrientableFlowLayout (int direction) ★

This constructor creates a `OrientableFlowLayout` in the given `direction`. Valid values are `OrientableFlowLayout.HORIZONTAL` or `OrientableFlowLayout.VERTICAL`.

public OrientableFlowLayout (int direction, int horizAlignment, int vertAlignment) ★

This constructor creates a `OrientableFlowLayout` in the given direction. Valid values are `OrientableFlowLayout.HORIZONTAL` or `OrientableFlowLayout.VERTICAL`. `horizAlignment` provides the horizontal alignment setting. `vertAlignment` provides a vertical alignment setting; it may be `OrientableFlowLayout.TOP`, `FlowLayout.CENTER`, or `OrientableFlowLayout.BOTTOM`. If `direction` is `HORIZONTAL`, the vertical alignment is ignored. If `direction` is `VERTICAL`, the horizontal alignment is ignored.

public OrientableFlowLayout (int direction, int horizAlignment, int vertAlignment, int horizHgap, int horizVgap, int vertHgap, int vertVgap) ★

The final constructor adds separate horizontal and vertical gaps to the settings of `OrientableFlowLayout`. The `horizHgap` and `horizVgap` parameters are the gaps when horizontally aligned. The `vertHgap` and `vertVgap` parameters are the gaps when vertically aligned.

LayoutManager methods

public Dimension preferredLayoutSize (Container target) ★

The `preferredLayoutSize()` method of `OrientableFlowLayout` calculates the preferred dimensions for the `target` container. The `OrientableFlowLayout` computes the preferred size by placing all the components in one row or column, depending upon the current orientation, and adding their individual preferred sizes along with gaps and insets.

public Dimension minimumLayoutSize (Container target) ★

The `minimumLayoutSize()` method of `OrientableFlowLayout` calculates the minimum dimensions for the container by adding up the sizes of the components. The `OrientableFlowLayout` computes the minimum size by placing all the components in one row or column, depending upon the current orientation, and adding their individual minimum sizes along with gaps and insets.

public void layoutContainer (Container target) ★

The `layoutContainer()` method draws `target`'s `Component`s on the screen, starting with the first row or column of the display, and going from left to right across the screen, or from top to bottom, based on the current orientation. When it reaches the margin of the container, it skips to the next row or column and continues drawing additional components.

Miscellaneous methods

public void orientHorizontally () ★

The `orientHorizontally()` method allows you to change the orientation of the `LayoutManager` to horizontal. The container must be validated before you see the effect of the change.

public void orientVertically () ★

The `orientVertically()` method allows you to change the orientation of the `LayoutManager` to vertical. The container must be validated before you see the effect of the change.

public String toString () ★

The `toString()` method of `OrientableFlowLayout` returns a string with the current orientation setting, along with the entire `FlowLayout.toString()` results. For example:

```
sun.awt.OrientableFlowLayout[orientation=vertical,
sun.awt.OrientableFlowLayout[hgap=5,vgap=5,align=center]]
```

7.12 Other Layouts Available on the Net

Many custom layout managers are available on the Internet. Many of these duplicate the layout behavior of other environments. For example, the `FractionalLayout` is based on Smalltalk's positioning mechanism; it is located at http://www.mcs.net/~elunt/Java/FractionalLayoutDescription.html. The `RelativeLayout` allows you to position components relative to others, similar to an X Window form; you can find it at http://www-elec.enst.fr/java/RelativeLayout.java. If you like the way Tcl/Tk arranges widgets, try the `PackerLayout`; it is available at http://www.geom.umn.edu/~daeron/apps/ui/pack/gui.html. If none of these suit you, you can find a collection of links to custom layout managers at http://www.softbear.com/people/larry/javalm.htm. Gamelan (http://www.gamelan.com/) is always a good source for Java classes; try searching for `LayoutManager`.

8.2 TextField

`TextField` is the `TextComponent` for single-line input. Some constructors permit you to set the width of the `TextField` on the screen, but the current `LayoutManager` may change it. The text in the `TextField` is left justified, and the justification is not customizable. To change the font and size of text within the `TextField`, call `setFont()` as shown in Chapter 3, *Fonts and Colors*.

The width of the field does not limit the number of characters that the user can type into the field. It merely suggests how wide the field should be. To limit the number of characters, it is necessary to override the `keyDown()` method for the `Component`. Extending TextField contains an example showing how to do this.

TextField Methods

Constructors

public TextField ()

> This constructor creates an empty `TextField`. The width of the `TextField` is zero columns, but it will be made wide enough to display just about one character, depending on the current font and size.

public TextField (int columns)

> This constructor creates an empty `TextField`. The `TextField` width is `columns`. The `TextField` will try to be wide enough to display `columns` characters in the current font and size. As I mentioned previously, the layout manager may change the size.

public TextField (String text)

> This constructor creates a `TextField` with `text` as its content. In Java 1.0 systems, the `TextField` is 0 columns wide (the `getColumns()` result), but the system will size it to fit the length of text. With Java 1.1, `getColumns()` actually returns `text.length`.

public TextField (String text, int columns)

> This constructor creates a `TextField` with `text` as its content and a width of `columns`.

The following example uses all four constructors; the results are shown in Figure 8.2. With the third constructor, you see that the `TextField` is not quite wide enough for our text. The system uses an average width per character to try to determine how wide the field should be. If you want to be on the safe side, specify the field's length explicitly, and add a few extra characters to ensure that there is enough room on the screen for the entire text.

```
import java.awt.TextField;
public class texts extends java.applet.Applet {
   public void init () {
        add (new TextField ());                      // A
        add (new TextField (15));                    // B
        add (new TextField ("Empty String"));        // C
        add (new TextField ("Empty String", 20)); // D
   }
}
```

Figure 8.2: Using the TextField constructors

[Graphic: Figure 8-2]

Sizing

public int getColumns ()

> The `getColumns()` method returns the number of columns set with the constructor or a later call to `setColumns()`. This could be different from the displayed width of the `TextField`, depending upon the current `LayoutManager`.

public void setColumns (int columns) ★

> The `setColumns()` method changes the preferred number of columns for the `TextField` to display to `columns`. Because the current `LayoutManager` will do what it wants, the new setting may be completely ignored. If `columns` < 0, `setColumns()` throws the run-time exception `IllegalArgumentException`.

public Dimension getPreferredSize (int columns) ★
public Dimension preferredSize (int columns) ☆

The `getPreferredSize()` method returns the `Dimension` (width and height) for the preferred size of a `TextField` with a width of `columns`. The `columns` specified may be different from the number of columns designated in the constructor.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getPreferredSize () ★
public Dimension preferredSize () ☆

The `getPreferredSize()` method returns the `Dimension` (width and height) for the preferred size of the `TextField`. Without the `columns` parameter, this `getPreferredSize()` uses the constructor's number of columns (or the value from a subsequent call to `setColumns()`) to calculate the `TextField`'s preferred size.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getMinimumSize (int columns) ★
public Dimension minimumSize (int columns) ☆

The `getMinimumSize`() method returns the minimum `Dimension` (width and height) for the size of a `TextField` with a width of `columns`. The `columns` specified may be different from the columns designated in the constructor.

`minimumSize()` is the Java 1.0 name for this method.

public Dimension getMinimumSize () ★
public Dimension minimumSize ()

The `getMinimumSize()` method returns the minimum `Dimension` (width and height) for the size of the `TextField`. Without the columns parameter, this `getMinimumSize()` uses the constructor's number of columns (or the value from a subsequent call to `setColumns()`) to calculate the `TextField`'s minimum size.

`minimumSize()` is the Java 1.0 name for this method.

Echoing character

It is possible to change the character echoed back to the user when he or she types. This is extremely useful for implementing password entry fields.

public char getEchoChar ()

The `getEchoChar()` method returns the currently echoed character. If the `TextField` is echoing normally, `getEchoChar()` returns zero.

public void setEchoChar (char c) ★
public void setEchoCharacter (char c) ☆

The `setEchoChar()` method changes the character that is displayed to the user to `c` for every character in the `TextField`. It is possible to change the echo character on the fly so that existing characters will be replaced. A `c` of zero, `(char)0`, effectively turns off any change and makes the `TextField` behave normally.

`setEchoCharacter()` is the Java 1.0 name for this method.

public boolean echoCharIsSet ()

The `echoCharIsSet()` method returns `true` if the echo character is set to a nonzero value. If the `TextField` is displaying input normally, this method returns `false`.

Miscellaneous methods

public synchronized void addNotify ()

The `addNotify()` method creates the `TextField` peer. If you override this method, first call `super.addNotify()`, then add your customizations for the new class. Then you will be able to do everything you need with the information about the newly created peer.

protected String paramString ()

When you call the `toString()` method of `TextField`, the default `toString()` method of `Component` is called. This in turn calls `paramString()`, which builds up the string to display. The `TextField` level can add only one item. If the echo character is nonzero, the current echo character is added (the method `getEchoChar()`). Using `` new TextField (`Empty String`, 20) ``, the results displayed could be:

```
java.awt.TextField[0,0,0x0,invalid,text="Empty String",editable,selection=0-0]
```

TextField Events

With the 1.0 event model, `TextField` components can generate `KEY_PRESS` and `KEY_ACTION` (which calls `keyDown()`), `KEY_RELEASE` and `KEY_ACTION_RELEASE` (which calls `keyUp()`), and `ACTION_EVENT` (which calls `action()`).

With the 1.1 event model, you register an `ActionListener` with the method `addActionListener()`. Then when the user presses Return within the `TextField` the `ActionListener.actionPerformed()` method is called through the protected `TextField.processActionEvent()` method. Key, mouse, and focus listeners are registered through the three `Component` methods of `addKeyListener()`, `addMouseListener()`, and `addFocusListener()`, respectively. Action

public boolean action (Event e, Object o)

> The `action()` method for a `TextField` is called when the input focus is in the `TextField` and the user presses the Return key. `e` is the `Event` instance for the specific event, while `o` is a `String` representing the current contents (the `getText()` method).

Keyboard

public boolean keyDown (Event e, int key)

> The `keyDown()` method is called whenever the user presses a key. `keyDown()` may be called many times in succession if the key remains pressed. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyDown()` could be either `Event.KEY_PRESS` for a regular key or `Event.KEY_ACTION` for an action-oriented key (i.e., an arrow or function key). Some of the things you can do through this method are validate input, convert each character to uppercase, and limit the number or type of characters entered. The technique is simple: you just need to remember that the user's keystroke is actually displayed by the `TextField` peer, which receives the event after the `TextField` itself. Therefore, a `TextField` subclass can modify the character displayed by modifying the `key` field (`e.key`) of the `Event` and returning `false`, which passes the `Event` on down the chain; remember that returning `false` indicates that the `Event` has not been completely processed. The following method uses this technique to convert all input to uppercase.

```
public boolean keyDown (Event e, int key) {
    e.key = Character.toUppercase (char(key));
    return false;
}
```

> If `keyDown()` returns `true`, it indicates that the `Event` has been completely processed. In this case, the `Event` never propagates to the peer, and the keystroke is never displayed.

public boolean keyUp (Event e, int key)

> The `keyUp()` method is called whenever the user releases a key. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyUp()` could be either `Event.KEY_RELEASE` for a regular key or `Event.KEY_ACTION_RELEASE` for an action-oriented key (i.e., an arrow or function key). Among other things, `keyUp()` may be used to determine how long the key has been pressed.

Mouse

Ordinarily, the `TextField` component does not trigger any mouse events.

> **NOTE:**

Mouse events are not generated for `TextField` with JDK 1.0.2. Your run-time environment may behave differently. See Appendix C for more information about platform dependencies.

Focus

The `TextField` component does not reliably generate focus events.

> **NOTE:**

The `GOT_FOCUS` and `LOST_FOCUS` events can be generated by `TextField`s, but these events are not reliable across platforms. With Java 1.0, they are generated on most UNIX platforms but not on Windows NT/95 platforms. They are generated on all platforms under Java 1.1. See Appendix C for more information about platform dependencies.

public boolean gotFocus (Event e, Object o)

> The `gotFocus()` method is triggered when the `TextField` gets the input focus. `e` is the `Event` instance for the specific event, while `o` is a `String` representation of the current contents (`getText()`).

public boolean lostFocus (Event e, Object o)

> The `lostFocus()` method is triggered when the input focus leaves the `TextField`. `e` is the `Event` instance for the specific event, while `o` is a `String` representation of the current contents (`getText()`).

Listeners and 1.1 event handling

With the 1.1 event model, you register event listeners that are told when an event occurs. You can register text event listeners by calling the method `TextComponent.addTextListener()`.

public void addActionListener(ActionListener listener) ★

> The `addActionListener()` method registers `listener` as an object interested in receiving notifications when an `ActionEvent` passes through the `EventQueue` with this `TextField` as its target. The `listener.actionPerformed()` method is called when these events occur. Multiple listeners can be registered. The following code demonstrates how to use an `ActionListener` to reverse the text in the `TextField`.

```
// Java 1.1 only
import java.applet.*;
import java.awt.*;
import java.awt.event.*;
class MyAL implements ActionListener {
    public void actionPerformed(ActionEvent e) {
        System.out.println ("The current text is: " +
            e.getActionCommand());
        if (e.getSource() instanceof TextField) {
            TextField tf = (TextField)e.getSource();
            StringBuffer sb = new StringBuffer (e.getActionCommand());
            tf.setText (sb.reverse().toString());
        }
    }
}
public class text11 extends Applet {
    public void init () {
        TextField tf = new TextField ("Help Text", 20);
        add (tf);
        tf.addActionListener (new MyAL());
   }
}
```

public void removeActionListener(ActionListener listener) ★

The `removeActionListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent`s with this `TextField` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `TextField`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processActionEvent(ActionEvent e) ★

The `processActionEvent()` method receives all `ActionEvent`s with this `TextField` as its target. `processActionEvent()` then passes them along to any listeners for processing. When you subclass `TextField`, overriding the method `processActionEvent()` allows you to process all action events yourself, before sending them to any listeners. In a way, overriding `processActionEvent()` is like overriding `action()` using the 1.0 event model.

If you override the `processActionEvent()` method, remember to call `super.processActionEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

The following applet is equivalent to the previous example, except that it overrides `processActionEvent()` to receive events, eliminating the need for an ActionListener. The constructor calls enableEvents() to make sure that events are delivered, even if no listeners are registered.

```
// Java 1.1 only
import java.applet.*;
import java.awt.*;
import java.awt.event.*;
class MyTextField extends TextField {
    public MyTextField (String s, int len) {
        super (s, len);
        enableEvents (AWTEvent.ACTION_EVENT_MASK);
    }
    protected void processActionEvent(ActionEvent e) {
        System.out.println ("The current text is: " +
            e.getActionCommand());
        TextField tf = (TextField)e.getSource();
        StringBuffer sb = new StringBuffer (e.getActionCommand());
        tf.setText (sb.reverse().toString());
        super.processActionEvent(e)
    }
}
public class text12 extends Applet {
   public void init () {
        TextField tf = new MyTextField ("Help Text", 20);
        add (tf);
   }
}
```

8.3 TextArea

TextArea is the TextComponent for multiline input. Some constructors permit you to set the rows and columns of the TextArea on the screen. However, the LayoutManager may change your settings. As with TextField, the only way to limit the number of characters that a user can enter is to override the keyDown() method. The text in a TextArea appears left justified, and the justification is not customizable.

In Java 1.1, you can control the appearance of a TextArea scrollbar; earlier versions gave you no control over the scrollbars. When visible, the vertical scrollbar is on the right of the TextArea, and the horizontal scrollbar is on the bottom. You can remove either scrollbar with the help of several new TextArea constants; you can't move them to another side. When the horizontal scrollbar is not present, the text wraps automatically when the user reaches the right side of the TextArea. Prior to Java 1.1, there was no way to enable word wrap.

TextArea Variables

Constants

The constants for TextArea are new to Java 1.1; they allow you to control the visibility and word wrap policy of a TextArea scrollbar. There is no way to listen for the events when a user scrolls a TextArea.

public static final int SCROLLBARS_BOTH ★

> The SCROLLBARS_BOTH mode is the default for TextArea. It shows both scrollbars all the time and does no word wrap.

public static final int SCROLLBARS_HORIZONTAL_ONLY ★

The `SCROLLBARS_HORIZONTAL_ONLY` mode displays a scrollbar along the bottom of the `TextArea`. When this scrollbar is present, word wrap is disabled.

public static final int SCROLLBARS_NONE ★

The `SCROLLBARS_NONE` mode displays no scrollbars around the `TextArea` and enables word wrap. If the text is too long, the `TextArea` displays the lines surrounding the cursor. You can use the cursor to move up and down within the `TextArea`, but you cannot use a scrollbar to navigate. Because this mode has no horizontal scrollbar, word wrap is enabled.

public static final int SCROLLBARS_VERTICAL_ONLY ★

The `SCROLLBARS_VERTICAL_ONLY` mode displays a scrollbar along the right edge of the `TextArea`. If the text is too long to display, you can scroll within the area. Because this mode has no horizontal scrollbar, word wrap is enabled.

TextArea Methods

Constructors

public TextArea ()

This constructor creates an empty `TextArea` with both scrollbars. The `TextArea` is 0 rows high and 0 columns wide. Depending upon the platform, the `TextArea` could be really small (and useless) or rather large. It is a good idea to use one of the other constructors to control the size of the `TextArea`.

public TextArea (int rows, int columns)

This constructor creates an empty `TextArea` with both scrollbars. The `TextArea` is `rows` high and `columns` wide.

public TextArea (String text)

This constructor creates a `TextArea` with an initial content of `text` and both scrollbars. The `TextArea` is 0 rows high and 0 columns wide. Depending upon the platform, the `TextArea` could be really small (and useless) or rather large. It is a good idea to use one of the other constructors to control the size of the `TextArea`.

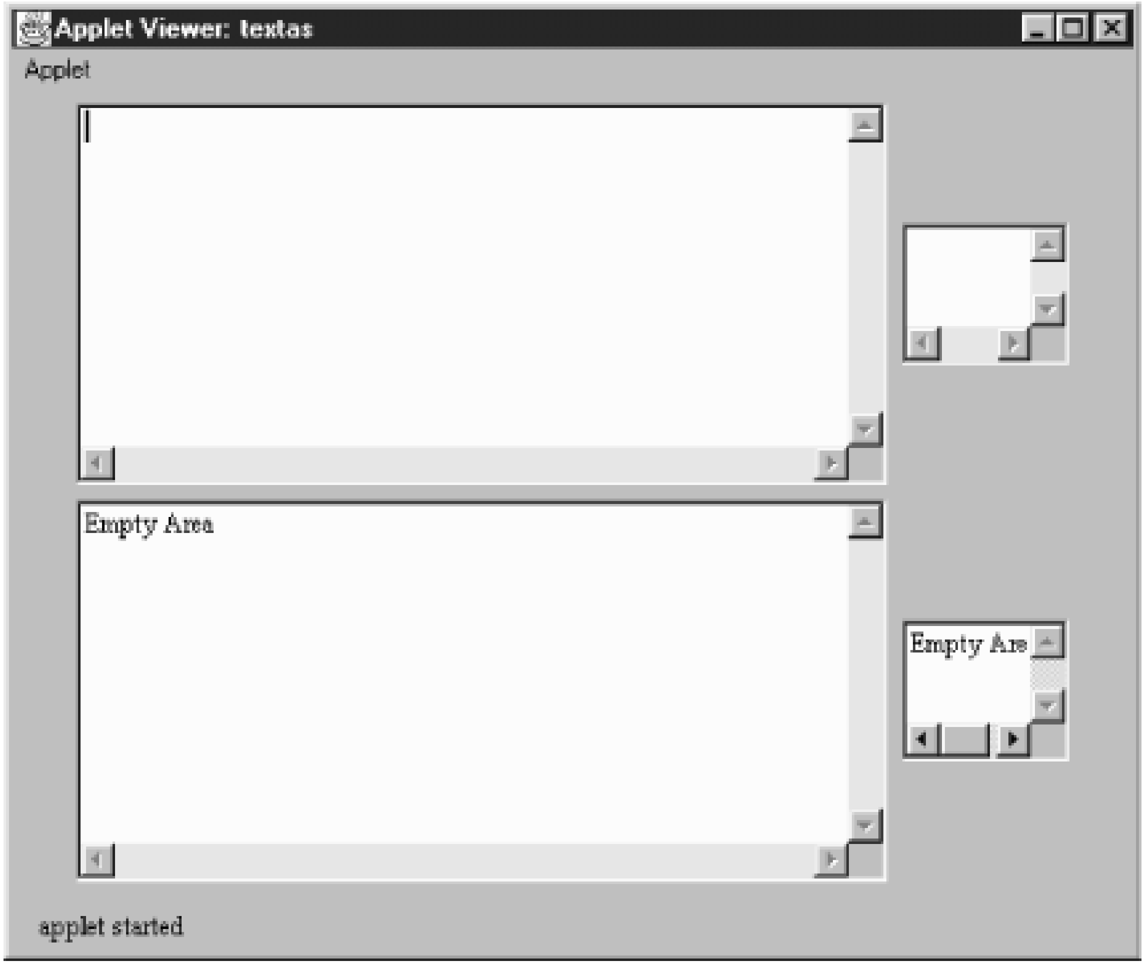
public TextArea (String text, int rows, int columns)

> This constructor creates a `TextArea` with an initial content of `text`. The `TextArea` is `rows` high and `columns` wide and has both scrollbars.

The following example uses the first four constructors. The results are shown in Figure 8.3. With the sizeless constructors, notice that Windows 95 creates a rather large `TextArea`. UNIX systems create a much smaller area. Depending upon the `LayoutManager`, the `TextArea`s could be resized automatically.

```
import java.awt.TextArea;
public class textas extends java.applet.Applet {
    public void init () {
        add (new TextArea ());                      // A
        add (new TextArea (3, 10));                 // B
        add (new TextArea ("Empty Area"));          // C
        add (new TextArea ("Empty Area", 3, 10));  // D
    }
}
```

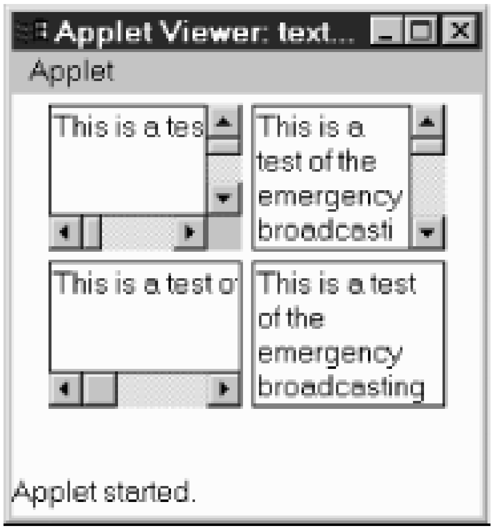
Figure 8.3: TextArea constructor



public TextArea (String text, int rows, int columns, int scrollbarPolicy) ★

> The final constructor creates a `TextArea` with an initial content of `text`. The `TextArea` is `rows` high and `columns` wide. The initial scrollbar display policy is designated by the `scrollbarPolicy` parameter and is one of the `TextArea` constants in the previous example. This constructor is the only way provided to change the scrollbar visibility; there is no `setScrollbarVisibility()` method. Figure 8.4 displays the different settings.

Figure 8.4: TextArea policies



Applet started.

Setting text

The text-setting methods are usually called in response to an external event. When you handle the insertion position, you must translate it from the visual row and column to a one-dimensional position. It is easier to position the insertion point based upon the beginning, end, or current selection (`getSelectionStart()` and `getSelectionEnd()`).

public void insert (String string, int position) ★
public void insertText (String string, int position) ☆

> The `insert()` method inserts `string` at `position` into the `TextArea`. If `position` is beyond the end of the `TextArea`, `string` is appended to the end of the `TextArea`.
>
> `insertText()` is the Java 1.0 name for this method.

public void append (String string) ★
public void appendText (String string) ☆

The `append()` method inserts `string` at the end of the `TextArea`.

`appendText()` is the Java 1.0 name for this method.

public void replaceRange (String string, int startPosition, int endPosition) ★
public void replaceText (String string, int startPosition, int endPosition) ☆

The `replaceRange()` method replaces the text in the current `TextArea` from `startPosition` to `endPosition` with `string`. If `endPosition` is before `startPosition`, it may or may not work as expected. (For instance, on a Windows 95 platform, it works fine when the `TextArea` is displayed on the screen. However, when the `TextArea` is not showing, unexpected results happen. Other platforms may vary.) If `startPosition` is 0 and `endPosition` is the length of the contents, this method functions the same as `TextComponent.setText()`.

`replaceText()` is the Java 1.0 name for this method.

Sizing

public int getRows ()

The `getRows()` method returns the number of rows set by the constructor or a subsequent call to `setRows()`. This could be different from the displayed height of the `TextArea`.

public void setRows (int rows) ★

The `setRows()` method changes the preferred number of rows to display for the `TextField` to `rows`. Because the current `LayoutManager` will do what it wants, the new setting may be ignored. If rows < 0, `setRows()` throws the run-time exception `IllegalArgumentException`.

public int getColumns ()

The `getColumns()` method returns the number of columns set by the constructor or a subsequent call to `setColumns()`. This could be different from the displayed width of the `TextArea`.

public void setColumns (int columns) ★

The `setColumns()` method changes the preferred number of columns to display for the `TextArea` to `columns`. Because the current `LayoutManager` will do what it wants, the new setting may be ignored. If `columns` < 0, `setColumns()` throws the run-time exception `IllegalArgumentException`.

public Dimension getPreferredSize (int rows, int columns) ★
public Dimension preferredSize (int rows, int columns) ☆

The `getPreferredSize()` method returns the `Dimension` (width and height) for the preferred size of the `TextArea` with a preferred height of `rows` and width of `columns`. The `rows` and `columns` specified may be different from the current settings.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getPreferredSize (int rows, int columns) ★
public Dimension preferredSize () ☆

The `getPreferredSize()` method returns the `Dimension` (width and height) for the preferred size of the `TextArea`. Without the rows and columns parameters, this `getPreferredSize()` uses the constructor's number of rows and columns to calculate the `TextArea`'s preferred size.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getMinimumSize (int rows, int columns) ★
public Dimension minimumSize (int rows, int columns) ☆

The `getMinimumSize()` method returns the minimum `Dimension` (width and height) for the size of the `TextArea` with a height of `rows` and width of `columns`. The `rows` and `columns` specified may be different from the current settings.

`minimumSize()` is the Java 1.0 name for this method.

public Dimension getMinimumSize () ★
public Dimension minimumSize () ☆

The `getMinimumSize()` method returns the minimum `Dimension` (width and height) for the size of the `TextArea`. Without the rows and columns parameters, this `getMinimumSize()` uses the current settings for rows and columns to calculate the `TextArea`'s minimum size.

`minimumSize()` is the Java 1.0 name for this method.

Miscellaneous methods

public synchronized void addNotify ()

The addNotify() method creates the TextArea peer. If you override this method, call super.addNotify() first, then add your customizations for the new class. You will then be able to do everything you need with the information about the newly created peer.

public int getScrollbarVisibility() ★

The getScrollbarVisibility() method retrieves the scrollbar visibility setting, which is set by the constructor. There is no setScollbarVisibility() method to change the setting. The return value is one of the TextArea constants: SCROLLBARS_BOTH, SCROLLBARS_HORIZONTAL_ONLY, SCROLLBARS_NONE, or SCROLLBARS_VERTICAL_ONLY.

protected String paramString ()

When you call the toString() method of TextArea, the default toString() method of Component is called. This in turn calls paramString(), which builds up the string to display. The TextArea level adds the number of rows and columns for the TextArea, and Java 1.1 adds the scrollbar visibility policy. Using new TextArea(`Empty Area`, 3, 10), the results displayed could be:

```
java.awt.TextArea[text0,0,0,0x0,invalid,text="Empty Area",
editable,selection=0-0, rows=3,columns=10, scrollbarVisibility=both]
```

TextArea Events

With the 1.0 event model, the TextArea component can generate KEY_PRESS and KEY_ACTION (which calls keyDown()) along with KEY_RELEASE and KEY_ACTION_RELEASE (which called keyUp()). There is no ACTION_EVENT generated for TextArea.

NOTE:

The GOT_FOCUS and LOST_FOCUS events can be generated by this component but not reliably across platforms. Currently, they are generated on most UNIX platforms but not on Microsoft Windows NT/95 under Java 1.0. These events are generated under Java 1.1.

Similarly, the mouse events are not generated with JDK 1.0.2. See Appendix C for more information about platform dependencies.

With the Java 1.1 event model, there are no listeners specific to TextArea. You can register key, mouse, and focus listeners through the Component methods of addKeyListener(), addMouseListener(), and addFocusListener(), respectively. To register listeners for text events, call TextComponent.addTextListener(). Action

The TextArea component has no way to trigger the action event, since carriage return is a valid character. You would need to put something like a Button on the screen to cause an action for a TextArea. The following Rot13 program demonstrates this technique. The user enters text in the TextArea and selects the Rotate Me button to rotate the text. If the user selects Rotate Me again, it rotates again, back to the original position. Without the button, there would be no way to trigger the event. Figure 8.5 shows this example in action.

```
import java.awt.*;
public class Rot13 extends Frame {
    TextArea ta;
    Component rotate, done;
    public Rot13 () {
        super ("Rot-13 Example");
        add ("North", new Label ("Enter Text to Rotate:"));
        ta = (TextArea)(add ("Center", new TextArea (5, 40)));
        Panel p = new Panel ();
        rotate = p.add (new Button ("Rotate Me"));
        done = p.add (new Button ("Done"));
        add ("South", p);
    }
    public static void main (String args[]) {
        Rot13 rot = new Rot13();
        rot.pack();
        rot.show();
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            hide();
            dispose();
            System.exit (0);
            return true;
        }
        return super.handleEvent (e);
    }
    public boolean action (Event e, Object o) {
        if (e.target == rotate) {
            ta.setText (rot13Text (ta.getText()));
            return true;
        } else if (e.target == done) {
            hide();
            dispose();
            System.exit (0);
        }
        return false;
    }
    String rot13Text (String s) {
        int len = s.length();
        StringBuffer returnString = new StringBuffer (len);
        char c;
        for (int i=0;i<len;i++) {
            c = s.charAt (i);
            if (((c >= 'A') && (c <= 'M')) ||
                ((c >= 'a') && (c <= 'm')))
                c += 13;
            else if (((c >= 'N') && (c <= 'Z')) ||
                ((c >= 'n') && (c <= 'z')))
                c -= 13;
            returnString.append (c);
        }
        return returnString.toString();
    }
}
```

Wnin vf tbbq.

Keyboard

Ordinarily, the `TextArea` component generates all the key events.

public boolean keyDown (Event e, int key)

The keyDown() method is called whenever the user presses a key. keyDown() may be called many times in succession if the key remains pressed. e is the Event instance for the specific event, while key is the integer representation of the character pressed. The identifier for the event (e.id) for keyDown() could be either Event.KEY_PRESS for a regular key or Event.KEY_ACTION for an action-oriented key (i.e., an arrow or function key). Some of the things you can do through this method are validate input, convert each character to uppercase, and limit the number or type of characters entered. The technique is simple: you just need to remember that the user's keystroke is actually displayed by the TextArea peer, which receives the event after the TextArea itself. Therefore, a TextArea subclass can modify the character displayed by modifying the key field (e.key) of the Event and returning false, which passes the Event on down the chain; remember that returning false indicates that the Event has not been completely processed. The following method uses this technique to convert all alphabetic characters to the opposite case:

```
public boolean keyDown (Event e, int key) {
    if (Character.isUpperCase ((char)key)) {
        e.key = Character.toLowerCase ((char)key);
    } else if (Character.isLowerCase ((char)key)) {
        e.key = Character.toUpperCase ((char)key);
    }
    return false;
}
```

If keyDown() returns true, it indicates that the Event has been completely processed. In this case, the Event never propagates to the peer, and the keystroke is never displayed.

public boolean keyUp (Event e, int key)

The keyUp() method is called whenever the user releases a key. e is the Event instance for the specific event, while key is the integer representation of the character pressed. The identifier for the event (e.id) for keyUp() could be either Event.KEY_RELEASE for a regular key, or Event.KEY_ACTION_RELEASE for an action-oriented key (i.e., an arrow or function key).

Mouse

Ordinarily, the TextArea component does not trigger any mouse events.

NOTE:

Mouse events are not generated for TextArea with JDK 1.0.2. See Appendix C for more information about platform dependencies.

Focus

The `TextArea` component does not reliably generate focus events.

> **NOTE:**

The `GOT_FOCUS` and `LOST_FOCUS` events can be generated by this component but not reliably across platforms. With the JDK, they are generated on most UNIX platforms but not on Microsoft Windows NT/95 under JDK 1.0. These events are generated with JDK 1.1. See Appendix C for more information about platform dependencies.

public boolean gotFocus (Event e, Object o)

> The `gotFocus()` method is triggered when the `TextArea` gets the input focus. `e` is the `Event` instance for the specific event, while `o` is a `String` representation of the current contents (`getText()`).

public boolean lostFocus (Event e, Object o)

> The `lostFocus()` method is triggered when the input focus leaves the `TextArea`. `e` is the `Event` instance for the specific event, while `o` is a `String` representation of the current contents (`getText()`).

Listeners and 1.1 event handling

There are no listeners specific to the `TextArea` class. You can register Key, mouse, and focus listeners through the `Component` methods of `addKeyListener()`, `addMouseListener()`, and `addFocusListener()`, respectively. Also, you register listeners for text events by calling `TextComponent.addTextListener()`.

8.4 Extending TextField

To extend what you learned so far, Example 8.1 creates a sub-class of `TextField` that limits the number of characters a user can type into it. Other than the six constructors, all the work is in the `keyDown()` method. The entire class follows.

Example 8.1: The SizedTextField Class Limits the Number of Characters a User can Type

```
import java.awt.*;
public class SizedTextField extends TextField {
    private int size;  // size = 0 is unlimited
    public SizedTextField () {
        super ("");
        this.size = 0;
    }
    public SizedTextField (int columns) {
        super (columns);
        this.size = 0;
    }
    public SizedTextField (int columns, int size) {
        super (columns);
        this.size = Math.max (0, size);
    }
    public SizedTextField (String text) {
        super (text);
        this.size = 0;
    }
    public SizedTextField (String text, int columns) {
        super (text, columns);
        this.size = 0;
    }
    public SizedTextField (String text, int columns, int size) {
        super (text, columns);
        this.size = Math.max (0, size);
    }
    public boolean keyDown (Event e, int key) {
        if ((e.id == Event.KEY_PRESS) && (this.size > 0) &&
            (((TextField)(e.target)).getText ().length () >= this.size)) {
            // Check for backspace / delete / tab--let these pass through
            if ((key == 127) || (key == 8) || (key == 9)) {
                return false;
            }
            return true;
        }
        return false;
    }
    protected String paramString () {
        String str = super.paramString ();
        if (size != 0) {
            str += ",size=" + size;
        }
        return str;
    }
}
```

Most of the `SizedTextField` class consists of constructors; you really don't need to provide an equivalent to all the superclass's constructors, but it's not a bad idea. The `keyDown()` method looks at what the user types before it reaches the screen and acts accordingly. It checks the length of the `TextField` and compares it to the maximum length. It then does another check to see if the user typed a Backspace, Delete, or Tab, all of which we want to allow: if the field has gotten too long, we want to allow the user to shorten it. We also want to allow tab under all circumstances, so that focus traversal works properly. The rest of the logic is simple:

- If the user typed Backspace, Delete, or Tab, return `false` to propagate the event.

- If the field is too long, return `true` to prevent the event from reaching the peer. This effectively ignores the character.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9.2 Lists

Like the `Choice` component, the `List` provides a way to present your user with a fixed sequence of choices to select. However, with `List`, several items can be displayed at a time on the screen. A `List` can also allow multiple selection, so that more than one choice can be selected.

Normally, a scrollbar is associated with the `List` to enable the user to move to the items that do not fit on the screen. On some platforms, the `List` may not display the scrollbar if there is enough room to display all choices. A `List` can be resized by the `LayoutManager` according to the space available. Figure 9.2 shows two lists, one of which has no items to display.

List Methods

Constructors

public List ()

> This constructor creates an empty `List` with four visible lines. You must rely on the current `LayoutManager` to resize the `List` or override the `preferredSize()` (version 1.0) or `getPreferredSize()` (version 1.1) method to affect the size of the displayed `List`. A `List` created with this constructor is in single-selection mode, so the user can select only one item at a time.

public List (int rows)

> This constructor creates a `List` that has `rows` visible lines. This is just a request; the `LayoutManager` is free to adjust the height of the `List` to some other amount based upon available space. A `List` created with this constructor is in single-selection mode, so the user will be able to select only one item at a time.

public List (int rows, boolean multipleSelections)

The final constructor for `List` creates a `List` that has `rows` visible lines. This is just a request; the `LayoutManager` is free to adjust the height of the `List` to some other amount based upon available space. If `multipleSelections` is `true`, this `List` permits multiple items to be selected. If `false`, this is a single-selection list.

Figure 9.2: Two lists; the list on the right is empty

[Graphic: Figure 9-2]

Content control

public int getItemCount () ★
public int countItems () ☆

The `getItemCount()` method returns the length of the list. The length of the list is the number of items in the list, not the number of visible rows.

`countItems()` is the Java 1.0 name for this method.

public String getItem (int index)

The `getItem()` method returns the `String` representation for the item at position `index`. The `String` is the parameter passed to the `addItem()` or `add()` method.

public String[] getItems () ★

The `getItems()` method returns a `String` array that contains all the elements in the `List`. This method does not care if an item is selected or not.

public synchronized void add (String item) ★
public synchronized void addItem (String item) ☆

The `add()` method adds `item` as the last entry in the `List`. If `item` already exists in the list, this method adds it again.

`addItem()` is the Java 1.0 name for this method.

public synchronized void add (String item, int index) ★
public synchronized void addItem (String item, int index) ☆

This version of the `add()` method has an additional parameter, `index`, which specifies where to add `item` to the `List`. If `index < 0` or `index >= getItemCount()`, `item` is added to the end of the `List`. The position count is zero based, so if `index` is 0, it will be added as the first item.

`addItem()` is the Java 1.0 name for this method.

public synchronized void replaceItem (String newItem, int index)

The `replaceItem()` method replaces the contents at position `index` with `newItem`. If the item at `index` has been selected, `newItem` will not be selected.

public synchronized void removeAll () ★
public synchronized void clear () ☆

The `removeAll()` method clears out all the items in the list.

`clear()` is the Java 1.0 name for this method.

NOTE:

Early versions (Java1.0) of the `clear()` method did not work reliably across platforms. You were better off calling the method `listVar.delItems(0, listVar.countItems()-1)`, where `listVar` is your `List` instance.

public synchronized void remove (String item) ★

The `remove()` method removes `item` from the list of available choices. If `item` appears in the `List` several times, only the first instance is removed. If `item` is `null`, `remove()` throws the run-time exception `NullPointerException`. If `item` is not found in the `List`, `remove()` throws the `IllegalArgumentException` run-time exception.

public synchronized void remove (int position) ★
public synchronized void delItem (int position) ☆

> The `remove()` method removes the entry at `position` from the `List`. If `position` is invalid--either `position` < 0 or `position` >= `getItemCount()`--`remove()` throws the `ArrayIndexOutOfBoundsException` run-time exception with a message indicating that `position` was invalid.
>
> `delItem()` is the Java 1.0 name for this method.

public synchronized void delItems (int start, int end) ☆

> The `delItems()` method removes entries from position `start` to position `end` from the `List`. If either parameter is invalid--either `start` < 0 or `end` >= `getItemCount()`--`delItems()` throws the `ArrayIndexOutOfBoundsException` run-time exception with a message indicating which position was invalid. If `start` is greater than `end`, nothing happens.

Selection and positioning

public synchronized int getSelectedIndex ()

> The `getSelectedIndex()` method returns the position of the selected item. If nothing is selected in the `List`, `getSelectedIndex()` returns -1. The value -1 is also returned if the `List` is in multiselect mode and multiple items are selected. For multiselection lists, use `getSelectedIndexes()` instead.

public synchronized int[] getSelectedIndexes ()

> The `getSelectedIndexes()` method returns an integer array of the selected items. If nothing is selected, the array will be empty.

public synchronized String getSelectedItem ()

> The `getSelectedItem()` method returns the label of the selected item. The label is the string used in the `add()` or `addItem()` call. If nothing is selected in the `List`, `getSelectedItem()` returns `null`. The return value is also `null` if `List` is in multiselect mode and multiple items are selected. For multiselection lists, use `getSelectedItems()` instead.

public synchronized String[] getSelectedItems ()

The `getSelectedItems()` method returns a `String` array of the selected items. If nothing is selected, the array is empty.

public synchronized Object[] getSelectedObjects ()

The `getSelectedObjects()` method returns the results of the method `getSelectedItems()` as an `Object` array instead of a `String` array, to conform to the `ItemSelectable` interface. If nothing is selected, the returned array is empty.

public synchronized void select (int index)

The `select()` method selects the item at position `index`, which is zero based. If the `List` is in single-selection mode, any other selected item is deselected. If the `List` is in multiple-selection mode, calling this method has no effect on the other selections. The item at position `index` is made visible.

NOTE:

A negative index seems to select everything within the `List`. This seems more like an irregularity than a feature to rely upon.

public synchronized void deselect (int index)

The `deselect()` method deselects the item at position `index`, which is zero based. `deselect()` does not reposition the visible elements.

public boolean isIndexSelected (int index) ★
public boolean isSelected (int index) ☆

The `isIndexSelected()` method checks whether `index` is currently selected. If it is, `isIndexSelected()` returns `true`; otherwise, it returns `false`.

`isSelected()` is the Java 1.0 name for this method.

public boolean isMultipleMode () ★
public boolean allowsMultipleSelections () ☆

The `isMultipleMode()` method returns the current state of the `List`. If the `List` is in multiselection mode, `isMultipleMode()` returns `true`; otherwise, it returns `false`.

`allowsMultipleSelections()` is the Java 1.0 name for this method.

public void setMultipleMode (boolean value) ★
public void setMultipleSelections (boolean value) ☆

The `setMultipleMode()` method allows you to change the current state of a `List` from one selection mode to the other. The currently selected items change when this happens. If `value` is `true` and the `List` is going from single- to multiple-selection mode, the selected item gets deselected. If `value` is `false` and the `List` is going from multiple to single, the last item physically selected remains selected (the last item clicked on in the list, not the item with the highest index). If there was no selected item, the first item in the list becomes selected, or the last item that was deselected becomes selected. If staying within the same mode, `setMultipleMode()` has no effect on the selected items.

`setMultipleSelections()` is the Java 1.0 name for this method.

public void makeVisible (int index)

The `makeVisible()` method ensures that the item at position `index` is displayed on the screen. This is useful if you want to make sure a certain entry is displayed when another action happens on the screen.

public int getVisibleIndex ()

The `getVisibleIndex()` method returns the last index from a call to the method `makeVisible()`. If `makeVisible()` was never called, -1 is returned.

Sizing

public int getRows ()

The `getRows()` method returns the number of rows passed to the constructor of the `List`. It does not return the number of visible rows. To get a rough idea of the number of visible rows, compare the `getSize()` of the component with the results of `getPreferredSize(getRows())`.

public Dimension getPreferredSize (int rows) ★
public Dimension preferredSize (int rows) ☆

The `getPreferredSize()` method returns the preferable `Dimension` (width and height) for the size of a `List` with a height of `rows`. The `rows` specified may be different from the rows designated in the constructor.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getPreferredSize () ★
public Dimension preferredSize () ☆

The `getPreferredSize()` method returns the `Dimension` (width and height) for the preferred size of the `List`. Without the rows parameter, this version of `getPreferredSize()` uses the constructor's number of rows to calculate the `List`'s preferred size.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getMiminumSize (int rows) ★
public Dimension minimumSize (int rows) ☆

The `getMinimumSize()` method returns the minimum `Dimension` (width and height) for the size of a `List` with a height of `rows`. The `rows` specified may be different from the rows designated in the constructor. For a `List`, `getMinimumSize()` and `getPreferredSize()` should return the same dimensions.

`minimumSize()` is the Java 1.0 name for this method.

public Dimension getMiminumSize () ★
public Dimension minimumSize () ☆

The `getMinimumSize()` method returns the minimum `Dimension` (width and height) for the size of the `List`. Without the rows parameter, this `getMinimumSize()` uses the constructor's number of rows to calculate the `List`'s minimum size.

`minimumSize()` is the Java 1.0 name for this method.

Miscellaneous methods

public synchronized void addNotify ()

The `addNotify()` method creates the `List` peer. If you override this method, call `super.addNotify()` first, then add your customizations for the new class. You will then be able to do everything you need with the information about the newly created peer.

public synchronized void removeNotify ()

The `removeNotify()` method destroys the peer of the `List` and removes it from the screen. Prior to the `List` peer's destruction, the last selected entry is saved. If you override this method for a specific `List`, issue the particular commands that you need for your new object, then call `super.removeNotify()` last.

protected String paramString ()

When you call the `toString()` method of `List`, the default `toString()` method of `Component` is called. This in turn calls `paramString()`, which builds up the string to display. At the `List` level, the currently selected item (`getSelectedItem()`) is appended to the output. Using Figure 9.2 as an example, the results would be the following:

```
java.awt.List[0,34,107x54,selected=null]
```

List Events

The primary event for a `List` occurs when the user selects an item in the list. With the 1.0 event model, double-clicking a selection causes an `ACTION_EVENT` and triggers the `action()` method, while single-clicking causes a `LIST_SELECT` or `LIST_DESELECT` event. Once the `List` has the input focus, it is possible to change the selection by using the arrow or keyboard keys. The arrow keys scroll through the list of choices, triggering the `KEY_ACTION`, `LIST_SELECT`, `LIST_DESELECT`, and `KEY_ACTION_RELEASE` events, and thus the `keyDown()`, `handleEvent()`, and `keyUp()` methods (no specific method gets called for `LIST_SELECT` and `LIST_DESELECT`). `action()` is called only when the user double-clicks on an item with the mouse. If the mouse is used to scroll through the list, no mouse events are triggered; `ACTION_EVENT` is generated only when the user double-clicks on an item.

With the 1.1 event model, you register an `ItemListener` with `addItemListener()` or an `ActionListener` with the `addActionListener()` method. When the user selects the `List`, either the `ItemListener.itemStateChanged()` method or the `ActionListener.actionPerformed()` method is called through the protected `List.processItemEvent()` method or `List.processActionEvent()` method. Key, mouse, and focus listeners are registered through the three `Component` methods of `addKeyListener()`, `addMouseListener()`, and `addFocusListener()`, respectively. Action

public boolean action (Event e, Object o)

The `action()` method for a `List` is called when the user double-clicks on any item in the `List`. `e` is the `Event` instance for the specific event, while `o` is the label for the item selected, from the `add()` or `addItem()` call. If `List` is in multiple-selection mode, you might not wish to catch this event because it's not clear whether the user wanted to choose the item just selected or all of the items selected. You can solve this problem by putting a multi-selecting list next to a `Button` that the user presses when the selection process is finished. Capture the event generated by the `Button`. The following example shows how to set up and handle a list in this manner, with the display shown in Figure 9.3. In this example, I just print out the selections to prove that I captured them.

```
import java.awt.*;
import java.applet.*;
public class list3 extends Applet {
   List l;
   public void init () {
        String fonts[];
        fonts = Toolkit.getDefaultToolkit().getFontList();
        l = new List(4, true);
        for (int i = 0; i < fonts.length; i++) {
            l.addItem (fonts[i]);
        }
        setLayout (new BorderLayout (10, 10));
        add ("North", new Label ("Pick Font Set"));
        add ("Center", l);
        add ("South", new Button ("Submit"));
        resize (preferredSize());
        validate();
   }
   public boolean action (Event e, Object o) {
        if (e.target instanceof Button) {
             String chosen[] = l.getSelectedItems();
             for (int i=0;i<chosen.length;i++)
                System.out.println (chosen[i]);
        }
        return false;
   }
}
```

Figure 9.3: Multiselect List

[Graphic: Figure 9-3]

Keyboard

Ordinarily, `List` generates all the `KEY` events once it has the input focus. But the way it handles keyboard input differs slightly depending upon the selection mode of the list. Furthermore, each platform offers slightly different behavior, so code that depends on keyboard events in `List` is not portable. One strategy is to take advantage of the keyboard events when they are available but allow for another way of managing the list in case they are not.

public boolean keyDown (Event e, int key)

> The `keyDown()` method is called whenever the user presses a key while the `List` has the input focus. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyDown()` could be either `KEY_PRESS` for a regular key or `KEY_ACTION` for an action-oriented key (i.e., arrow or function key). If you check the current selection in this method through `getSelectedItem()` or `getSelectedIndex()`, you will actually be told the previously selected item because the `List`'s selection has not changed yet. `keyDown()` is not called when the user selects items with the mouse.

public boolean keyUp (Event e, int key)

> The `keyUp()` method is called whenever the user releases a key while the `List` has the input focus. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyUp()` could be either `KEY_RELEASE` for a regular key or `KEY_ACTION_RELEASE` for an action-oriented key (i.e., arrow or function key).

Mouse

Ordinarily, the `List` component does not trigger any mouse events. Double-clicking the mouse over any element in the list generates an `ACTION_EVENT`. Single-clicking could result in either a

LIST_SELECT or LIST_DESELECT, depending on the mode of the List and the current state of the item chosen. When the user changes the selection with the mouse, the ACTION_EVENT is posted only when an item is double-clicked. List

There is a special pair of events for lists: LIST_SELECT and LIST_DESELECT. No special method is called when these events are triggered. However, you can catch them in the handleEvent() method. If the List is in single-selection mode, a LIST_SELECT event is generated whenever the user selects one of the items in the List. In multiple-selection mode, you will get a LIST_SELECT event when an element gets selected and a LIST_DESELECT event when it is deselected. The following code shows how to use this event type.

```
public boolean handleEvent (Event e) {
    if (e.id == Event.LIST_SELECT) {
        System.out.println ("Selected item: " + e.arg);
        return true;
    } else {
        return super.handleEvent (e);
    }
}
```

Focus

Normally, the List component does not reliably trigger any focus events. Listeners and 1.1 event handling

With the 1.1 event model, you register listeners, and they are told when the event happens.

public void addItemListener(ItemListener listener) ★

> The addItemListener() method registers listener as an object interested in being notified when an ItemEvent passes through the EventQueue with this List as its target. The listener.itemStateChanged() method is called when these events occur. Multiple listeners can be registered.

public void removeItemListener(ItemListener listener) ★

> The removeItemListener() method removes listener as an interested listener. If listener is not registered, nothing happens.

public void addActionListener(ActionListener listener) ★

The `addActionListener()` method registers `listener` as an object interested in being notified when an `ActionEvent` passes through the `EventQueue` with this `List` as its target. The `listener.actionPerformed()` method is called when these events occur. Multiple listeners can be registered.

public void removeActionListener(ActionListener listener) ★

The `removeActionListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent`s with this `List` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `List`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding the method `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processItemEvent(ItemEvent e) ★

The `processItemEvent()` method receives all `ItemEvent`s with this `List` as its target. `processItemEvent()` then passes them along to any listeners for processing. When you subclass `List`, overriding `processItemEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processItemEvent()` is like overriding `handleEvent()` to deal with `LIST_SELECT` and `LIST_DESELECT` using the 1.0 event model.

If you override `processItemEvent()`, remember to call the method `super.processItemEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processActionEvent(ActionEvent e) ★

The `processActionEvent()` method receives all `ActionEvent`s with this `List` as its target. `processActionEvent()` then passes them along to any listeners for processing. When you subclass `List`, overriding `processActionEvent()` allows you to process all action events yourself, before sending them to any listeners. In a way, overriding `processActionEvent()` is like overriding `action()` using the 1.0 event model.

If you override `processActionEvent()`, remember to call the method `super.processActionEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

9.3 Checkbox

The Checkbox is a general purpose way to record a true or false state. When several checkboxes are associated in a CheckboxGroup (CheckboxGroup), only one can be selected at a time; selecting each Checkbox causes the previous selection to become deselected. The CheckboxGroup is Java's way of offering the interface element known as radio buttons or a radio box. When you create a Checkbox, you decide whether to place it into a CheckboxGroup by setting the proper argument in its constructor.

Every Checkbox has both a label and a state, although the label could be empty. You can change the label based on the state of the Checkbox. Figure 9.4 shows what several Checkbox components might look like. The two on the left are independent, while the five on the right are in a CheckboxGroup. Note that the appearance of a Checkbox varies quite a bit from platform to platform. However, the appearance of a CheckboxGroup is always different from the appearance of an ungrouped Checkbox, and the appearance of a checked Checkbox is different from an unchecked Checkbox.

Figure 9.4: Two separate checkboxes and a CheckboxGroup

[Graphic: Figure 9-4]

Checkbox Methods

Constructors

public Checkbox ()

This constructor for `Checkbox` creates a new instance with no label or grouping. The initial state of the item is `false`. A checkbox doesn't necessarily need a label; however, a checkbox without a label might be confusing, unless it is being used as a column in a table or a spreadsheet.

public Checkbox (String label)

The second constructor creates a new `Checkbox` with a label of `label` and no grouping. The initial state of the item is `false`. If you want a simple yes/no choice and plan to make no the default, use this constructor. If the `Checkbox` will be in a group or you want its initial value to be `true`, use the next constructor.

public Checkbox (String label, boolean state) ★

This constructor allows you to specify the `Checkbox`'s initial state. With it you create a `Checkbox` with a label of `label` and an initial state of `state`.

public Checkbox (String label, boolean state, CheckboxGroup group) ★
public Checkbox (String label, CheckboxGroup group, boolean state)

The final constructor for `Checkbox` is the most flexible. With this constructor you create a `Checkbox` with a label of `label`, a `CheckboxGroup` of `group`, and an initial state of `state`. If `group` is `null`, the `Checkbox` is independent.

In Java 1.0, you created an independent `Checkbox` with an initial value of `true` by using `null` as the group:

```
Checkbox cb = new Checkbox ("Help", null, true)
```

The shape of the `Checkbox` reflects whether it's in a `CheckboxGroup` or independent. On Microsoft Windows, grouped checkboxes are represented as circles. On a UNIX system, they are diamonds. On both systems, independent checkboxes are squares.

Label

public String getLabel ()

The `getLabel()` method retrieves the current label on the `Checkbox` and returns it as a `String` object.

public synchronized void setLabel (String label)

The `setLabel()` method changes the label of the `Checkbox` to `label`. If the new label is a different size than the old one, you have to `validate()` the container after the change to ensure the entire label will be seen.

State

A state of `true` means the `Checkbox` is selected. A state of `false` means that the `Checkbox` is not selected.

public boolean getState ()

The `getState()` method retrieves the current state of the `Checkbox` and returns it as a boolean.

public void setState (boolean state)

The `setState()` method changes the state of the `Checkbox` to `state`. If the `Checkbox` is in a `CheckboxGroup` and `state` is true, the other items in the group become false.

ItemSelectable method

public Objects[] getSelectedObjects () ★

The `getSelectedObjects()` method returns the `Checkbox` label as a one-element `Object` array if it is currently selected, or `null` if the `Checkbox` is not selected. Because this method is part of the `ItemSelectable` interface, you can use it to look at the selected items in a `Choice`, `List`, or `Checkbox`.

CheckboxGroup

This section lists methods that you issue to `Checkbox` to affect its relationship to a `CheckboxGroup`. Methods provided by the `CheckboxGroup` itself can be found later in this chapter.

public CheckboxGroup getCheckboxGroup ()

The `getCheckboxGroup()` method returns the current `CheckboxGroup` for the

Checkbox. If the Checkbox is not in a group, this method returns null.

public void setCheckboxGroup (CheckboxGroup group)

The setCheckboxGroup() method allows you to insert a Checkbox into a different CheckboxGroup. To make the Checkbox independent, pass a group argument of null. The method sets every Checkbox in the original CheckboxGroup to false (cb.getCheckboxGroup().setCurrent(null)), then the Checkbox is added to the new group without changing any values in the new group.

Checkbox components take on a different shape when they are in a CheckboxGroup. If the checkbox was originally not in a CheckboxGroup, the shape of the checkbox does not change automatically when you put it in one with setCheckboxGroup(). (This also holds when you remove a Checkbox from a CheckboxGroup and make it independent or vice versa.) In order for the Checkbox to look right once added to group, you need to destroy and create (removeNotify() and addNotify(), respectively) the Checkbox peer to correct the shape. Also, it is possible to get multiple true Checkbox components in group this way, since the new CheckboxGroup's current selection does not get adjusted. To avoid this problem, make sure it is grouped properly the first time, or be sure to clear the selections with a call to getCheckboxGroup().setCurrent(null).

Miscellaneous methods

public synchronized void addNotify ()

The addNotify() method will create the Checkbox peer in the appropriate shape. If you override this method, call super.addNotify() first, then add your customizations for the new class. You will then be able to do everything you need with the information about the newly created peer.

protected String paramString ()

When you call the toString() method of Checkbox, the default toString() method of Component is called. This in turn calls paramString() which builds up the string to display. At the Checkbox level, the label (if non-null) and the state of the item are appended. Assuming the Dialog Checkbox in Figure 9.4 was selected, the results would be:

```
java.awt.Checkbox[85,34,344x32,label=Dialog,state=true]
```

Checkbox Events

The primary event for a Checkbox occurs when the user selects it. With the 1.0 event model, this generates an ACTION_EVENT and triggers the action() method. Once the Checkbox has the input focus, the various keyboard events can be generated, but they do not serve any useful purpose because the Checkbox doesn't change. The sole key of value for a Checkbox is the spacebar. This may generate the ACTION_EVENT after KEY_PRESS and KEY_RELEASE; thus the sequence of method calls would be keyDown(), keyUp(), and then action().

With the version 1.1 event model, you register an ItemListener with the method addItemListener(). Then when the user selects the Checkbox, the method ItemListener.itemStateChanged() is called through the protected Checkbox.processItemEvent() method. Key, mouse, and focus listeners are registered through the Component methods of addKeyListener(), addMouseListener(), and addFocusListener(), respectively. Action

public boolean action (Event e, Object o)

> The action() method for a Checkbox is called when the user selects it. e is the Event instance for the specific event, while o is the opposite of the old state of the toggle. If the Checkbox was true when it was selected, o will be false. Likewise, if it was false, o will be true. This incantation sounds unnecessarily complex, and for a single Checkbox, it is: o is just the new state of the Checkbox. The following code uses action() with a single Checkbox.
>
> ```
> public boolean action (Event e, Object o) {
>     if (e.target instanceof Checkbox) {
>         System.out.println ("Checkbox is now " + o);
>     }
>     return false;
> }
> ```
>
> On the other hand, if the Checkbox is in a CheckboxGroup, o is still the opposite of the old state of the toggle, which may or may not be the new state of the Checkbox. If the Checkbox is initially false, o will be true, and the Checkbox's new state will be true. However, if the Checkbox is initially true, selecting the Checkbox doesn't change anything because one Checkbox in the group must always be true. In this case, o is false (the opposite of the old state), though the Checkbox's state remains true.
>
> Therefore, if you're working with a CheckboxGroup and need to do something once when the selection changes, perform your action only when o is true. To find out which Checkbox was actually chosen, you need to call the getLabel() method for the target of event e. (It would be nice if o gave us the label of the Checkbox that was selected, but it doesn't.) An example of this follows:

```
public boolean action (Event e, Object o) {
    if (e.target instanceof Checkbox) {
        System.out.println (((Checkbox)(e.target)).getLabel() +
            " was selected.");
        if (new Boolean (o.toString()).booleanValue()) {
            System.out.println ("New option chosen");
        } else {
            System.out.println ("Use re-selected option");
        }
    }
    return false;
}
```

One other unfortunate twist of `CheckboxGroup`: it would be nice if there was some easy way to find out about checkboxes that change state without selection--for example, if you could find out which `Checkbox` was deselected when a new `Checkbox` was selected. Unfortunately, you can't, except by keeping track of the state of all your checkboxes at all times. When a `Checkbox` state becomes `false` because another `Checkbox` was selected, no additional event is generated, in either Java 1.0 or 1.1. Keyboard

`Checkbox`es are able to capture keyboard-related events once the `Checkbox` has the input focus, which happens when it is selected. If you can find a use for this, you can use `keyDown()` and `keyUp()`. For most interface designs I can think of, `action()` is sufficient. A possible use for keyboard events is to jump to other `Checkbox` options in a `CheckboxGroup`, but I think that is more apt to confuse users than help.

public boolean keyDown (Event e, int key)

> The `keyDown()` method is called whenever the user presses a key while the `Checkbox` has the input focus. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyDown()` could be either `KEY_PRESS` for a regular key or `KEY_ACTION` for an action-oriented key (i.e., arrow or function key). There is no visible indication that the user has pressed a key over the checkbox.

public boolean keyUp (Event e, int key)

> The `keyUp()` method is called whenever the user releases a key while the `Checkbox` has the input focus. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyUp()` could be either `KEY_RELEASE` for a regular key or `KEY_ACTION_RELEASE` for an action-oriented key (i.e., arrow or function key). `keyUp()` may be used to determine how long `key` has been

pressed.

Mouse

Ordinarily, the `Checkbox` component does not reliably trigger any mouse events. Focus

Ordinarily, the `Checkbox` component does not reliably trigger any focus events. Listeners and 1.1 event handling

With the 1.1 event model, you register listeners, and they are told when the event happens.

public void addItemListener(ItemListener listener) ★

The `addItemListener()` method registers `listener` as an object interested in being notified when an `ItemEvent` passes through the `EventQueue` with this `Checkbox` as its target. Then, the `listener.itemStateChanged()` method will be called. Multiple listeners can be registered.

public void removeItemListener(ItemListener listener) ★

The `removeItemListener()` method removes `listener` as a interested listener. If listener is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives every `AWTEvent` with this `Checkbox` as its target. `processEvent()` then passes it along to any listeners for processing. When you subclass `Checkbox`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processItemEvent(ItemEvent e) ★

The `processItemEvent()` method receives every `ItemEvent` with this `Checkbox` as its target. `processItemEvent()` then passes it along to any listeners for processing. When you subclass `Checkbox`, overriding `processItemEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processItemEvent()` is like overriding `action()` using the 1.0 event model.

If you override `processItemEvent()`, remember to call the method `super.processItemEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

Lists | BOOK INDEX | CheckboxGroup

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9.4 CheckboxGroup

The `CheckboxGroup` lets multiple checkboxes work together to provide a mutually exclusion choice (at most one `Checkbox` can be selected at a time). Because the `CheckboxGroup` is neither a `Component` nor a `Container`, you should normally put all the `Checkbox` components associated with a `CheckboxGroup` in their own `Panel` (or other `Container`). The `LayoutManager` of the `Panel` should be `GridLayout (0, 1)` if you want them in one column. Figure 9.5 shows both a good way and bad way of positioning a set of `Checkbox` items in a `CheckboxGroup`. The image on the left is preferred because the user can sense that the items are grouped; the image on the right suggests three levels of different checkboxes and can therefore surprise the user when checkboxes are deselected.

Figure 9.5: Straightforward and confusing layouts of Checkbox components

[Graphic: Figure 9-5]

CheckboxGroup Methods

Constructors

public CheckboxGroup ()

> This constructor creates an instance of `CheckboxGroup`.

Miscellaneous methods

public int getSelectedCheckbox () ★
public Checkbox getCurrent () ☆

> The `getSelectedCheckbox()` method returns the `Checkbox` within the `CheckboxGroup` whose value is `true`. If no item is selected, `null` is returned.
>
> `getCurrent()` is the Java 1.0 name for this method.

public synchronized void setSelectedCheckbox (Checkbox checkbox) ★
public synchronized void setCurrent (Checkbox checkbox) ☆

> The `setSelectedCheckbox()` method makes `checkbox` the currently selected `Checkbox` within the `CheckboxGroup`. If `checkbox`is `null`, the method deselects all the items in the `CheckboxGroup`. If `checkbox` is not within the `CheckboxGroup`, nothing happens.
>
> `setCurrent()` is the Java 1.0 name for this method.

public String toString ()

> The `toString()` method of `CheckboxGroup` creates a `String` representation of the current choice (as returned by `getSelectedCheckbox()`). Using the "straightforward" layout in Figure 9.5 as an example, the results would be:

```
java.awt.CheckboxGroup[current=java.awt.Checkbox[0,31,85x21,
    label=Helvetica,state=true]]
```

> If there is no currently selected item, the results within the square brackets would be `current=null`.

10.3 MenuShortcut

`MenuShortcut` is a class used to represent a keyboard shortcut for a `MenuItem`. When these events occur, an action event is generated that triggers the menu component. When a shortcut is associated with a `MenuItem`, the `MenuItem` automatically displays a visual clue, which indicates that a keyboard accelerator is available.

MenuShortcut Methods

Constructors

public MenuShortcut (int key) ★

> The first `MenuShortcut` constructor creates a `MenuShortcut` with `key` as its designated hot key. The `key` parameter can be any of the virtual key codes from the `KeyEvent` class (e.g., VK_A, VK_B, etc.). These constants are listed in Table 4.4. To use the shortcut, the user must combine the given `key` with a platform-specific modifier key. On Windows and Motif platforms, the modifier is the Control key; on the Macintosh, it is the Command key. For example, if the shortcut key is F1 (`VK_F1`) and you're using Windows, you would press Ctrl+F1 to execute the shortcut. To find out the platform's modifier key, call the `Toolkit.getMenuShortcutKeyMask()` method.

public MenuShortcut(int key, boolean useShiftModifier) ★

> This `MenuShortcut` constructor creates a `MenuShortcut` with `key` as its designated hot key. If `useShiftModifier` is `true`, the Shift key must be depressed for this shortcut to trigger the action event (in addition to the shortcut key). The `key` parameter represents the integer value of a `KEY_PRESS` event, so in addition to ASCII values, possible values include the various `Event` keyboard constants (listed in Table 4.2) like `Event.F1`, `Event.HOME`, and

Event.PAUSE. For example, if key is the ASCII value for A and useShiftModifier is true, the shortcut key is Shift+Ctrl+A on a Windows/Motif platform.

Miscellaneous methods

public int getKey () ★

The getKey() method retrieves the virtual key code for the key that triggered this MenuShortcut. The virtual key codes are the VK constants defined by the KeyEvent class (see Table 4.4).

public boolean usesShiftModifier() ★

The usesShiftModifier() method returns true if this MenuShortcut requires the Shift key be pressed, false otherwise.

public boolean equals(MenuShortcut s) ★

The equals() method overrides Object's equals() method to define equality for menu shortcuts. Two MenuShortcut objects are equal if their key and useShiftModifier values are equal.

protected String paramString () ★

The paramString() method of MenuShortcut helps build up a string describing the shortcut; it appends the shortcut key and a shift modifier indicator to the string under construction. Oddly, this method is not currently used, nor can you call it; MenuShortcut has its own toString() method that does the job itself.

public String toString() ★

The toString() method of MenuShortcut builds a String to display the contents of the MenuShortcut.

MenuContainer | BOOK INDEX | MenuItem

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

10.4 MenuItem

A `MenuItem` is the basic item that goes on a `Menu`. Menus themselves are menu items, allowing submenus to be nested inside of menus. `MenuItem` is a subclass of `MenuComponent`.

MenuItem Methods

Constructors

public MenuItem () ★

> The first `MenuItem` constructor creates a `MenuItem` with an empty label and no keyboard shortcut. To set the label at later time, use `setLabel()`.

public MenuItem (String label)

> This `MenuItem` constructor creates a `MenuItem` with a label of `label` and no keyboard shortcut. A label of "-" represents a separator.

public MenuItem (String label, MenuShortcut shortcut) ★

> The final `MenuItem` constructor creates a `MenuItem` with a label of `label` and a `MenuShortcut` of `shortcut`. Pressing the shortcut key is the same as selecting the menu item.

Menu labels

Each `MenuItem` has a label. This is the text that is displayed on the menu.

NOTE:

Prior to Java 1.1, there was no portable way to associate a hot key with a `MenuItem`. However, in Java 1.0, if you precede a character with an & on a Windows platform, it will appear underlined, and that key will act as the menu's mnemonic key (a different type of shortcut from `MenuShortcut`). Unfortunately, on a Motif platform, the user will see the &. Because the & is part of the label, even if it is not displayed, you must include it explicitly whenever you compare the label to a string.

public String getLabel ()

The `getLabel()` method retrieves the label associated with the `MenuItem`.

public void setLabel (String label)

The `setLabel()` method changes the label of the `MenuItem` to `label`.

Shortcuts

public MenuShortcut getMenuShortcut () ★

The `getMenuShortcut()` method retrieves the shortcut associated with this `MenuItem`.

public void setShortcut (MenuShortcut shortcut) ★

The `setShortcut()` method allows you to change the shortcut associated with a `MenuItem` to `shortcut` after the `MenuItem` has been created.

public void deleteMenuShortcut () ★

The `deleteMenuShortcut()` method removes any associated `MenuShortcut` from the `MenuItem`. If there was no shortcut, nothing happens.

Enabling

public boolean isEnabled ()

The `isEnabled()` method checks to see if the `MenuItem` is currently enabled. An enabled `MenuItem` can be selected by the user. A disabled `MenuItem`, by convention, appears grayed out on the `Menu`. Initially, each `MenuItem` is enabled.

public synchronized void setEnabled(boolean b) ★
public void enable (boolean condition) ☆

> The setEnabled() method either enables or disables the MenuItem based on the value of condition. If condition is true, the MenuItem is enabled. If condition is false, it is disabled. When enabled, the user can select it, generating ACTION_EVENT or notifying the ActionListener. When disabled, the peer does not generate an ACTION_EVENT if the user tries to select the MenuItem. A disabled MenuItem is usually grayed out to signify its state. The way that disabling is signified is platform specific.
>
> enable() is the Java 1.0 name for this method.

public synchronized void enable () ☆

> The enable() method enables the MenuItem. In Java 1.1, it is better to use setEnabled().

public synchronized void disable () ☆

> The disable() method disables the component so that the user cannot select it. In Java 1.1, it is better to use setEnabled().

Miscellaneous methods

public synchronized void addNotify ()

> The addNotify() method creates the MenuItem peer.

public String paramString ()

> The paramString() method of MenuItem should be protected like other paramString() methods. However, it is public so you have access to it. When you call the toString() method of a MenuItem, the default toString() method of MenuComponent is called. This in turn calls paramString() which builds up the string to display. At the MenuItem level, the current label of the object and the shortcut (if present) is appended to the output. If the constructor for the MenuItem was new MenuItem(`File`), the results of toString() would be:

```
java.awt.MenuItem[label=File]
```

MenuItem Events

Event handling

With 1.0 event handing, a `MenuItem` generates an `ACTION_EVENT` when it is selected. The argument to `action()` will be the label of the `MenuItem`. But the target of the `ACTION_EVENT` is the `Frame` containing the menu. You cannot subclass `MenuItem` and catch the `Event` within it with `action()`, but you can with `postEvent()`. No other events are generated for `MenuItem` instances.

public boolean action (Event e, Object o)--overridden by user, called by system

The `action()` method for a `MenuItem` signifies that the user selected it. `e` is the `Event` instance for the specific event, while `o` is the label of the `MenuItem`.

Listeners and 1.1 event handling

With the 1.1 event model, you register listeners, and they are told when the event happens.

public String getActionCommand() ★

The `getActionCommand()` method retrieves the command associated with this `MenuItem`. By default, it is the label. However, the default can be changed by using the `setActionCommand()` method (described next). The command acts like the second parameter to the `action()` method in the 1.0 event model.

public void setActionCommand(String command) ★

The `setActionCommand()` method changes the command associated with a `MenuItem`. When an `ActionEvent` happens, the `command` is part of the event. By default, this would be the label of the `MenuItem`. However, you can change the action command by calling this method. Using action commands is a good idea, particularly if you expect your code to run in a multilingual environment.

public void addActionListener(ItemListener listener) ★

The `addActionListener()` method registers `listener` as an object interested in being notified when an `ActionEvent` passes through the `EventQueue` with this `MenuItem` as its target. The `listener.actionPerformed()` method is called whenever these events occur. Multiple listeners can be registered.

public void removeActionListener(ItemListener listener) ★

The `removeActionListener()` method removes `listener` as an interested listener. If `listener` is not registered, nothing happens.

protected final void enableEvents(long eventsToEnable) ★

Using the `enableEvents()` method is usually not necessary. When you register an action listener, the `MenuItem` listens for action events. However, if you wish to listen for events when listeners are not registered, you must enable the events explicitly by calling this method. The settings for the `eventsToEnable` parameter are found in the `AWTEvent` class; you can use any of the `EVENT_MASK` constants like `COMPONENT_EVENT_MASK`, `MOUSE_EVENT_MASK`, and `WINDOW_EVENT_MASK` ORed together for the events you care about. For instance, to listen for action events, call:

```
enableEvents (AWTEvent.ACTION_EVENT_MASK);
```

protected final void disableEvents(long eventsToDisable) ★

Using the `disableEvents()` method is usually not necessary. When you remove an action listener, the `MenuItem` stops listening for action events if there are no more listeners. However, if you need to, you can disable events explicitly by calling `disableEvents()`. The settings for the `eventsToDisable` parameter are found in the `AWTEvent` class; you can use any of the `EVENT_MASK` constants such as `FOCUS_EVENT_MASK`, `MOUSE_MOTION_EVENT_MASK`, and `ACTION_EVENT_MASK` ORed together for the events you no longer care about.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent`s with this `MenuItem` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `MenuItem`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `postEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` to ensure that events are delivered even in the absence of registered listeners.

protected void processActionEvent(ItemEvent e) ★

The `processActionEvent()` method receives all `ActionEvent`s with this `MenuItem` as its target. `processActionEvent()` then passes them along to any listeners for processing.

When you subclass `MenuItem`, overriding `processActionEvent()` allows you to process all action events yourself, before sending them to any listeners. In a way, overriding `processActionEvent()` is like overriding `action()` using the 1.0 event model.

If you override `processActionEvent()`, remember to call the method `super.processActionEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` to ensure that events are delivered even in the absence of registered listeners.

10.5 Menu

`Menu`s are the pull-down objects that appear on the `MenuBar` of a `Frame` or within other menus. They contain `MenuItem`s or `CheckboxMenuItem`s for the user to select. The `Menu` class subclasses `MenuItem` (so it can appear on a `Menu`, too) and implements `MenuContainer`. Tear-off menus are menus that can be dragged, placed elsewhere on the screen, and remain on the screen when the input focus moves to something else. Java supports tear-off menus if the underlying platform does. Motif (UNIX) supports tear-off menus; Microsoft Windows platforms do not.

Menu Methods

Constructors

public Menu () ★

> The first constructor for `Menu` creates a menu that has no label and cannot be torn off. To set the label at a later time, use `setLabel()`.

public Menu (String label)

> This constructor for `Menu` creates a `Menu` with `label` displayed on it. The `Menu` cannot be torn off.

public Menu (String label, boolean tearOff)

> This constructor for `Menu` creates a `Menu` with `label` displayed on it. The handling of `tearOff` is platform dependent.
>
> Figure 10.3 shows a tear-off menu for Windows NT/95 and Motif. Since Windows does not

support tear-off menus, the Windows menu looks and acts like a regular menu.

Figure 10.3: Tear-off menu

[Graphic: Figure 10-3]

Items

public int getItemCount() ★
public int countItems () ☆

The `getItemCount()` method returns the number of items within the `Menu`. Only top-level items are counted: if an item is a submenu, this method doesn't include the items on it.

`countItems()` is the Java 1.0 name for this method.

public MenuItem getItem (int index)

The `getItem()` method returns the `MenuItem` at position `index`. If `index` is invalid, `getItem()` throws the `ArrayIndexOutOfBoundsException` run-time exception.

public synchronized MenuItem add (MenuItem item)

The `add()` method puts `item` on the menu. The label assigned to `item` when it was created is displayed on the menu. If `item` is already in another menu, it is removed from that menu. If `item` is a `Menu`, it creates a submenu. (Remember that `Menu` subclasses `MenuItem`.)

public void add (String label)

This version of `add()` creates a `MenuItem` with `label` as the text and adds that to the menu. If `label` is the `String` "-", a separator bar is added to the `Menu`.

public synchronized void insert(MenuItem item, int index) ★

The `insert()` method puts `item` on the menu at position `index`. The label assigned to `item` when it was created is displayed on the menu. Positions are zero based, and if `index` < 0, `insert()` throws the `IllegalArgumentException` run-time exception.

public synchronized void insert(String label, int index) ★

This version of `insert()` method creates a `MenuItem` with `label` as the text and adds that to the menu at position `index`. If `label` is the String "--", a separator bar is added to the `Menu`. Positions are zero based, and if `index` < 0, this method throws the `IllegalArgumentException` run-time exception.

public void addSeparator ()

The `addSeparator()` method creates a separator `MenuItem` and adds that to the menu. Separator menu items are strictly cosmetic and do not generate events when selected.

public void insertSeparator(int index) ★

The `insertSeparator()` method creates a separator `MenuItem` and adds that to the menu at position `index`. Separator menu items are strictly cosmetic and do not generate events when selected. Positions are zero based. If `index` < 0, `insertSeparator()` throws the `IllegalArgumentException` run-time exception.

public synchronized void remove (int index)

The `remove()` method removes the `MenuItem` at position `index` from the `Menu`. If `index` is invalid, `remove()` throws the `ArrayIndexOutOfBoundsException` run-time exception. `index` is zero based, so it can range from 0 to `getItemCount()-1`.

public synchronized void remove (MenuComponent component)

This version of `remove()` removes the menu item `component` from the `Menu`. If component is not in the `Menu`, nothing happens.

public synchronized void removeAll()

The `removeAll()` removes all `MenuItems` from the `Menu`.

Peers

public synchronized void addNotify ()

> The addNotify() method creates the Menu peer with all the MenuItems on it.

public synchronized void removeNotify ()

> The removeNotify() method destroys the peer of the MenuComponent and removes it from the screen. The peers of the items on the menu are also destroyed.

Miscellaneous methods

public boolean isTearOff ()

> The isTearOff() method returns true if this Menu is a tear-off menu, and false otherwise. Once a menu is created, there is no way to change the tear-off setting. This method can return true even on platforms that do not support tear-off menus.

public String paramString () ★

> The paramString() method of Menu should be protected like other paramString() methods. However, it is public so you have access to it. When you call the toString() method of a Menu, the default toString() method of MenuComponent is called. This in turn calls paramString(), which builds up the string to display. At the Menu level, the setting for TearOff (from constructor) and whether or not it is the help menu (from MenuBar.setHelpMenu()) for the menu bar are added. If the constructor for the Menu was new Menu (`File`), the results of toString() would be:

```
java.awt.Menu [menu0,label=File,tearOff=false,isHelpMenu=false]
```

Menu Events

A Menu does not generate any event when it is selected. An event is generated when a MenuItem on the menu is selected, as long as it is not another Menu. You can capture all the events that happen on a Menu by overriding postEvent().

PREVIOUS
MenuItem

BOOK INDEX
NEXT
CheckboxMenuItem

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

10.6 CheckboxMenuItem

The `CheckboxMenuItem` is a subclass of `MenuItem` that can be toggled. It is similar to a `Checkbox` but appears on a `Menu`. The appearance depends upon the platform. There may or may not be a visual indicator next to the choice. However, when the `MenuItem` is selected (`true`), a checkmark or some similar graphic will be displayed next to the label.

There is no way to put `CheckboxMenuItem` components into a `CheckboxGroup` to form a radio menu group.

An example of a `CheckboxMenuItem` is the Show Java Console menu item in Netscape Navigator.

CheckboxMenuItem Methods

Constructors

public CheckboxMenuItem (String label)

> The first `CheckboxMenuItem` constructor creates a `CheckboxMenuItem` with no label displayed next to the check toggle. The initial value of the `CheckboxMenuItem` is `false`. To set the label at a later time, use `setLabel()`.

public CheckboxMenuItem (String label)

> The next `CheckboxMenuItem` constructor creates a `CheckboxMenuItem` with `label` displayed next to the check toggle. The initial value of the `CheckboxMenuItem` is `false`.

public CheckboxMenuItem (String label, boolean state)

> The final `CheckboxMenuItem` constructor creates a `CheckboxMenuItem` with `label`

displayed next to the check toggle. The initial value of the `CheckboxMenuItem` is `state`.

Selection

public boolean getState ()

The `getState()` method retrieves the current state of the `CheckboxMenuItem`.

public void setState (boolean condition)

The `setState()` method changes the current state of the `CheckboxMenuItem` to `condition`. When `true`, the `CheckboxMenuItem` will have the toggle checked.

public Object[] getSelectedObjects () ★

The `getSelectedItems()` method returns the currently selected item as an `Object` array. This method, which is required by the `ItemSelectable` interface, allows you to use the same methods to retrieve the selected items of any `Checkbox`, `Choice`, or `List`. The array has at most one element, which contains the label of the selected item; if no item is selected, `getSelectedItems()` returns `null`.

Miscellaneous methods

public synchronized void addNotify ()

The `addNotify()` method creates the `CheckboxMenuItem` peer.

public String paramString ()

The `paramString()` method of `CheckboxMenuItem` should be protected like other `paramString()` methods. However, it is public, so you have access to it. When you call the `toString()` method of a `CheckboxMenuItem`, the default `toString()` method of `MenuComponent` is called. This in turn calls `paramString()` which builds up the string to display. At the `CheckboxMenuItem` level, the current state of the object is appended to the output. If the constructor for the `CheckboxMenuItem` was ``new CheckboxMenuItem(`File`)`` the results would be:

```
java.awt.CheckboxMenuItem[label=File,state=false]
```

CheckboxMenuItem Events

Event handling

A `CheckboxMenuItem` generates an `ACTION_EVENT` when it is selected. The argument to `action()` is the label of the `CheckboxMenuItem`, like the method provided by `MenuItem`, not the state of the `CheckboxMenuItem` as used in `Checkbox`. The target of the `ACTION_EVENT` is the `Frame` containing the menu. You cannot subclass `CheckboxMenuItem` and handle the `Event` within the subclass unless you override `postEvent()`. Listeners and 1.1 event handling

With the Java 1.1 event model, you register listeners, which are told when the event happens.

public void addItemListener(ItemListener listener) ★

The `addItemListener()` method registers `listener` as an object that is interested in being notified when an `ItemEvent` passes through the `EventQueue` with this `CheckboxMenuItem` as its target. When these item events occur, the `listener.itemStateChanged()` method is called. Multiple listeners can be registered.

public void removeItemListener(ItemListener listener) ★

The `removeItemListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives every `AWTEvent` with this `CheckboxMenuItem` as its target. `processEvent()` then passes it along to any listeners for processing. When you subclass `CheckboxMenuItem`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `postEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` to ensure that events are delivered, even in the absence of registered listeners.

protected void processItemEvent(ItemEvent e) ★

The `processItemEvent()` method receives every `ItemEvent` with this `CheckboxMenuItem` as its target. `processItemEvent()` then passes it along to any listeners for processing. When you subclass `CheckboxMenuItem`, overriding `processItemEvent()` allows you to process all item events yourself, before sending them to any listeners. In a way, overriding `processItemEvent()` is like overriding `action()` using the 1.0 event model.

If you override `processItemEvent()`, remember to call the method `super.processItemEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` to ensure that events are delivered even in the absence of registered listeners.

10.7 MenuBar

The `MenuBar` is the component you add to the `Frame` that is displayed on the top line of the `Frame`; the `MenuBar` contains menus. A `Frame` can display only one `MenuBar` at a time. However, you can change the `MenuBar` based on the state of the program so that different menus can appear at different points. The `MenuBar` class extends `MenuComponent` and implements the `MenuContainer` interface.

A `MenuBar` can be used only as a child component of a `Frame`. An applet cannot have a `MenuBar` attached to it, unless you implement the whole thing yourself. Normally, you cannot modify the `MenuBar` of the applet holder (the browser), unless it is Java based. In other words, you cannot affect the menus of Netscape Navigator, but you can customize *appletviewer* and HotJava, as shown in the following code with the result shown in Figure 10.4. The `getTopLevelParent()` method was introduced in Window with `Window`.

```
import java.awt.*;
public class ChangeMenu extends java.applet.Applet {
    public void init ()  {
        Frame f = ComponentUtilities.getTopLevelParent(this);
        if (f != null) {
            MenuBar mb = f.getMenuBar();
            Menu m = new Menu ("Cool");
            mb.add (m);
        }
    }
}
```

Figure 10.4: Customizing appletviewer's MenuBar

[Graphic: Figure 10-4]

NOTE:

When you add a MenuBar to a Frame, it takes up space that is part of the drawing area. You need to get the top insets to find out how much space is occupied by the MenuBar and be careful not to draw under it. If you do, the MenuBar will cover what you draw.

MenuBar Methods

Constructors

public MenuBar()

The MenuBar constructor creates an empty MenuBar. To add menus to the MenuBar, use the add()method.

Menus

public int getMenuCount () ★
public int countMenus () ☆

The getMenuCount() method returns the number of top-level menus within the MenuBar.

countMenus() is the Java 1.0 name for this method.

public Menu getMenu (int index)

The getMenu() method returns the Menu at position index. If index is invalid, getMenu() throws the run-time exception ArrayIndexOutOfBoundsException.

public synchronized Menu add (Menu m)

The `add()` method puts choice `m` on the `MenuBar`. The label used to create `m` is displayed on the `MenuBar`. If `m` is already in another `MenuBar`, it is removed from it. The order of items added determines the order displayed on the `MenuBar`, with one exception: if a menu is designated as a help menu by `setHelpMenu()`, it is placed at the right end of the menu bar. Only a `Menu` can be added to a `MenuBar`; you can't add a `MenuItem`. In other words, a `MenuItem` has to lie under at least one menu.

public synchronized void remove (int index)

The `remove()` method removes the `Menu` at position `index` from the `MenuBar`. If `index` is invalid, `remove()` throws the `ArrayIndexOutOfBoundsException` run-time exception. `index` is zero based.

public synchronized void remove (MenuComponent component)

This version of `remove()` removes the menu `component` from the `MenuBar`. If `component` is not in `MenuBar`, nothing happens. The system calls this method when you add a new `Menu` to make sure it does not exist on another `MenuBar`.

Shortcuts

public MenuItem getShortcutMenuItem (MenuShortcut shortcut) ★

The `getShortcutMenuItem()` method retrieves the `MenuItem` associated with the `MenuShortcut shortcut`. If `MenuShortcut` does not exist for this `Menu`, the method returns `null`. `getShortcutMenuItem()` walks through the all submenus recursively to try to find `shortcut`.

public synchronized Enumeration shortcuts() ★

The `shortcuts()` method retrieves an `Enumeration` of all the `MenuShortcut` objects associated with this `MenuBar`.

public void deleteShortcut (MenuShortcut shortcut) ★

The `deleteShortcut()` method removes `MenuShortcut` from the associated `MenuItem` in the `MenuBar`. If the shortcut is not associated with any menu item, nothing happens.

Help menus

It is the convention on many platforms to display help menus as the last menu on the `MenuBar`. The

MenuBar class lets you designate one of the menus as this special menu. The physical position of a help menu depends on the platform, but those giving special treatment to help menus place them on the right. A Menu designated as a help menu doesn't have to bear the label "Help"; the label is up to you.

public Menu getHelpMenu ()

> The getHelpMenu() method returns the Menu that has been designated as the help menu with setHelpMenu(). If the menu bar doesn't have a help menu, getHelpMenu() returns null.

public synchronized void setHelpMenu (Menu m)

> The setHelpMenu() method sets the menu bar's help menu to m. This makes m the rightmost menu on the MenuBar, possibly right justified. If m is not already on the MenuBar, nothing happens.

Peers

public synchronized void addNotify ()

> The addNotify() method creates the MenuBar peer with all the menus on it, and in turn their menu items.

public synchronized void removeNotify ()

> The removeNotify() method destroys the peer of the MenuBar and removes it from the screen. The peers of the items on the MenuBar are also destroyed.

MenuBar Events

A MenuBar does not generate any events.

10.8 Putting It All Together

Now that you know about all the different menu classes, it is time to show an example. Example 10.1 contains the code to put up a functional `MenuBar` attached to a `Frame`, using the 1.0 event model. Figure 10.2 (earlier in the chapter) displays the resulting screen. The key parts to examine are how the menus are put together in the `MenuTest` constructor and how their actions are handled within `action()`. I implement one real action in the example: the one that terminates the application when the user chooses Quit. Any other action just displays the label of the item and (if it was a `CheckBoxMenuItem`) the item's state, to give you an idea of how you can use the information returned in the event.

Example 10.1: MenuTest 1.0 Source Code

```
import java.awt.*;
public class MenuTest extends Frame {
    MenuTest () {
        super ("MenuTest");
        MenuItem mi;
        Menu file = new Menu ("File", true);
        file.add ("Open");
        file.add (mi = new MenuItem ("Close"));
        mi.disable();
        Menu extras = new Menu ("Extras", false);
        extras.add (new CheckboxMenuItem ("What"));
        extras.add ("Yo");
        extras.add ("Yo");
        file.add (extras);
        file.addSeparator();
        file.add ("Quit");
        Menu help = new Menu("Help");
        help.add ("About");
        MenuBar mb = new MenuBar();
        mb.add (file);
        mb.add (help);
        mb.setHelpMenu (help);
        setMenuBar (mb);
        resize (200, 200);
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            System.exit(0);
        }
        return super.handleEvent (e);
    }
    public boolean action (Event e, Object o) {
        if (e.target instanceof MenuItem) {
            if ("Quit".equals (o)) {
                dispose();
                System.exit(1);
            } else {
                System.out.println ("User selected " + o);
                if (e.target instanceof CheckboxMenuItem) {
                    CheckboxMenuItem cb = (CheckboxMenuItem)e.target;
                    System.out.println ("The value is: " + cb.getState());
                }
            }
            return true;
        }
        return false;
    }
    public static void main (String []args) {
        MenuTest f = new MenuTest ();
        f.show();
    }
}
```

The `MenuTest` constructor builds all the menus, creates a menu bar, adds the menus to the menu bar, and adds the menu bar to the `Frame`. To show what is possible, I've included a submenu, a separator bar, a disabled item, and a help menu.

The `handleEvent()` method exists to take care of `WINDOW_DESTROY` events, which are generated if the user uses a native command to exit from the window.

The `action()` method does the work; it received the action events generated whenever the user selects a menu. We ignore most of them, but a real application would need to do more work figuring out the user's selection. As it is, `action()` is fairly simple. If the user selected a menu item, we check to see whether the item's label was "Quit"; if it was, we exit. If the user selected anything else, we print the selection and return `true` to indicate that we handled the event.

Using Java 1.1 Events

Example 10.2 uses the Java 1.1 event model but is otherwise very similar to Example 10.1. Take a close look at the differences and similarities. Although the code that builds the GUI is basically the same in both examples, the event handling is completely different. The helper class `MyMenuItem` is necessary to simplify event handling. In Java 1.1, every menu item can be an event source, so you have to register a listener for each item. Rather than calling `addActionListener()` explicitly for each item, we create a subclass of `MenuItem` that registers a listener automatically. The listener is specified in the constructor to `MyMenuItem`; in this example, the object that creates the menus (`MenuTest12`) always registers itself as the listener. An alternative would be to override `processActionEvent()` in `MyMenuItem`, but then we'd also need to write a subclass for `CheckboxMenuItem`.

Having said all that, the code is relatively simple. `MenuTest12` implements `ActionListener` so it can receive action events from the menus. As I noted previously, it registers itself as the listener for every menu item when it builds the interface. The `actionPerformed()` method is called whenever the user selects a menu item; the logic of this method is virtually the same as it was in Example 10.1. Notice, though, that we use `getActionCommand()` to read the label of the menu item. (Note also that `getActionCommand()` doesn't necessarily return the label; you can change the command associated with the menu item by calling `setActionCommand()`.) Similarly, we call the event's `getSource()` method to get the menu item that actually generated the event; we need this to figure out whether the user selected a `CheckboxMenuItem` (which implements `ItemSelectable`).

We override `processWindowEvent()` so that we can receive `WINDOW_CLOSING` events without registering a listener. Window closings occur when the user uses the native display manager to close the application. If one of these events arrives, we shut down cleanly. To make sure that we receive window events even if there are no listeners, the `MenuTest12` constructor calls `enableEvents(WINDOW_EVENT_MASK)`.

Example 10.2: MenuTest12 Source Code, Using Java 1.1 Event Handling

```
// Java 1.1 only
import java.awt.*;
import java.awt.event.*;
public class MenuTest12 extends Frame implements ActionListener {
    class MyMenuItem extends MenuItem {
        public MyMenuItem (String s, ActionListener al) {
            super (s);
            addActionListener (al);
        }
    }
    public MenuTest12 () {
        super ("MenuTest");
        MenuItem mi;
        Menu file = new Menu ("File", true);
        file.add (new MyMenuItem ("Open", this));
        mi = file.add (new MyMenuItem ("Close", this));
        mi.setEnabled (false);
        Menu extras = new Menu ("Extras", false);
        mi = extras.add (new CheckboxMenuItem ("What"));
        mi.addActionListener(this);
        mi = extras.add (new MyMenuItem ("Yo", this));
        mi.setActionCommand ("Yo1");
        mi = extras.add (new MyMenuItem ("Yo", this));
        mi.setActionCommand ("Yo2");
        file.add (extras);
        file.addSeparator();
        file.add (new MyMenuItem ("Quit", this));
        Menu help = new Menu("Help");
        help.add (new MyMenuItem ("About", this));
        MenuBar mb = new MenuBar();
        mb.add (file);
        mb.add (help);
        mb.setHelpMenu (help);
        setMenuBar (mb);
        setSize (200, 200);
        enableEvents (AWTEvent.WINDOW_EVENT_MASK);
    }
// Cannot override processActionEvent since method of MenuItem
// Would have to subclass both MenuItem and CheckboxMenuItem
    public void actionPerformed(ActionEvent e) {
        if (e.getActionCommand().equals("Quit")) {
            System.exit(0);
        }
        System.out.println ("User selected " + e.getActionCommand());
        if (e.getSource() instanceof ItemSelectable) {
            ItemSelectable is = (ItemSelectable)e.getSource();
            System.out.println ("The value is: " +
                (is.getSelectedObjects().length != 0)));
        }
    }
    protected void processWindowEvent(WindowEvent e) {
        if (e.getID() == WindowEvent.WINDOW_CLOSING) {
            // Notify others we are closing
            super.processWindowEvent(e);
            System.exit(0);
        } else {
            super.processWindowEvent(e);
        }
    }
    public static void main (String []args) {
        MenuTest12 f = new MenuTest12 ();
        f.show();
    }
}
```

I took the opportunity when writing the 1.1 code to make one additional improvement to the program. By using action commands, you can easily differentiate between the two Yo menu items. Just call `setActionCommand()` to assign a different command to each item. (I used "Yo1" and "Yo2".) You could also differentiate between the items by saving a reference to each menu item, calling `getSource()` in the event handler, and comparing the result to the saved references. However, if the `ActionListener` is another class, it would need access to those references. Using action commands is simpler and results in a cleaner event handler.

The intent of the `setActionCommand()` and `getActionCommand()` methods is more for internationalization support. For example, you could use `setActionCommand()` to associate the command Quit with a menu item, then set the item's label to the appropriate text for the user's locality.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

10.9 PopupMenu

The `PopupMenu` class is new to Java 1.1; it allows you to associate context-sensitive menus with Java components. To associate a pop-up menu with a component, create the menu, and add it to the component using the `add(PopupMenu)` method, which all components inherit from the `Component` class.

In principle, any GUI object can have a pop-up menu. In practice, there are a few exceptions. If the component's peer has its own pop-up menu (i.e., a pop-up menu provided by the run-time platform), that pop-up menu effectively overrides the pop-up menu provided by Java. For example, under Windows NT/95, a `TextArea` has a pop-up menu provided by the Windows NT/95 platforms. Java can't override this menu; although you can add a pop-up menu to a `TextArea`, you can't display that menu under Windows NT/95 with the usual mouse sequence.

PopupMenu Methods

Constructors

public PopupMenu() ★

> The first `PopupMenu` constructor creates an untitled `PopupMenu`. Once created, the menu can be populated with menu items like any other menu.

public PopupMenu(String label) ★

> This constructor creates a `PopupMenu` with a title of `label`. The title appears only on platforms that support titles for context menus. Once created, the menu can be populated with menu items like any other menu.

Miscellaneous methods

public void show(Component origin, int x, int y) ★

Call the show() method to display the PopupMenu. x and y specify the location at which the pop-up menu should appear; origin specifies the Component whose coordinate system is used to locate x and y. In most cases, you'll want the menu to appear at the point where the user clicked the mouse; to do this, set origin to the Component that received the mouse event, and set x and y to the location of the mouse click. It is easy to extract this information from an old-style (1.0) Event or a Java 1.1 MouseEvent. In Java 1.1, the platform-independent way to say "give me the mouse events that are supposed to trigger pop-up menus" is to call MouseEvent.isPopupTrigger(). If this method returns true, you should show the pop-up menu if one is associated with the event source. (Note that the mouse event could also be used for some other purpose.)

If the PopupMenu is not associated with a Component, show() throws the run-time exception NullPointerException. If origin is not the MenuContainer for the PopupMenu and origin is not within the Container that the pop-up menu belongs to, show() throws the run-time exception IllegalArgumentException. Finally, if the Container of origin does not exist or is not showing, show() throws a run-time exception.

public synchronized void addNotify () ★

The addNotify() method creates the PopupMenu peer with all the MenuItems on it.

Example 10.3 is a simple applet that raises a pop-up menu if the user clicks the appropriate mouse button anywhere within the applet. Although the program could use the 1.0 event model, under the 1.0 model, it is impossible to tell which mouse event is appropriate to display the pop-up menu.

Example 10.3: Using a PopupMenu

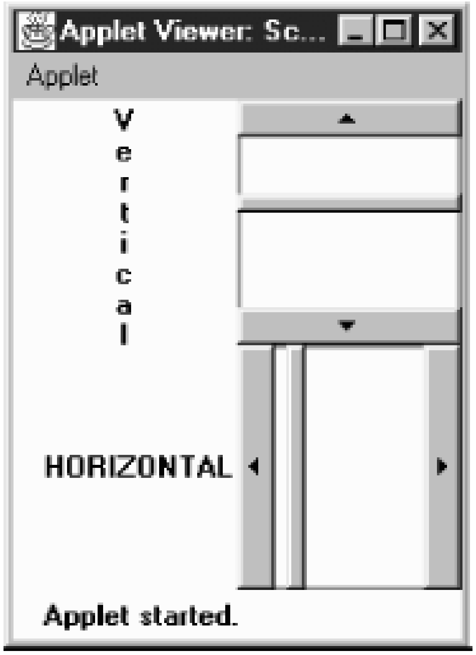
```
// Java 1.1 only
import java.awt.*;
import java.applet.*;
import java.awt.event.*;
public class PopupTest extends Applet implements ActionListener {
    PopupMenu popup;
    public void init() {
        MenuItem mi;
        popup = new PopupMenu("Title Goes Here");
        popup.add(mi = new MenuItem ("Undo"));
        mi.addActionListener (this);
        popup.addSeparator();
        popup.add(mi = new MenuItem("Cut")).setEnabled(false);
        mi.addActionListener (this);
        popup.add(mi = new MenuItem("Copy")).setEnabled(false);
        mi.addActionListener (this);
        popup.add(mi = new MenuItem ("Paste"));
        mi.addActionListener (this);
        popup.add(mi = new MenuItem("Delete")).setEnabled(false);
        mi.addActionListener (this);
        popup.addSeparator();
        popup.add(mi = new MenuItem ("Select All"));
        mi.addActionListener (this);
        add (popup);
        resize(200, 200);
        enableEvents (AWTEvent.MOUSE_EVENT_MASK);
    }
    protected void processMouseEvent (MouseEvent e) {
        if (e.isPopupTrigger())
            popup.show(e.getComponent(), e.getX(), e.getY());
        super.processMouseEvent (e);
    }
    public void actionPerformed(ActionEvent e) {
        System.out.println (e);
    }
}
```

11.2 Scrolling An Image

Example 11.1 is a Java application that displays any image in the current directory in a viewing area. The viewing area scrolls to accommodate larger images; the user can use the scrollbars or keypad keys to scroll the image. In Java 1.1, it is trivial to implement this example with a `ScrollPane`; however, if you're using 1.0, you don't have this luxury. Even if you're using 1.1, this example shows a lot about how to use scrollbars.

Our application uses a `Dialog` to select which file to display; a `FilenameFilter` limits the list to image files. We use a menu to let the user request a file list or exit the program. After the user picks a file, the application loads it into the display area. Figure 11.3 shows the main scrolling window.

Figure 11.3: Scrolling an image



Applet started.

The code for the scrolling image consists of a `ScrollingImage` class, plus several helper classes. It places everything into the file *ScrollingImage.java* for compilation.

Example 11.1: Source Code for Scrolling an Image

```
import java.awt.*;
import java.io.FilenameFilter;
import java.io.File;
```

The first class contains the `FilenameFilter` used to select relevant filenames: that is, files that are likely to contain GIF, JPEG, or XBM images. If the filename has an appropriate ending, the `accept()` method returns `true`; otherwise, it returns `false`.

```
// True for files ending in jpeg/jpg/gif/xbm
class ImageFileFilter implements FilenameFilter {
    public boolean accept (File dir, String name) {
        String tempname = name.toLowerCase();
        return (tempname.endsWith ("jpg") || tempname.endsWith ("jpeg") ||
                tempname.endsWith ("gif") || tempname.endsWith ("xbm"));
    }
}
```

The `ImageListDialog` class displays a list of files from which the user can select. Instead of using `FileDialog`, we created a customized `List` to prevent the user from roaming around the entire hard drive; choices are limited to appropriate files in the current directory. When the user selects an entry (by double-clicking), the image is then displayed in the scrolling area.

```
class ImageListDialog extends Dialog {
    private String name = null;
    private String entries[];
    private List list;
    ImageListDialog (Frame f) {
        super (f, "Image List", true);
        File dir = new File (System.getProperty("user.dir"));
        entries = dir.list (new ImageFileFilter());
        list = new List (10, false);
        for (int i=0;i<entries.length;i++) {
            list.addItem (entries[i]);
        }
        add ("Center", list);
        pack();
    }
    public String getName () {
        return name;
    }
    public boolean action (Event e, Object o) {
        name = (String)e.arg;
        ((ScrollingImage)getParent()).processImage();
        dispose();
        return true;
    }
}
```

The code in this class is straightforward. The constructor reads the current directory from the system property list, uses the `list()` method of the `File` class to create a list of files that match our filename filter, and then creates a `List` object that lists these files. `getName()` returns the name of the selected file. `action()` is called when the user selects a file; it sets the name of the selected file from the `arg` field of the `Event` and then calls the `processImage()` method of its parent container. The parent container of our `ImageListDialog` is the `ScrollingImage` class we are defining; its `processImage()` method displays a scrollable image.

The next class, `ImageCanvas`, is the `Canvas` that the image is drawn onto. We use a separate `Canvas` rather than drawing directly onto the `Frame` so that the scrollbars do not overlap the edges of the image. You will notice that the `paint()` method uses negative `x` and `y` values. This starts the drawing outside the `Canvas` area; as a result, the `Canvas` displays only part of the image. This is how we do the actual scrolling. (`xPos`, `yPos`) are the values given to us from the scrollbars; by positioning the image at (`-xPos`, `-yPos`), we ensure that the point (`xPos`, `yPos`) appears in the upper left corner of the canvas.

```
class ImageCanvas extends Canvas {
    Image image;
    int xPos, yPos;
    public void redraw (int xPos, int yPos, Image image) {
        this.xPos = xPos;
        this.yPos = yPos;
        this.image = image;
        repaint();
    }
    public void paint (Graphics g) {
        if (image != null)
            g.drawImage (image, -xPos, -yPos, this);
    }
}
```

`ScrollingImage` provides the framework for the rest of the program. It provides a menu to bring up the `Dialog` to choose the file, the scrollbars to scroll the scrolling canvas, and the image canvas area. This class also implements event handling methods to capture the scrollbar events, paging keys, and menu events.

```
public class ScrollingImage extends Frame {
    static Scrollbar horizontal, vertical;
    ImageCanvas center;
    int xPos, yPos;
    Image image;
    ImageListDialog ild;
    ScrollingImage () {
        super ("Image Viewer");
        add ("Center", center = new ImageCanvas ());
        add ("South",  horizontal = new Scrollbar (Scrollbar.HORIZONTAL));
        add ("East", vertical = new Scrollbar (Scrollbar.VERTICAL));
        Menu m = new Menu ("File", true);
        m.add ("Open");
        m.add ("Close");
        m.add ("-");
        m.add ("Quit");
        MenuBar mb = new MenuBar();
        mb.add (m);
        setMenuBar (mb);
        resize (400, 300);
    }
    public static void main (String args[]) {
        ScrollingImage si = new ScrollingImage ();
        si.show();
    }
    public boolean handleEvent (Event e) {
         if (e.id == Event.WINDOW_DESTROY) {
            System.exit(0);
        } else if (e.target instanceof Scrollbar) {
            if (e.target == horizontal) {
                xPos = ((Integer)e.arg).intValue();
            } else if (e.target == vertical) {
                yPos = ((Integer)e.arg).intValue();
            }
            center.redraw (xPos, yPos, image);
        }
        return super.handleEvent (e);
    }
```

This `handleEvent()` method kills the program if the user used the windowing system to exit from it (`WINDOW_DESTROY`). More to the point, if a `Scrollbar` generated the event, `handleEvent()` figures out if it was the horizontal or vertical scrollbar, saves its value as the `x` or `y` position, and redraws the image in the new location. Finally, it calls `super.handleEvent()`; as we will see in the following code, other events that we care about (key events and menu events) we don't want to handle here--we would rather handle them normally, in `action()` and `keyDown()` methods.

```
    public void processImage () {
        image = getToolkit().getImage (ild.getName());
        MediaTracker tracker = new MediaTracker (this);
        tracker.addImage (image, 0);
        try {
            tracker.waitForAll();
        } catch (InterruptedException ie) {
        }
        xPos = 0;
        yPos = 0;
        int imageHeight = image.getHeight (this);
        int imageWidth = image.getWidth (this);
        vertical.setValues (0, 5, 0, imageHeight);
        horizontal.setValues (0, 5, 0, imageWidth);
        center.redraw (xPos, yPos, image);
    }
```

`processImage()` reads the image's filename, calls `getImage()`, and sets up a `MediaTracker` to wait for the image to load. Once the image has loaded, it reads the height and width, and uses these to set the maximum values for the vertical and horizontal scrollbars by calling `setValues()`. The scrollbars' minimum and initial values are both 0. The size of the scrollbar "handle" is set to 5, rather than trying to indicate the visible portion of the image.

```
    public boolean action (Event e, Object o) {
        if (e.target instanceof MenuItem) {
            if ("Open".equals (o)) {
                // If showing already, do not show again
                if ((ild == null) || (!ild.isShowing())) {
                    ild = new ImageListDialog (this);
                    ild.show();
                }
            } else if ("Close".equals(o)) {
                image = null;
                center.redraw (xPos, yPos, image);
            } else if ("Quit".equals(o)) {
                System.exit(0);
            }
            return true;
        }
        return false;
    }
```

`action()` handles menu events. If the user selected Open, it displays the dialog box that selects a file. Close redraws the canvas with a null image; Quit exits the program. If any of these events occurred, `action()` returns `true`, indicating that the event was fully handled. If any other event occurred, `action()` returns `false`, so that the system will deliver the event to any other methods that might be interested in it.

```
    public boolean keyDown (Event e, int key) {
        if (e.id == Event.KEY_ACTION) {
            Scrollbar target = null;
            switch (key) {
```

```
            case Event.HOME:
                target = vertical;
                vertical.setValue(vertical.getMinimum());
                break;
            case Event.END:
                target = vertical;
                vertical.setValue(vertical.getMaximum());
                break;
            case Event.PGUP:
                target = vertical;
                vertical.setValue(vertical.getValue()
                         - vertical.getPageIncrement());
                break;
            case Event.PGDN:
                target = vertical;
                vertical.setValue(vertical.getValue()
                         + vertical.getPageIncrement());
                break;
            case Event.UP:
                target = vertical;
                vertical.setValue(vertical.getValue()
                         - vertical.getLineIncrement());
                break;
            case Event.DOWN:
                target = vertical;
                vertical.setValue(vertical.getValue()
                         + vertical.getLineIncrement());
                break;
            case Event.LEFT:
                target = horizontal;
                if (e.controlDown())
                    horizontal.setValue(horizontal.getValue() -
                        horizontal.getPageIncrement());
                else
                    horizontal.setValue(horizontal.getValue() -
                        horizontal.getLineIncrement());
                break;
            case Event.RIGHT:
                target = horizontal;
                if (e.controlDown())
                    horizontal.setValue(horizontal.getValue() +
                        horizontal.getPageIncrement());
                else
                    horizontal.setValue(horizontal.getValue() +
                        horizontal.getLineIncrement());
                    break;
                default:
                    return false;
            }
            Integer value = new Integer (target.getValue());
            postEvent (new Event ((Object)target,
                       Event.SCROLL_ABSOLUTE, (Object)value));
            return true;
        }
        return false;
    }
}
```

`keyDown()` isn't really necessary, but it adds a nice extension to our scrollbars: in addition to using the mouse, the user can scroll with the arrow keys. Pressing an arrow key generates a `KEY_ACTION` event. If we have one of these events, we check what kind of key it was, then compute a new scrollbar value, then call `setValue()` to set the appropriate scrollbar to this value. For example, if the user presses the page up key, we read the page increment, add it to the current value of the vertical scrollbar, and then set the vertical scrollbar accordingly. (Note that this works even though nondefault page and line increments aren't implemented correctly.) The one trick here is that we have to get the rest of the program to realize that the scrollbar values have changed. To do so, we create a new `SCROLL_ABSOLUTE` event, and call `postEvent()` to deliver it.

Scrollbar | BOOK INDEX | The Adjustable Interface

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

11.3 The Adjustable Interface

The `Adjustable` interface is new to Java 1.1. It provides the method signatures required for an object that lets you adjust a bounded integer value. It is currently implemented by `Scrollbar` and returned by two methods within `ScrollPane`.

Constants of the Adjustable Interface

There are two direction specifiers for `Adjustable`.

public final static int HORIZONTAL ★

> `HORIZONTAL` is the constant for horizontal orientation.

public final static int VERTICAL ★

> `VERTICAL` is the constant for vertical orientation.

Methods of the Adjustable Interface

public abstract int getOrientation () ★

> The `getOrientation()` method is for returning the current orientation of the adjustable object, either `Adjustable.HORIZONTAL` or `Adjustable.VERTICAL`.
>
> `setOrientation()` is not part of the interface. Not all adjustable objects need to be able to alter orientation. For example, `Scrollbar` instances can change their orientation, but each `Adjustable` instance associated with a `ScrollPane` has a fixed, unchangeable orientation.

public abstract int getVisibleAmount () ★

The `getVisibleAmount()` method lets you retrieve the size of the visible slider of the adjustable object.

public abstract void setVisibleAmount (int amount) ★

The `setVisibleAmount()` method lets you change the size of the visible slider to `amount`.

public abstract int getValue () ★

The `getValue()` method lets you retrieve the current value of the adjustable object.

public abstract void setValue (int value) ★

The `setValue()` method lets you change the value of the adjustable object to `value`.

public abstract int getMinimum ()

The `getMinimum()` method lets you retrieve the current minimum setting for the object.

public abstract void setMinimum (int minimum) ★

The `setMinimum()` method lets you change the minimum value of the adjustable object to `minimum`.

public abstract int getMaximum () ★

The `getMaximum()` method lets you retrieve the current maximum setting for the object.

public abstract void setMaximum (int maximum) ★

The `setMaximum()` method lets you change the maximum value of the adjustable object to `maximum`.

public abstract int getUnitIncrement () ★

The `getUnitIncrement()` method lets you retrieve the current line increment.

public abstract void setUnitIncrement (int amount) ★

The `setUnitIncrement()` method lets you change the line increment amount of the adjustable object to `amount`.

public abstract int getBlockIncrement () ★

The `getBlockIncrement()` method lets you retrieve the current page increment.

public abstract void setBlockIncrement (int amount) ★

The `setBlockIncrement()` method lets you change the paging increment amount of the adjustable object to `amount`.

public abstract void addAdjustmentListener(AdjustmentListener listener) ★

The `addAdjustmentListener()` method lets you register `listener` as an object interested in being notified when an `AdjustmentEvent` passes through the `EventQueue` with this `Adjustable` object as its target.

public abstract void removeAdjustmentListener(ItemListener listener) ★

The `removeAdjustmentListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

11.4 ScrollPane

A ScrollPane is a Container with built-in scrollbars that can be used to scroll its contents. In the current implementation, a ScrollPane can hold only one Component and has no layout manager. The component within a ScrollPane is always given its preferred size. While the scrollpane's inability to hold multiple components sounds like a deficiency, it isn't; there's no reason you can't put a Panel inside a ScrollPane, put as many components as you like inside the Panel, and give the Panel any layout manager you wish.

Scrolling is handled by the ScrollPane peer, so processing is extremely fast. In Example 11.1, the user moves a Scrollbar to trigger a scrolling event, and the peer sends the event to the Java program to find someone to deal with it. Once it identifies the target, it posts the event, then tries to find a handler. Eventually, the applet's handleEvent() method is called to reposition the ImageCanvas. The new position is then given to the peer, which finally redisplays the Canvas. Although most of the real work is behind the scenes, it is still happening. With ScrollPane, the peer generates and handles the event itself, which is much more efficient.

ScrollPane Methods

Constants

The ScrollPane class contains three constants that can be used to control its scrollbar display policy. The constants are fairly self-explanatory. The constants are used in the constructor for a ScrollPane instance.

public static final int SCROLLBARS_AS_NEEDED ★

> SCROLLBARS_AS_NEEDED is the default scrollbar display policy. With this policy, the ScrollPane displays each scrollbar only if the Component is too large in the scrollbar's direction.

public static final int SCROLLBARS_ ALWAYS ★

> With the SCROLLBARS_ALWAYS display policy, the ScrollPane should always display both scrollbars, whether or not they are needed.

public static final int SCROLLBARS_ NEVER ★

> With the SCROLLBARS_NEVER display policy, the ScrollPane should never display scrollbars, even when the object is bigger than the ScrollPane's area. When using this mode, you should provide some means for the

user to scroll, either through a button outside the container or by listening for events happening within the container.

Constructors

public ScrollPane () ★

The first constructor creates an instance of `ScrollPane` with the default scrollbar display policy setting, `SCROLLBARS_AS_NEEDED`.

public ScrollPane (int scrollbarDisplayPolicy) ★

The other constructor creates an instance of `ScrollPane` with a scrollbar setting of `scrollbarDisplayPolicy`. If `scrollbarDisplayPolicy` is not one of the class constants, this constructor throws the `IllegalArgumentException` run-time exception.

Layout methods

public final void setLayout(LayoutManager mgr) ★

The `setLayout()` method of `ScrollPane` throws an `AWTError`. It overrides the `setLayout()` method of `Container` to prevent you from changing a `ScrollPane`'s layout manager.

public void doLayout () ★
public void layout () ☆

The `doLayout()` method of `ScrollPane` shapes the contained object to its preferred size.

`layout()` is another name for this method.

public final void addImpl(Component comp, Object constraints, int index) ★

The `addImpl()` method of `ScrollPane` permits only one object to be added to the `ScrollPane`. It overides the `addImpl()` method of `Container` to enforce the `ScrollPane`'s limitations on adding components. If `index > 0`, `addImpl()` throws the run-time exception `IllegalArgumentException`. If a component is already within the `ScrollPane`, it is removed before `comp` is added. The `constraints` parameter is ignored.

Scrolling methods

public int getScrollbarDisplayPolicy() ★

The `getScrollbarDisplayPolicy()` method retrieves the current display policy, as set by the constructor. You cannot change the policy once it has been set. The return value is one of the class constants: `SCROLLBARS_AS_NEEDED`, `SCROLLBARS_ALWAYS`, or `SCROLLBARS_NEVER`.

public Dimension getViewportSize() ★

The `getViewportSize()` method returns the current size of the `ScrollPane`, less any `Insets`, as a `Dimension` object. The size is given in pixels and has an initial value of 100 x 100.

public int getHScrollbarHeight() ★

The `getHScrollbarHeight()` method retrieves the height in pixels of a horizontal scrollbar. The value returned is without regard to the display policy; that is, you may be given a height even if the scrollbar is not displayed. This method may return 0 if the scrollbar's height cannot be calculated at this time (no peer) or if you are using the `SCROLLBARS_NEVER` display policy.

The width of a horizontal scrollbar is just `getViewportSize().width`.

public int getVScrollbarWidth() ★

The `getVScrollbarWidth()` method retrieves the width in pixels of a vertical scrollbar. The value returned is without regard to the display policy; that is, you may be given a width even if the scrollbar is not displayed. This method may return 0 if the scrollbar's width cannot be calculated at this time (no peer) or if you are using the `SCROLLBARS_NEVER` display policy.

The height of a vertical scrollbar is just `getViewportSize().height`.

public Adjustable getHAdjustable() ★

The `getHAdjustable()` method returns the adjustable object representing the horizontal scrollbar (or `null` if it is not present). Through the methods of `Adjustable`, you can get the different settings of the scrollbar.

The object that this method returns is an instance of the package private class `ScrollPaneAdjustable`, which implements the `Adjustable` interface. this class allows you to register listeners for the scrollpane's events and inquire about various properties of the pane's scrollbars. It does not let you set some scrollbar properties; the `setMinimum()`, `setMaximum()`, and `setVisibleAmount()` methods throw an `AWTError` when called.

public Adjustable getVAdjustable() ★

The `getVAdjustable()` method returns the adjustable object representing the vertical scrollbar (or `null` if it is not present). Through the methods of `Adjustable`, you can get the different settings of the scrollbar.

The object that this method returns is an instance of the package private class `ScrollPaneAdjustable`, which implements the `Adjustable` interface. this class allows you to register listeners for the scrollpane's events and inquire about various properties of the pane's scrollbars. It does not let you set some scrollbar properties; the `setMinimum()`, `setMaximum()`, and `setVisibleAmount()` methods throw an `AWTError` when called.

public void setScrollPosition(int x, int y) ★

This `setScrollPosition()` method moves the `ScrollPane` to the designated location if possible. The `x` and `y` arguments are scrollbar settings, which should be interpreted in terms of the minimum and maximum values given to you by the horizontal and vertical `Adjustable` objects (returned by the previous two methods). If the `ScrollPane` does not have a child component, this method throws the run-time exception `NullPointerException`. You can also move the `ScrollPane` by calling the `Adjustable.setValue()` method of one of the scrollpane's `Adjustable` objects.

public void setScrollPosition(Point p) ★

This `setScrollPosition()` method calls the previous with parameters of `p.x`, and `p.y`.

public Point getScrollPosition() ★

The `getScrollPosition()` method returns the current position of both the scrollpane's `Adjustable` objects as a `Point`. If there is no component within the `ScrollPane`, `getScrollPosition()` throws the `NullPointerException` run-time exception. Another way to get this information is by calling the `Adjustable.getValue()` method of each `Adjustable` object.

Miscellaneous methods

public void printComponents (Graphics g) ★

The `printComponents()` method of `ScrollPane` prints the single component it contains. This is done by clipping the context `g` to the size of the display area and calling the contained component's `printAll()` method.

public synchronized void addNotify () ★

The `addNotify()` method creates the `ScrollPane` peer. If you override this method, call `super.addNotify()` first, then add your customizations for the new class. You will then be able to do everything you need with the information about the newly created peer.

protected String paramString () ★

`ScrollPane` doesn't have its own `toString()` method; so when you call the `toString()` method of a `ScrollPane`, you are actually calling the `Component.toString()` method. This in turn calls `paramString()`, which builds the string to display. For a `ScrollPane`, `paramString()` adds the current scroll position, insets, and scrollbar display policy. For example:

```
java.awt.ScrollPane[scrollpane0,0,0,0x0,invalid,ScrollPosition=(0,0),
        Insets=(0,0,0,0),ScrollbarDisplayPolicy=always]
```

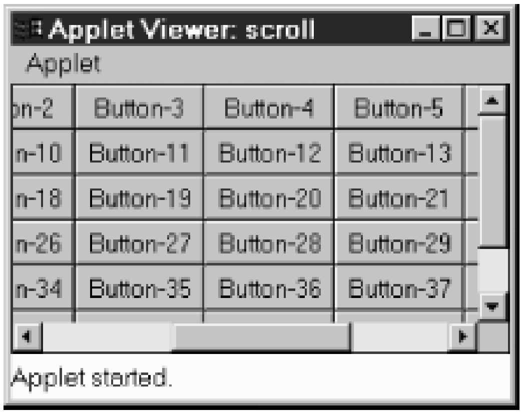
ScrollPane Events

The `ScrollPane` peer deals with the scrolling events for you. It is not necessary to catch or listen for these events. As with any other `Container`, you can handle the 1.0 events of the object you contain or listen for 1.1 events that happen within you.

Using a ScrollPane

The following applet demonstrates one way to use a `ScrollPane`. Basically, you place the object you want to scroll in the `ScrollPane` by calling the `add()` method. This can be a `Panel` with many objects on it or a `Canvas` with an image drawn on it. You then add as many objects as you want to the `Panel` or scribble on the `Canvas` to your heart's delight. No scrolling event handling is necessary. That is all there is to it. To make this example a little more interesting, whenever you select a button, the `ScrollPane` scrolls to a randomly selected position. Figure 11.4 displays the screen.

Figure 11.4: A ScrollPane containing many buttons



Here's the code:

```
// Java 1.1 only
import java.awt.*;
import java.awt.event.*;
import java.applet.*;
public class scroll extends Applet implements ActionListener, ContainerListener {
    ScrollPane sp = new ScrollPane (ScrollPane.SCROLLBARS_ALWAYS);
    public void init () {
        setLayout (new BorderLayout ());
        Panel p = new Panel(new GridLayout (7, 8));
        p.addContainerListener (this);
        for (int j=0;j<50;j++)
            p.add (new Button ("Button-" + j));
        sp.add (p);
        add (sp, "Center");
    }
    public void componentAdded(ContainerEvent e) {
        if (e.getID() == ContainerEvent.COMPONENT_ADDED) {
            if (e.getChild() instanceof Button) {
                Button b = (Button)e.getChild();
                b.addActionListener(this);
            }
        }
    }
    public void componentRemoved(ContainerEvent e) {
    }
    public void actionPerformed (ActionEvent e) {
        Component c = sp.getComponent();
            Dimension d = c.getSize();
            sp.setScrollPosition ((int)(Math.random()*d.width),
                (int)(Math.random()*d.height));
    }
}
```

Working with the `ScrollPane` itself is easy; we just create one, add a `Panel` to it, set the `Panel`'s layout manager to `GridLayout`, and add a lot of buttons to the `Panel`. The applet itself is the action listener for all the buttons; when anybody clicks a button, `actionPerformed()` is called, which generates a new random position based on the viewport size and sets the new scrolling position accordingly by calling `setScrollPosition()`.

The more interesting part of this applet is the way it works with buttons. Instead of directly adding a listener for each button, we add a `ContainerListener` to the containing panel and let it add listeners. Although this may seem like extra work here, it demonstrates how you can use container events to take actions whenever someone adds or removes a component. At first glance, you might ask why I didn't just call `enableEvents(AWTEvent.CONTAINER_EVENT_MASK)` and override the applet's `processContainerEvent()` to attach the listeners. If we were only adding our components to the applet, that would work great. Unfortunately, the applet is not notified when buttons are added to an unrelated panel. It would be notified only when the panel was added to the applet.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

12.2 ColorModel

A color model determines how colors are represented within AWT. `ColorModel` is an abstract class that you can subclass to specify your own representation for colors. AWT provides two concrete subclasses of `ColorModel` that you can use to build your own color model; they are `DirectColorModel` and `IndexColorModel`. These two correspond to the two ways computers represent colors internally.

Most modern computer systems use 24 bits to represent each pixel. These 24 bits contain 8 bits for each primary color (red, green, blue); each set of 8 bits represents the intensity of that color for the particular pixel. This arrangement yields the familiar "16 million colors" that you see in advertisements. It corresponds closely to Java's direct color model.

However, 24 bits per pixel, with something like a million pixels on the screen, adds up to a lot of memory. In the dark ages, memory was expensive, and devoting this much memory to a screen buffer cost too much. Therefore, designers used fewer bits--possibly as few as three, but more often eight--for each pixel. Instead of representing the colors directly in these bits, the bits were an index into a color map. Graphics programs would load the color map with the colors they were interested in and then represent each pixel by using the index of the appropriate color in the map. For example, the value 1 might represent fuschia; the value 2 might represent puce. Full information about how to display each color (the red, green, and blue components that make up fuschia or puce) is contained only in the color map. This arrangement corresponds closely to Java's indexed color model.

Because Java is platform-independent, you don't need to worry about how your computer or the user's computer represents colors. Your programs can use an indexed or direct color map as appropriate. Java will do the best it can to render the colors you request. Of course, if you use 5,000 colors on a computer that can only display 256, Java is going to have to make compromises. It will decide which colors to put in the color map and which colors are close enough to the colors in the color map, but that's done behind your back.

Java's default color model uses 8 bits per pixel for red, green, and blue, along with another 8 bits for alpha (transparency) level. However, as I said earlier, you can create your own `ColorModel` if you want to work in some other scheme. For example, you could create a grayscale color model for black and white pictures, or an HSB (hue, saturation, brightness) color model if you are more comfortable working with this system. Your color model's job will be to take a pixel value in your representation and translate that value into the corresponding alpha, red, green, and blue values. If you are working with a grayscale image, your image producer could deliver grayscale values to the image consumer, plus a `ColorModel` that tells the consumer how to render these gray values in terms of ARGB components.

ColorModel Methods

Constructors

public ColorModel (int bits)

> There is a single constructor for `ColorModel`. It has one parameter, `bits`, which describes the number of bits required per pixel of an image. Since this is an abstract class, you cannot call this constructor directly. Since each pixel value must be stored within an integer, the maximum value for `bits` is 32. If you request more, you get 32.

Pseudo-constructors

public static ColorModel getRGBdefault()

> The `getRGBdefault()` method returns the default `ColorModel,` which has 8 bits for each of the components alpha, red, green, and blue. The order the pixels are stored in an integer is 0xAARRGGBB, or alpha in highest order byte, down to blue in the lowest.

Other methods

public int getPixelSize ()

> The `getPixelSize()` method returns the number of bits required for each pixel as described by this color model. That is, it returns the number of bits passed to the constructor.

public abstract int getAlpha (int pixel)

> The `getAlpha()` method returns the alpha component of `pixel` for a color model. Its range must be between 0 and 255, inclusive. A value of 0 means the pixel is completely transparent and the background will appear through the pixel. A value of 255 means the pixel is opaque and you cannot see the background behind it.

public abstract int getRed (int pixel)

> The `getRed()` method returns the red component of `pixel` for a color model. Its range must be between 0 and 255, inclusive. A value of 0 means the pixel has no red in it. A value of 255 means red is at maximum intensity.

public abstract int getGreen (int pixel)

> The `getGreen()` method returns the green component of `pixel` for a color model. Its range must be between 0 and 255, inclusive. A value of 0 means the pixel has no green in it. A value of 255 means green is at maximum intensity.

public abstract int getBlue (int pixel)

The `getBlue()` method returns the blue component of `pixel` for a color model. Its range must be between 0 and 255, inclusive. A value of 0 means the pixel has no blue in it. A value of 255 means blue is at maximum intensity.

public int getRGB(int pixel)

The `getRGB()` method returns the color of `pixel` in the default RGB color model. If a subclass has changed the ordering or size of the different color components, `getRGB()` will return the pixel in the RGB color model (0xAARRGGBB order). In theory, the subclass does not need to override this method, unless it wants to make it final. Making this method final may yield a significant performance improvement.

public void finalize ()

The garbage collector calls `finalize()` when it determines that the `ColorModel` object is no longer needed. `finalize()` frees any internal resources that the `ColorModel` object has used.

DirectColorModel

The `DirectColorModel` class is a concrete subclass of `ColorModel`. It specifies a color model in which each pixel contains all the color information (alpha, red, green, and blue values) explicitly. Pixels are represented by 32-bit (`int`) quantities; the constructor lets you change which bits are allotted to each component.

All of the methods in this class, except constructors, are final, because of assumptions made by the implementation. You can create subclasses of `DirectColorModel`, but you can't override any of its methods. However, you should not need to develop your own subclass. Just create an instance of `DirectColorModel` with the appropriate constructor. Any subclassing results in serious performance degradation, because you are going from fast, static final method calls to dynamic method lookups.Constructors

public DirectColorModel (int bits, int redMask, int greenMask, int blueMask, int alphaMask)

This constructor creates a `DirectColorModel` in which `bits` represents the total number of bits used to represent a pixel; it must be less than or equal to 32. The `redMask`, `greenMask`, `blueMask`, and `alphaMask` specify where in a pixel each color component exists. Each of the bit masks must be contiguous (e.g., red cannot be the first, fourth, and seventh bits of the pixel), must be smaller than 2^bits, and should not exceed 8 bits. (You cannot display more than 8 bits of data for any color component, but the mask can be larger.) Combined, the masks together should be `bits` in length. The default RGB color model is:

```
new DirectColorModel (32, 0x00ff0000, 0x0000ff00, 0x000000ff, 0xff000000)
```

The run-time exception `IllegalArgumentException` is thrown if any of the following occur:

- The bits that are set in a mask are not contiguous.

- Mask bits overlap (i.e., the same bit is set in two or more masks).

- The number of mask bits exceeds `bits`.

public DirectColorModel (int bits, int redMask, int greenMask, int blueMask)

This constructor for `DirectColorModel` calls the first with an alpha mask of 0, which means that colors in this color model have no transparency component. All colors will be fully opaque with an alpha value of 255. The same restrictions for the red, green, and blue masks apply.

Methods

final public int getAlpha (int pixel)

The `getAlpha()` method returns the alpha component of `pixel` for the color model as a number from 0 to 255, inclusive. A value of 0 means the pixel is completely transparent, and the background will appear through the pixel. A value of 255 means the pixel is opaque, and you cannot see the background behind it.

final public int getRed (int pixel)

The `getRed()` method returns the red component of `pixel` for the color model. Its range is from 0 to 255. A value of 0 means the pixel has no red in it. A value of 255 means red is at maximum intensity.

final public int getGreen (int pixel)

The `getGreen()` method returns the green component of `pixel` for the color model. Its range is from 0 to 255. A value of 0 means the pixel has no green in it. A value of 255 means green is at maximum intensity.

final public int getBlue (int pixel)

The `getBlue()` method returns the blue component of `pixel` for the color model. Its range is from 0 to 255. A value of 0 means the pixel has no blue in it. A value of 255 means blue is at maximum intensity.

final public int getRGB (int pixel)

The `getRGB()` method returns the color of `pixel` in the default RGB color model. If a subclass has changed the ordering or size of the different color components, `getRGB()` will return the pixel in the RGB color model (0xAARRGGBB order). The `getRGB()` method in this subclass is identical to the method in `ColorModel` but overrides it to make it final.

Other methods

final public int getAlphaMask ()

The `getAlphaMask()` method returns the `alphaMask` from the `DirectColorModel` constructor (or 0 if constructor did not have `alphaMask`). The `alphaMask` specifies which bits in the pixel represent the alpha transparency component of the color model.

final public int getRedMask ()

The getRedMask() method returns the redMask from the DirectColorModel constructor. The redMask specifies which bits in the pixel represent the red component of the color model.

final public int getGreenMask ()

The getGreenMask() method returns the greenMask from the DirectColorModel constructor. The greenMask specifies which bits in the pixel represent the green component of the color model.

final public int getBlueMask ()

The getBlueMask() method returns the blueMask from the DirectColorModel constructor. The blueMask specifies which bits in the pixel represent the blue component of the color model.

IndexColorModel

The IndexColorModel is another concrete subclass of ColorModel. It specifies a ColorModel that uses a color map lookup table (with a maximum size of 256), rather than storing color information in the pixels themselves. Pixels are represented by an index into the color map, which is at most an 8-bit quantity. Each entry in the color map gives the alpha, red, green, and blue components of some color. One entry in the map can be designated "transparent." This is called the "transparent pixel"; the alpha component of this map entry is ignored.

All of the methods in this class, except constructors, are final because of assumptions made by the implementation. You shouldn't need to create subclasses; you can if necessary, but you can't override any of the IndexColorModel methods. Example 12.2 (later in this chapter) uses an IndexColorModel. Constructors

There are two sets of constructors for IndexColorModel. The first two constructors use a single-byte array for the color map. The second group implements the color map with separate byte arrays for each color component.

public IndexColorModel (int bits, int size, byte colorMap[], int start, boolean hasalpha, int transparent)

This constructor creates an IndexColorModel. bits is the number of bits used to represent each pixel and must not exceed 8. size is the number of elements in the map; it must be less than 2^bits. hasalpha should be true if the color map includes alpha (transparency) components and false if it doesn't. transparent is the location of the transparent pixel in the map (i.e., the pixel value that is considered transparent). If there is no transparent pixel, set transparent to -1.

The colorMap describes the colors used to paint pixels. start is the index within the colorMap array at which the map begins; prior elements of the array are ignored. An entry in the map consists of three or four consecutive bytes, representing the red, green, blue, and (optionally) alpha components. If hasalpha is false, a map entry consists of three bytes, and no alpha components are present; if hasalpha is true, map entries consist of four bytes, and all four components must be present.

For example, consider a pixel whose value is `p`, and a color map with a `hasalpha` set to `false`. Therefore, each element in the color map occupies three consecutive array elements. The red component of that pixel will be located at `colorMap[start + 3*p]`; the green component will be at `colorMap[start + 3*p + 1]`; and so on. The value of size may be smaller than 2^bits, meaning that there may be pixel values with no corresponding entry in the color map. These pixel values (i.e., `size <= p` < 2^bits) are painted with the color components set to 0; they are transparent if `hasalpha` is `true`, opaque otherwise.

If `bits` is too large (greater than 8), `size` is too large (greater than 2^bits), or the `colorMap` array is too small to hold the map, the run-time exception `ArrayIndexOutOfBoundsException` will be thrown.

public IndexColorModel (int bits, int size, byte colorMap[], int start, boolean hasalpha)

This version of the `IndexColorModel` constructor calls the previous constructor with a `transparent` index of -1; that is, there is no transparent pixel. If `bits` is too large (greater than 8), or `size` is too large (greater than 2^bits), or the `colorMap` array is too small to hold the map, the run-time exception, `ArrayIndexOutOfBoundsException` will be thrown.

public IndexColorModel (int bits, int size, byte red[], byte green[], byte blue[], int transparent)

The second set of constructors for `IndexColorModel` is similar to the first group, with the exception that these constructors use three or four separate arrays (one per color component) to represent the color map, instead of a single array.

The `bits` parameter still represents the number of bits in a pixel. `size` represents the number of elements in the color map. `transparent` is the location of the transparent pixel in the map (i.e., the pixel value that is considered transparent). If there is no transparent pixel, set `transparent` to -1.

The `red`, `green`, and `blue` arrays contain the color map itself. These arrays must have at least `size` elements. They contain the red, green, and blue components of the colors in the map. For example, if a pixel is at position `p`, `red[p]` contains the pixel's red component; `green[p]` contains the green component; and `blue[p]` contains the blue component. The value of `size` may be smaller than 2^bits, meaning that there may be pixel values with no corresponding entry in the color map. These pixel values (i.e., `size <= p <` 2^bits) are painted with the color components set to 0.

If `bits` is too large (greater than 8), `size` is too large (greater than 2^bits), or the red, green, and blue arrays are too small to hold the map, the run-time exception `ArrayIndexOutOfBoundsException` will be thrown.

public IndexColorModel (int bits, int size, byte red[], byte green[], byte blue[])

This version of the `IndexColorModel` constructor calls the previous one with a `transparent` index of -1; that is, there is no transparent pixel. If `bits` is too large (greater than 8), `size` is too large (greater than 2^bits), or the red, green, and blue arrays are too small to hold the map, the run-time exception `ArrayIndexOutOfBoundsException` will be thrown.

public IndexColorModel (int bits, int size, byte red[], byte green[], byte blue[], byte alpha[])

Like the previous constructor, this version creates an `IndexColorModel` with no transparent pixel. It differs from the previous constructor in that it supports transparency; the array alpha contains the map's transparency values. If `bits` is too large (greater than 8), `size` is too large (greater than 2^bits), or the red, green, blue, and alpha arrays are too small to hold the map, the run-time exception `ArrayIndexOutOfBoundsException` will be thrown.

Methods

final public int getAlpha (int pixel)

The `getAlpha()` method returns the alpha component of `pixel` for a color model, which is a number between 0 and 255, inclusive. A value of 0 means the pixel is completely transparent and the background will appear through the pixel. A value of 255 means the pixel is opaque and you cannot see the background behind it.

final public int getRed (int pixel)

The `getRed()` method returns the red component of `pixel` for a color model, which is a number between 0 and 255, inclusive. A value of 0 means the pixel has no red in it. A value of 255 means red is at maximum intensity.

final public int getGreen (int pixel)

The `getGreen()` method returns the green component of `pixel` for a color model, which is a number between 0 and 255, inclusive. A value of 0 means the pixel has no green in it. A value of 255 means green is at maximum intensity.

final public int getBlue (int pixel)

The `getBlue()` method returns the blue component of `pixel` for a color model, which is a number between 0 and 255, inclusive. A value of 0 means the pixel has no blue in it. A value of 255 means blue is at maximum intensity.

final public int getRGB (int pixel)

The `getRGB()` method returns the color of `pixel` in the default RGB color model. If a subclass has changed the ordering or size of the different color components, `getRGB()` will return the pixel in the RGB color model (0xAARRGGBB order). This version of `getRGB` is identical to the version in the `ColorModel` class but overrides it to make it final.

Other methods

final public int getMapSize()

The `getMapSize()` method returns the size of the color map (i.e., the number of distinct colors).

final public int getTransparentPixel ()

The `getTransparentPixel()` method returns the color map index for the transparent pixel in the color model. If no transparent pixel exists, it returns -1. It is not possible to change the transparent pixel after the color model has been created.

final public void getAlphas (byte alphas[])

The `getAlphas()` method copies the alpha components of the `ColorModel` into elements 0 through `getMapSize()-1` of the `alphas` array. Space must already be allocated in the `alphas` array.

final public void getReds (byte reds[])

The `getReds()` method copies the red components of the `ColorModel` into elements 0 through `getMapSize()-1` of the `reds` array. Space must already be allocated in the `reds` array.

final public void getGreens (byte greens[])

The `getGreens()` method copies the green components of the `ColorModel` into elements 0 through `getMapSize()-1` of the `greens` array. Space must already be allocated in the `greens` array.

final public void getBlues (byte blues[])

The `getBlues()` method copies the blue components of the `ColorModel` into elements 0 through `getMapSize()-1` of the `blues` array. Space must already be allocated in the `blues` array.

12.3 ImageProducer

The ImageProducer interface defines the methods that ImageProducer objects must implement. Image producers serve as sources for pixel data; they may compute the data themselves or interpret data from some external source, like a GIF file. No matter how it generates the data, an image producer's job is to hand that data to an image consumer, which usually renders the data on the screen. The methods in the ImageProducer interface let ImageConsumer objects register their interest in an image. The business end of an ImageProducer--that is, the methods it uses to deliver pixel data to an image consumer--are defined by the ImageConsumer interface. Therefore, we can summarize the way an image producer works as follows:

- It waits for image consumers to register their interest in an image.
- As image consumers register, it stores them in a Hashtable, Vector, or some other collection mechanism.
- As image data becomes available, it loops through all the registered consumers and calls their methods to transfer the data.

There's a sense in which you have to take this process on faith; image consumers are usually well hidden. If you call createImage(), an image consumer will eventually show up.

Every Image has an ImageProducer associated with it; to acquire a reference to the producer, use the getSource() method of Image.

Because an ImageProducer must call methods in the ImageConsumer interface, we won't show an example of a full-fledged producer until we have discussed ImageConsumer.

ImageProducer Interface

Methods

public void addConsumer (ImageConsumer ic)

> The addConsumer() method registers ic as an ImageConsumer interested in the Image information. Once an ImageConsumer is registered, the ImageProducer can deliver Image pixels immediately or

wait until `startProduction()` has been called.

Note that one image may have many consumers; therefore, `addConsumer()` usually stores image consumers in a collection like a `Vector` or `Hashtable`. There is one notable exception: if the producer has the image data in memory, `addConsumer()` can deliver the image to the consumer immediately. When `addConsumer()` returns, it has finished with the consumer. In this case, you don't need to manage a list of consumers, because there is only one image consumer at a time. (In this case, `addConsumer()` should be implemented as a synchronized method.)

public boolean isConsumer (ImageConsumer ic)

The `isConsumer()` method checks to see if `ic` is a registered `ImageConsumer` for this `ImageProducer`. If `ic` is registered, `true` is returned. If `ic` is not registered, `false` is returned.

public void removeConsumer (ImageConsumer ic)

The `removeConsumer()` method removes `ic` as a registered `ImageConsumer` for this `ImageProducer`. If `ic` was not a registered `ImageConsumer`, nothing should happen. This is not an error that should throw an exception. Once `ic` has been removed from the registry, the `ImageProducer` should no longer send data to it.

public void startProduction (ImageConsumer ic)

The `startProduction()` method registers `ic` as an `ImageConsumer` interested in the `Image` information and tells the `ImageProducer` to start sending the `Image` data immediately. The `ImageProducer` sends the image data to `ic` and all other registered `ImageConsumer` objects, through `addConsumer()`.

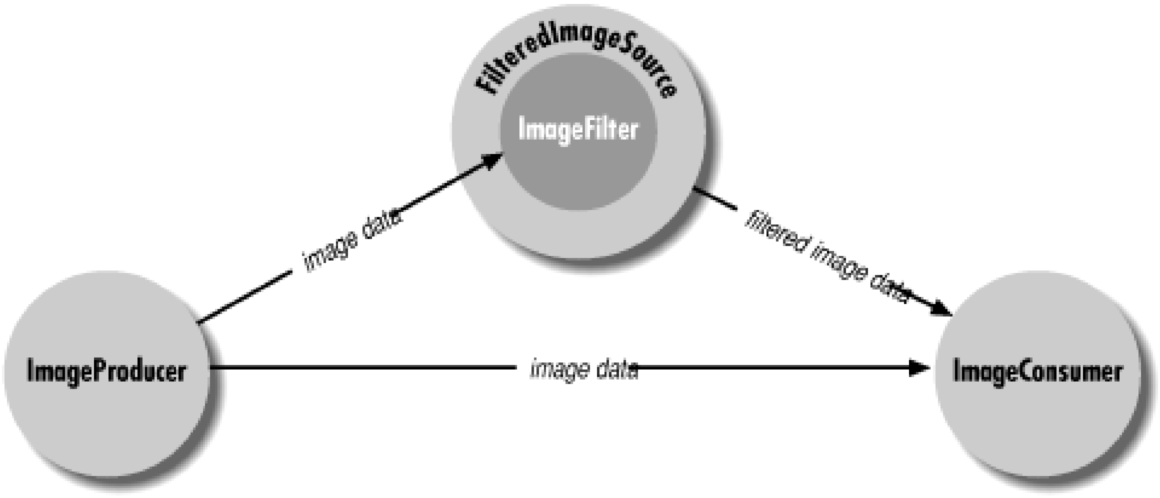
public void requestTopDownLeftRightResend (ImageConsumer ic)

The `requestTopDownLeftRightResend()` method is called by the `ImageConsumer` `ic` requesting that the `ImageProducer` retransmit the `Image` data in top-down, left-to-right order. If the `ImageProducer` is unable to send the data in that order or always sends the data in that order (like with `MemoryImageSource`), it can ignore the call.

FilteredImageSource

The `FilteredImageSource` class combines an `ImageProducer` and an `ImageFilter` to create a new `Image`. The image producer generates pixel data for an original image. The `FilteredImageSource` takes this data and uses an `ImageFilter` to produce a modified version: the image may be scaled, clipped, or rotated, or the colors shifted, etc. The `FilteredImageSource` is the image producer for the new image. The `ImageFilter` object transforms the original image's data to yield the new image; it implements the `ImageConsumer` interface. We cover the `ImageConsumer` interface in ImageConsumer and the `ImageFilter` class in ImageFilter. Figure 12.1 shows the relationship between an `ImageProducer`, `FilteredImageSource`, `ImageFilter`, and the `ImageConsumer`.

Figure 12.1: Image producers, filters, and consumers



Constructors

public FilteredImageSource (ImageProducer original, ImageFilter filter)

> The `FilteredImageSource` constructor creates an image producer that combines an image, `original`, and a filter, `filter`, to create a new image. The `ImageProducer` of the original image is the constructor's first parameter; given an `Image`, you can acquire its `ImageProducer` by using the `getSource()` method. The following code shows how to create a new image from an original. ImageFilter shows several extensive examples of image filters.

```
Image image = getImage (new URL
      ("http://www.ora.com/graphics/headers/homepage.gif"));
Image newOne = createImage (new FilteredImageSource
      (image.getSource(), new SomeImageFilter()));
```

ImageProducer interface methods

The `ImageProducer` interface methods maintain an internal table for the image consumers. Since this is private, you do not have direct access to it.

public synchronized void addConsumer (ImageConsumer ic)

> The `addConsumer()` method adds `ic` as an `ImageConsumer` interested in the pixels for this image.

public synchronized boolean isConsumer (ImageConsumer ic)

> The `isConsumer()` method checks to see if `ic` is a registered `ImageConsumer` for this `ImageProducer`. If `ic` is registered, `true` is returned. If not registered, `false` is returned.

public synchronized void removeConsumer (ImageConsumer ic)

The `removeConsumer()` method removes `ic` as a registered `ImageConsumer` for this `ImageProducer`.

public void startProduction (ImageConsumer ic)

The `startProduction()` method registers `ic` as an `ImageConsumer` interested in the `Image` information and tells the `ImageProducer` to start sending the `Image` data immediately.

public void requestTopDownLeftRightResend (ImageConsumer ic)

The `requestTopDownLeftRightResend()` method registers `ic` as an `ImageConsumer` interested in the `Image` information and requests the `ImageProducer` to retransmit the `Image` data in top-down, left-to-right order.

MemoryImageSource

The `MemoryImageSource` class allows you to create images completely in memory; you generate pixel data, place it in an array, and hand that array and a `ColorModel` to the `MemoryImageSource` constructor. The `MemoryImageSource` is an image producer that can be used with a consumer to display the image on the screen. For example, you might use a `MemoryImageSource` to display a Mandelbrot image or some other image generated by your program. You could also use a `MemoryImageSource` to modify a pre-existing image; use `PixelGrabber` to get the image's pixel data, modify that data, and then use a `MemoryImageSource` as the producer for the modified image. Finally, you can use `MemoryImageSource` to simplify implementation of a new image type; you can develop a class that reads an image in some unsupported format from a local file or the network; interprets the image file and puts pixel data into an array; and uses a `MemoryImageSource` to serve as an image producer. This is simpler than implementing an image producer yourself, but it isn't quite as flexible; you lose the ability to display partial images as the data becomes available.

In Java 1.1, `MemoryImageSource` supports multiframe images to animate a sequence. In earlier versions, it was necessary to create a dynamic `ImageFilter` to animate the image. Constructors

There are six constructors for `MemoryImageSource`, each with slightly different parameters. They all create an image producer that delivers some array of data to an image consumer. The constructors are:

public MemoryImageSource (int w, int h, ColorModel cm, byte pix[], int off, int scan)
public MemoryImageSource (int w, int h, ColorModel cm, byte pix[], int off, int scan, Hashtable props)
public MemoryImageSource (int w, int h, ColorModel cm, int pix[], int off, int scan)
public MemoryImageSource (int w, int h, ColorModel cm, int pix[], int off, int scan, Hashtable props)
public MemoryImageSource (int w, int h, int pix[], int off, int scan)
public MemoryImageSource (int w, int h, int pix[], int off, int scan, Hashtable props)

The parameters that might be present are:

`w`

Width of the image being created, in pixels.

`h`

Height of the image being created, in pixels.

`cm`

The `ColorModel` that describes the color representation used in the pixel data. If this parameter is not present, the `MemoryImageSource` uses the default RGB color model (`ColorModel.getRGBDefault()`).

`pix[]`

The array of pixel information to be converted into an image. This may be either a `byte` array or an `int` array, depending on the color model. If you're using a direct color model (including the default RGB color model), `pix` is usually an `int` array; if it isn't, it won't be able to represent all 16 million possible colors. If you're using an indexed color model, the array should be a `byte` array. However, if you use an `int` array with an indexed color model, the `MemoryImageSource` ignores the three high-order bytes because an indexed color model has at most 256 entries in the color map. In general: if your color model requires more than 8 bits of data per pixel, use an `int` array; if it requires 8 bits or less, use a `byte` array.

`off`

The first pixel used in the array (usually 0); prior pixels are ignored.

`scan`

The number of pixels per line in the array (usually equal to `w`). The number of pixels per scan line in the array may be larger than the number of pixels in the scan line. Extra pixels in the array are ignored.

`props`

A `Hashtable` of the properties associated with the image. If this argument isn't present, the constructor assumes there are no properties.

The pixel at location (`x`, `y`) in the image is located at `pix[y * scan + x + off]`. ImageProducer interface methods

In Java 1.0, the `ImageProducer` interface methods maintain a single internal variable for the image consumer because the image is delivered immediately and synchronously. There is no need to worry about multiple consumers; as soon as one registers, you give it the image, and you're done. These methods keep track of this single `ImageConsumer`.

In Java 1.1, `MemoryImageSource` supports animation. One consequence of this new feature is that it isn't always possible to deliver all the image's data immediately. Therefore, the class maintains a list of image consumers that are notified when each frame is generated. Since this list is private, you do not have direct access to it.

public synchronized void addConsumer (ImageConsumer ic)

> The `addConsumer()` method adds `ic` as an `ImageConsumer` interested in the pixels for this image.

public synchronized boolean isConsumer (ImageConsumer ic)

> The `isConsumer()` method checks to see if `ic` is a registered `ImageConsumer` for this `ImageProducer`. If `ic` is registered, `true` is returned. If `ic` is not registered, `false` is returned.

public synchronized void removeConsumer (ImageConsumer ic)

> The `removeConsumer()` method removes `ic` as a registered `ImageConsumer` for this `ImageProducer`.

public void startProduction (ImageConsumer ic)

> The `startProduction()` method calls `addConsumer()`.

public void requestTopDownLeftRightResend (ImageConsumer ic)

> The `requestTopDownLeftRightResend()` method does nothing since in-memory images are already in this format or are multiframed, with each frame in this format.

Animation methods

In Java 1.1, `MemoryImageSource` supports animation; it can now pass multiple frames to interested image consumers. This feature mimics GIF89a's multiframe functionality. (If you have GIF89a animations, you can display them using `getImage()` and `drawImage()`; you don't have to build a complicated creature using `MemoryImageSource`.) . An animation example follows in [Example 12.3] (later in this chapter).

public synchronized void setAnimated(boolean animated) ★

> The `setAnimated()` method notifies the `MemoryImageSource` if it will be in animation mode (`animated` is `true`) or not (`animated` is `false`). By default, animation is disabled; you must call this method to generate an image sequence. To prevent losing data, call this method immediately after calling the `MemoryImageSource` constructor.

public synchronized void setFullBufferUpdates(boolean fullBuffers) ★

> The `setFullBufferUpdates()` method controls how image updates are done during an animation. It is ignored if you are not creating an animation. If `fullBuffers` is `true`, this method tells the `MemoryImageSource` that it should always send all of an image's data to the consumers whenever it received new data (by a call to `newPixels()`). If `fullBuffers` is `false`, the `MemoryImageSource` sends only the changed portion of the image and notifies consumers (by a call to `ImageConsumer.setHints()`) that frames sent will be complete.

Like `setAnimated()`, `setFullBufferUpdates()` should be called immediately after calling the `MemoryImageSource` constructor, before the animation is started.

To do the actual animation, you update the image array `pix[]` that was specified in the constructor and call one of the overloaded `newPixels()` methods to tell the `MemoryImageSource` that you have changed the image data. The parameters to `newPixels()` determine whether you are animating the entire image or just a portion of the image. You can also supply a new array to take pixel data from, replacing `pix[]`. In any case, `pix[]` supplies the initial image data (i.e., the first frame of the animation).

If you have not called `setAnimated(true)`, calls to any version of `newPixels()` are ignored.

public void newPixels() ★

The version of `newPixels()` with no parameters tells the `MemoryImageSource` to send the entire pixel data (frame) to all the registered image consumers again. Data is taken from the original array `pix[]`. After the data is sent, the `MemoryImageSource` notifies consumers that a frame is complete by calling `imageComplete(ImageConsumer.SINGLEFRAMEDONE)`, thus updating the display when the image is redisplayed. Remember that in many cases, you don't need to update the entire image; updating part of the image saves CPU time, which may be crucial for your application. To update part of the image, call one of the other versions of `newPixels()`.

public synchronized void newPixels(int x, int y, int w, int h) ★

This `newPixels()` method sends part of the image in the array `pix[]` to the consumers. The portion of the image sent has its upper left corner at the point (`x`, `y`), width `w` and height `h`, all in pixels. Changing part of the image rather than the whole thing saves considerably on system resources. Obviously, it is appropriate only if most of the image is still. For example, you could use this method to animate the steam rising from a cup of hot coffee, while leaving the cup itself static (an image that should be familiar to anyone reading JavaSoft's Web site). After the data is sent, consumers are notified that a frame is complete by a call to `imageComplete(ImageConsumer.SINGLEFRAMEDONE)`, thus updating the display when the image is redisplayed.

If `setFullBufferUpdates()` was called, the entire image is sent, and the dimensions of the bounding box are ignored.

public synchronized void newPixels(int x, int y, int w, int h, boolean frameNotify) ★

This `newPixels()` method is identical to the last, with one exception: consumers are notified that new image data is available only when `frameNotify` is `true`. This method allows you to generate new image data in pieces, updating the consumers only once when you are finished.

If `setFullBufferUpdates()` was called, the entire image is sent, and the dimensions of the bounding box are ignored.

public synchronized void newPixels(byte[] newpix, ColorModel newmodel, int offset, int scansize) ★

public synchronized void newPixels(int[] newpix, ColorModel newmodel, int offset, int scansize) ★

> These `newPixels()` methods change the source of the animation to the `byte` or `int` array `newpix[]`, with a `ColorModel` of `newmodel`. `offset` marks the beginning of the data in `newpix` to use, while `scansize` states the number of pixels in `newpix` per line of `Image` data. Future calls to other versions of `newPixels()` should modify `newpix[]` rather than `pix[]`.

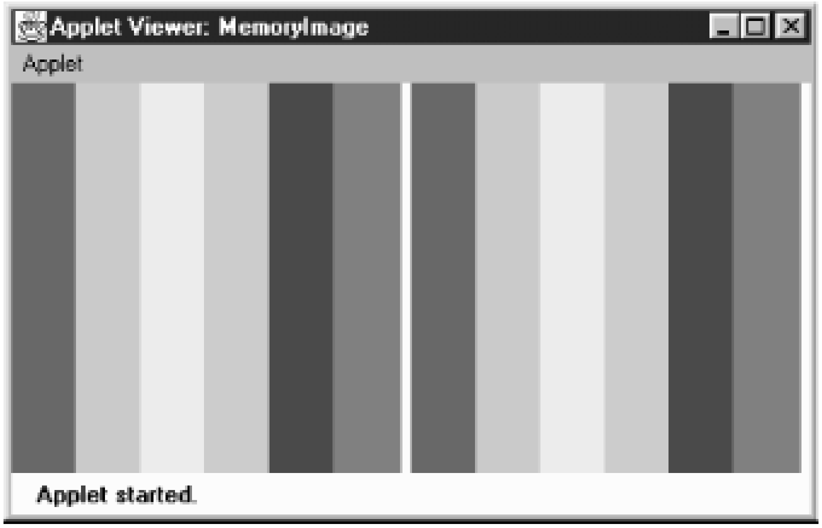
Using MemoryImageSource to create a static image

You can create an image by generating an integer or byte array in memory and converting it to an image with `MemoryImageSource`. The following `MemoryImage` applet generates two identical images that display a series of color bars from left to right. Although the images look the same, they were generated differently: the image on the left uses the default `DirectColorModel`; the image on the right uses an `IndexColorModel`.

Because the image on the left uses a `DirectColorModel`, it stores the actual color value of each pixel in an array of integers (`rgbPixels[]`). The image on the right can use a byte array (`indPixels[]`) because the `IndexColorModel` puts the color information in its color map instead of the pixel array; elements of the pixel array need to be large enough only to address the entries in this map. Images that are based on `IndexColorModel` are generally more efficient in their use of space (integer vs. byte arrays, although `IndexColorModel` requires small support arrays) and in performance (if you filter the image).

The output from this example is shown in Figure 12.2. The source is shown in Example 12.2.

Figure 12.2: MemoryImage applet output



Example 12.2: MemoryImage Test Program

```
import java.applet.*;
import java.awt.*;
import java.awt.image.*;
public class MemoryImage extends Applet {
    Image i, j;
    int width = 200;
    int height = 200;
    public void init () {
        int rgbPixels[] = new int [width*height];
        byte indPixels[] = new byte [width*height];
        int index = 0;
        Color colorArray[] = {Color.red, Color.orange, Color.yellow,
                Color.green, Color.blue, Color.magenta};
        int rangeSize = width / colorArray.length;
        int colorRGB;
        byte colorIndex;
        byte reds[]   = new byte[colorArray.length];
        byte greens[] = new byte[colorArray.length];
        byte blues[]  = new byte[colorArray.length];
        for (int i=0;i<colorArray.length;i++) {
            reds[i]   = (byte)colorArray[i].getRed();
            greens[i] = (byte)colorArray[i].getGreen();
            blues[i]  = (byte)colorArray[i].getBlue();
        }
        for (int y=0;y<height;y++) {
            for (int x=0;x<width;x++) {
                if (x < rangeSize) {
                    colorRGB = Color.red.getRGB();
                    colorIndex = 0;
                } else if (x < (rangeSize*2)) {
                    colorRGB = Color.orange.getRGB();
                    colorIndex = 1;
                } else if (x < (rangeSize*3)) {
                    colorRGB = Color.yellow.getRGB();
                    colorIndex = 2;
                } else if (x < (rangeSize*4)) {
                    colorRGB = Color.green.getRGB();
                    colorIndex = 3;
                } else if (x < (rangeSize*5)) {
                    colorRGB = Color.blue.getRGB();
                    colorIndex = 4;
                } else {
                    colorRGB = Color.magenta.getRGB();
                    colorIndex = 5;
                }
                rgbPixels[index] = colorRGB;
                indPixels[index] = colorIndex;
                index++;
            }
        }
        i = createImage (new MemoryImageSource (width, height, rgbPixels,
            0, width));
        j = createImage (new MemoryImageSource (width, height,
            new IndexColorModel (8, colorArray.length, reds, greens, blues),
            indPixels, 0, width));
    }
    public void paint (Graphics g) {
        g.drawImage (i, 0, 0, this);
        g.drawImage (j, width+5, 0, this);
    }
}
```

Almost all of the work is done in `init()` (which, in a real applet, isn't a terribly good idea; ideally `init()` should be lightweight). Previously, we explained the color model's use for the images on the left and the right. Toward the end of `init()`, we create the images `i` and `j` by calling `createImage()` with a `MemoryImageSource` as the image producer. For image `i`, we used the simplest `MemoryImageSource` constructor, which uses the default RGB color model. For `j`, we called the `IndexColorModel` constructor within the `MemoryImageSource` constructor, to create a color map that has only six entries: one for each of the colors we use. Using MemoryImageSource for animation

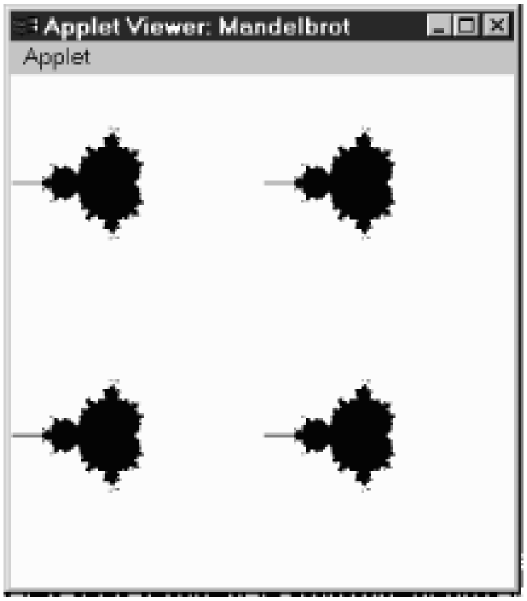
As we've seen, Java 1.1 gives you the ability to create an animation using a `MemoryImageSource` by updating the image data in memory; whenever you have finished an update, you can send the resulting frame to the consumers. This technique gives you a way to do animations that consume very little memory, since you keep overwriting the original image. The applet in Example 12.3 demonstrates `MemoryImageSource`'s animation capability by creating a Mandelbrot image in memory, updating the image as new points are added. Figure 12.3 shows the results, using four consumers to display the image four times.

Example 12.3: Mandelbrot Program

```
// Java 1.1 only
import java.awt.*;
import java.awt.image.*;
import java.applet.*;
public class Mandelbrot extends Applet implements Runnable {
    Thread animator;
    Image im1, im2, im3, im4;
    public void start() {
        animator = new Thread(this);
        animator.start();
    }
    public synchronized void stop() {
        animator = null;
    }
    public void paint(Graphics g) {
        if (im1 != null)
            g.drawImage(im1, 0, 0, null);
        if (im2 != null)
            g.drawImage(im2, 0, getSize().height / 2, null);
        if (im3 != null)
            g.drawImage(im3, getSize().width / 2, 0, null);
        if (im4 != null)
```

```
            g.drawImage(im4, getSize().width / 2, getSize().height / 2, null);
    }
    public void update (Graphics g) {
        paint (g);
    }
    public synchronized void run() {
        Thread.currentThread().setPriority(Thread.MIN_PRIORITY);
        int width = getSize().width / 2;
        int height = getSize().height / 2;
        byte[] pixels = new byte[width * height];
        int index = 0;
        int iteration=0;
        double a, b, p, q, psq, qsq, pnew, qnew;
        byte[] colorMap = {(byte)255, (byte)255, (byte)255, // white
                           (byte)0, (byte)0, (byte)0};      // black
        MemoryImageSource mis = new MemoryImageSource(
            width, height,
            new IndexColorModel (8, 2, colorMap, 0, false, -1),
            pixels, 0, width);
        mis.setAnimated(true);
        im1 = createImage(mis);
        im2 = createImage(mis);
        im3 = createImage(mis);
        im4 = createImage(mis);
        // Generate Mandelbrot
        final int ITERATIONS = 16;
        for (int y=0; y<height; y++) {
            b = ((double)(y-64))/32;
            for (int x=0; x<width; x++) {
                a = ((double)(x-64))/32;
                p=q=0;
                iteration = 0;
                while (iteration < ITERATIONS) {
                    psq = p*p;
                    qsq = q*q;
                    if ((psq + qsq) >= 4.0)
                        break;
                    pnew = psq - qsq + a;
                    qnew = 2*p*q+b;
                    p = pnew;
                    q = qnew;
                    iteration++;
                }
                if (iteration == ITERATIONS) {
                    pixels[index] = 1;
                    mis.newPixels(x, y, 1, 1);
                    repaint();
                }
                index++;
            }
        }
    }
}
```

Figure 12.3: Mandelbrot output



Most of the applet in Example 12.3 should be self-explanatory. The `init()` method starts the thread in which we do our computation. `paint()` just displays the four images we create. All the work, including the computation, is done in the thread's `run()` method. `run()` starts by setting up a color map, creating a `MemoryImageSource` with animation enabled and creating four images using that source as the producer. It then does the computation, which I won't explain; for our purposes, the interesting part is what happens when we've computed a pixel. We set the appropriate byte in our data array, `pixels[]`, and then call `newPixels()`, giving the location of the new pixel and its size (1 by 1) as arguments. Thus, we redraw the images for every new pixel. In a real application, you would probably compute a somewhat larger chunk of new data before updating the screen, but the same principles apply.

12.4 ImageConsumer

The `ImageConsumer` interface specifies the methods that must be implemented to receive data from an `ImageProducer`. For the most part, that is the only context in which you need to know about the `ImageConsumer` interface. If you write an image producer, it will be handed a number of obscure objects, about which you know nothing except that they implement `ImageConsumer`, and that you can therefore call the methods discussed in this section to deliver your data. The chances that you will ever implement an image consumer are rather remote, unless you are porting Java to a new environment. It is more likely that you will want to subclass `ImageFilter`, in which case you may need to implement some of these methods. But most of the time, you will just need to know how to hand your data off to the next element in the chain.

The `java.awt.image` package includes two classes that implement `ImageConsumer: PixelGrabber` and `ImageFilter` (and its subclasses). These classes are unique in that they don't display anything on the screen. `PixelGrabber` takes the image data and stores it in a pixel array; you can use this array to save the image in a file, generate a new image, etc. `ImageFilter`, which is used in conjunction with `FilteredImageSource`, modifies the image data; the `FilteredImageSource` sends the modified image to another consumer, which can further modify or display the new image. When you draw an image on the screen, the JDK's `ImageRepresentation` class is probably doing the real work. This class is part of the `sun.awt.image` package. You really don't need to know anything about it, although you may see `ImageRepresentation` mentioned in a stack trace if you try to filter beyond the end of a pixel array.

ImageConsumer Interface

Constants

There are two sets of constants for `ImageConsumer`. One set represents those that can be used for the `imageComplete()` method. The other is used with the `setHints()` method. See the descriptions of those methods on how to use them.

The first set of flags is for the `imageComplete()` method:

public static final int IMAGEABORTED

> The `IMAGEABORTED` flag signifies that the image creation process was aborted and the image is not complete. In the image production process, an abort could mean multiple things. It is possible that retrying the production would succeed.

public static final int IMAGEERROR

> The `IMAGEERROR` flag signifies that an error was encountered during the image creation process and the image is not complete. In the image production process, an error could mean multiple things. More than likely, the image file or pixel data is invalid, and retrying won't succeed.

public static final int SINGLEFRAMEDONE

> The `SINGLEFRAMEDONE` flag signifies that a frame other than the last has completed loading. There are additional frames to display, but a new frame is available and is complete. For an example of this flag in use, see the dynamic `ImageFilter` example in Example 12.8.

public static final int STATICIMAGEDONE

> The `STATICIMAGEDONE` flag signifies that the image has completed loading. If this is a multiframe image, all frames have been generated. For an example of this flag in use, see the dynamic `ImageFilter` example in Example 12.8.

The following set of flags can be ORed together to form the single parameter to the `setHints()` method. Certain flags do not make sense set together, but it is the responsibility of the concrete `ImageConsumer` to enforce this.

public static final int COMPLETESCANLINES

> The `COMPLETESCANLINES` flag signifies that each call to `setPixels()` will deliver at least one complete scan line of pixels to this consumer.

public static final int RANDOMPIXELORDER

> The `RANDOMPIXELORDER` flag tells the consumer that pixels are not provided in any particular order. Therefore, the consumer cannot perform optimization that depends on pixel delivery order. In the absence of both `COMPLETESCANLINES` and `RANDOMPIXELORDER`, the `ImageConsumer` should assume pixels will arrive in `RANDOMPIXELORDER`.

public static final int SINGLEFRAME

> The `SINGLEFRAME` flag tells the consumer that this image contains a single non-changing frame. This is the case with most image formats. An example of an image that does not contain a single frame is the multiframe GIF89a image.

public static final int SINGLEPASS

> The `SINGLEPASS` flag tells the consumer to expect each pixel once and only once. Certain image formats, like progressive JPEG images, deliver a single image several times, with each pass yielding a sharper image.

public static final int TOPDOWNLEFTRIGHT

> The final `setHints()` flag, `TOPDOWNLEFTRIGHT`, tells the consumer to expect the pixels in a top-down, left-right order. This flag will almost always be set.

Methods

The interface methods are presented in the order in which they are normally called by an `ImageProducer`.

void setDimensions (int width, int height)

> The `setDimensions()` method should be called once the `ImageProducer` knows the `width` and `height` of the image. This is the actual `width` and `height`, not necessarily the scaled size. It is the consumer's responsibility to do the scaling and resizing.

void setProperties (Hashtable properties)

> The `setProperties()` method should only be called by the `ImageProducer` if the image has any properties that should be stored for later retrieval with the `getProperty()` method of `Image`. Every image format has its own property set. One property that tends to be common is the "comment" property. `properties` represents the `Hashtable` of properties for the image; the name of each property is used as the `Hashtable` key.

void setColorModel (ColorModel model)

> The `setColorModel()` method gives the `ImageProducer` the opportunity to tell the `ImageConsumer` that the `ColorModel` `model` will be used for the majority of pixels in the image. The `ImageConsumer` may use this information for optimization. However, each call to `setPixels()` contains its own `ColorModel`, which isn't necessarily the same as the color model given here. In other words, `setColorModel()` is only advisory; it does not guarantee that all (or any) of the pixels in the image will use this model. Using different color models for different parts of an image is possible, but not recommended.

void setHints (int hints)

> An `ImageProducer` should call the `setHints()` method prior to any `setPixels()` calls. The `hints` are formed by ORing the constants `COMPLETESCANLINES`, `RANDOMPIXELORDER`, `SINGLEFRAME`, `SINGLEPASS`, and `TOPDOWNLEFTRIGHT`. These hints give the image consumer information about the order in which the producer will deliver pixels. When the `ImageConsumer` is receiving pixels, it can take advantage of these hints for optimization.

void setPixels (int x, int y, int width, int height, ColorModel model, byte pixels[], int offset, int scansize)

> An ImageProducer calls the `setPixels()` method to deliver the image pixel data to the `ImageConsumer`. The bytes are delivered a rectangle at a time. (`x`, `y`) represents the top left corner of the rectangle; its dimensions are `width` x `height`. `model` is the `ColorModel` used for this set of pixels; different calls to `setPixels()` may use different color models. The pixels themselves are taken from the byte array `pixels`. `offset` is the first element of the pixel array that will be used. `scansize` is the length of the scan lines in the array. In most cases, you want the consumer to render all the pixels on the scan line; in this case, `scansize` will equal `width`. However, there are cases in which you want the consumer to ignore part of the scan line; you may be clipping an image, and the ends of the scan line fall outside the clipping region. In this case, rather than copying the pixels you want into a new array, you can specify a `width` that is smaller than `scansize`.

That's a lot of information, but it's easy to summarize. A pixel located at point (`x1`, `y1`) within the rectangle being delivered to the consumer is located at position `((y1 - y) * scansize + (x1 - x) + offset)` within the array `pixels[]`. Figure 12.4 shows how the pixels delivered by `setPixels()` fit into the complete image; Figure 12.5 shows how pixels are stored within the array.

Figure 12.4: Delivering pixels for an image

[Graphic: Figure 12-4]

Figure 12.5: Storing pixels in an array

[Graphic: Figure 12-5]

void setPixels (int x, int y, int width, int height, ColorModel model, int pixels[], int offset, int scansize)

The second `setPixels()` method is similar to the first. `pixels[]` is an array of `int`s; this is necessary when you have more than eight bits of data per pixel.

void imageComplete (int status)

The `ImageProducer` calls `imageComplete()` to tell an `ImageConsumer` that it has transferred a complete image. The status argument is a flag that describes exactly why the `ImageProducer` has finished. It may have one of the following values: `IMAGEABORTED` (if the image production was aborted); `IMAGEERROR` (if an error in producing the image occurred); `SINGLEFRAMEDONE` (if a single frame of a multiframe image has been completed); or `STATICIMAGEDONE` (if all pixels have been delivered). When `imageComplete()` gets called, the `ImageConsumer` should call the image producer's `removeConsumer()` method, unless it wants to receive additional frames (status of `SINGLEFRAMEDONE`).

PPMImageDecoder

Now that we have discussed the `ImageConsumer` interface, we're finally ready to give an example of a full-fledged `ImageProducer`. This producer uses the methods of the `ImageConsumer` interface to communicate with image consumers; image consumers use the `ImageProducer` interface to register themselves with this producer.

Our image producer will interpret images in the PPM format.[1] PPM is a simple image format developed by Jef Poskanzer as part of the *pbmplus* image conversion package. A PPM file starts with a header consisting of the image type, the image's width and height in pixels, and the maximum value of any RGB component. The header is entirely in ASCII. The pixel data follows the header; it is either in binary (if the image type is P6) or ASCII (if the image type is P3). The pixel data is simply a series of bytes describing the color of each pixel, moving left to right and top to bottom. In binary format, each pixel is represented by three bytes: one for red, one for green, and one for blue. In ASCII format, each pixel is represented by three numeric values, separated by white space (space, tab, or newline). A comment may occur anywhere in the file, but it would be surprising to see one outside of the header. Comments start with # and continue to the end of the line. ASCII format files are obviously much larger than binary files. There is no compression on either file type.

> [1] For more information about PPM and the *pbmplus* package, see *Encyclopedia of Graphics File Formats*, by James D. Murray and William VanRyper (from O'Reilly & Associates). See also http://www.acme.com/.

The `PPMImageDecoder` source is listed in Example 12--4. The applet that uses this class is shown in Example 12.5. You can reuse a lot of the code in the `PPMImageDecoder` when you implement your own image producers.

Example 12.4: PPMImageDecoder Source

```
import java.awt.*;
import java.awt.image.*;
import java.util.*;
import java.io.*;
public class PPMImageDecoder implements ImageProducer {
/* Since done in-memory, only one consumer */
    private ImageConsumer consumer;
    boolean loadError = false;
    int width;
    int height;
    int store[][];
    Hashtable props = new Hashtable();
/* Format of Ppm file is single pass/frame, w/ complete scan lines in order */
    private static int PpmHints = (ImageConsumer.TOPDOWNLEFTRIGHT |
                                   ImageConsumer.COMPLETESCANLINES |
                                   ImageConsumer.SINGLEPASS |
                                   ImageConsumer.SINGLEFRAME);
```

The class starts by declaring class variables and constants. We will use the variable `PpmHints` when we call `setHints()`. Here, we set this variable to a collection of "hint" constants that indicate we will produce pixel data in top-down, left-right order; we will always send complete scan lines; we will make only one pass over the pixel data (we will send each pixel once); and there is one frame per image (i.e., we aren't producing a multiframe sequence).

The next chunk of code implements the `ImageProducer` interface; consumers use it to request image data:

```
/* There is only a single consumer. When it registers, produce image. */
/* On error, notify consumer. */
    public synchronized void addConsumer (ImageConsumer ic) {
        consumer = ic;
        try {
            produce();
        }catch (Exception e) {
            if (consumer != null)
                consumer.imageComplete (ImageConsumer.IMAGEERROR);
        }
        consumer = null;
    }
/* If consumer passed to routine is single consumer, return true, else false. */
    public synchronized boolean isConsumer (ImageConsumer ic) {
        return (ic == consumer);
    }
/* Disables consumer if currently consuming. */
    public synchronized void removeConsumer (ImageConsumer ic) {
        if (consumer == ic)
            consumer = null;
    }
/* Production is done by adding consumer. */
    public void startProduction (ImageConsumer ic) {
        addConsumer (ic);
    }
    public void requestTopDownLeftRightResend (ImageConsumer ic) {
        // Not needed.  The data is always in this format.
    }
```

The previous group of methods implements the `ImageProducer` interface. They are quite simple, largely because of the way this `ImageProducer` generates images. It builds the image in memory before delivering it to the consumer; you must call the `readImage()` method (discussed shortly) before you can create an image with this consumer. Because the image is in memory before any consumers can register their interest, we can write an `addConsumer()` method that registers a consumer and delivers all the data to that consumer before returning. Therefore, we don't need to manage a list of consumers in a `Hashtable` or some other collection object. We can store the current consumer in an instance variable `ic` and forget about any others: only one consumer exists at a time. To make sure that only one consumer exists at a time, we synchronize the `addConsumer()`, `isConsumer()`, and `removeConsumer()` methods. Synchronization prevents another consumer from registering itself before the current consumer has finished. If you write an `ImageProducer` that builds the image in memory before delivering it, you can probably use this code verbatim.

`addConsumer()` is little more than a call to the method `produce()`, which handles "consumer relations": it delivers the pixels to the consumer using the methods in the `ImageConsumer` interface. If `produce()` throws an exception, `addConsumer()` calls `imageComplete()` with an `IMAGEERROR` status code. Here's the code for the `produce()` method:

```
/* Production Process:
        Prerequisite: Image already read into store array. (readImage)
                      props / width / height already set (readImage)
        Assumes RGB Color Model - would need to filter to change.
        Sends Ppm Image data to consumer.
        Pixels sent one row at a time.
*/
    private void produce () {
        ColorModel cm = ColorModel.getRGBdefault();
        if (consumer != null) {
            if (loadError) {
                consumer.imageComplete (ImageConsumer.IMAGEERROR);
            } else {
                consumer.setDimensions (width, height);
                consumer.setProperties (props);
                consumer.setColorModel (cm);
                consumer.setHints (PpmHints);
                for (int j=0;j<height;j++)
                    consumer.setPixels (0, j, width, 1, cm, store[j], 0, width);
                consumer.imageComplete (ImageConsumer.STATICIMAGEDONE);
            }
        }
    }
```

`produce()` just calls the `ImageConsumer` methods in order: it sets the image's dimensions, hands off an empty `Hashtable` of properties, sets the color model (the default RGB model) and the hints, and then calls `setPixels()` once for each row of pixel data. The data is in the integer array `store[][]`, which has already been loaded by the `readImage()` method (defined in the following code). When the data is delivered, the method `setPixels()` calls `imageComplete()` to indicate that the image has been finished successfully.

```
/* Allows reading to be from internal byte array, in addition to disk/socket */
    public void readImage (byte b[]) {
        readImage (new ByteArrayInputStream (b));
    }
/* readImage reads image data from Stream */
/* parses data for PPM format             */
/* closes inputstream when done           */
    public void readImage (InputStream is) {
        long tm = System.currentTimeMillis();
        boolean raw=false;
        DataInputStream dis = null;
        BufferedInputStream bis = null;
        try {
            bis = new BufferedInputStream (is);
            dis = new DataInputStream (bis);
            String word;
            word = readWord (dis);
            if ("P6".equals (word)) {
                raw = true;
            } else if ("P3".equals (word)) {
                raw = false;
            } else {
                throw (new AWTException ("Invalid Format " + word));
            }
            width = Integer.parseInt (readWord (dis));
            height = Integer.parseInt (readWord (dis));
            // Could put comments in props - makes readWord more complex
            int maxColors = Integer.parseInt (readWord (dis));
            if ((maxColors < 0) || (maxColors > 255)) {
                throw (new AWTException ("Invalid Colors " + maxColors));
            }
            store = new int[height][width];
            if (raw) {                   // binary format (raw) pixel data
                byte row[] = new byte [width*3];
                for (int i=0;i<height;i++){
                    dis.readFully (row);
                    for (int j=0,k=0;j<width;j++,k+=3) {
                        int red = row[k];
                        int green = row[k+1];
                        int blue = row[k+2];
                        if (red < 0)
                            red +=256;
                        if (green < 0)
                            green +=256;
                        if (blue < 0)
                            blue +=256;
                        store[i][j] = (0xff<< 24) | (red << 16) |
                                      (green << 8) | blue;
                    }
                }
            } else {                     // ASCII pixel data
                for (int i=0;i<height;i++) {
                    for (int j=0;j<width;j++) {
                        int red = Integer.parseInt (readWord (dis));
                        int green = Integer.parseInt (readWord (dis));
                        int blue = Integer.parseInt (readWord (dis));
                        store[i][j] = (0xff<< 24) | (red << 16) |
                                      (green << 8) | blue;
                    }
                }
            }
        } catch (IOException io) {
            loadError = true;
            System.out.println ("IO Exception " + io.getMessage());
        } catch (AWTException awt) {
            loadError = true;
            System.out.println ("AWT Exception " + awt.getMessage());
        } catch (NoSuchElementException nse) {
            loadError = true;
            System.out.println ("No Such Element Exception " + nse.getMessage());
        } finally {
            try {
                if (dis != null)
```

```
                dis.close();
            if (bis != null)
                bis.close();
            if (is != null)
                is.close();
        } catch (IOException io) {
            System.out.println ("IO Exception " + io.getMessage());
        }
    }
    System.out.println ("Done in " + (System.currentTimeMillis() - tm)
                        + " ms");
}
```

`readImage()` reads the image data from an `InputStream` and converts it into the array of pixel data that `produce()` transfers to the consumer. Code using this class must call `readImage()` to process the data before calling `createImage()`; we'll see how this works shortly. Although there is a lot of code in `readImage()`, it's fairly simple. (It would be much more complex if we were dealing with an image format that compressed the data.) It makes heavy use of `readWord()`, a utility method that we'll discuss next; `readWord()` returns a word of ASCII text as a string.

`readImage()` starts by converting the `InputStream` into a `DataInputStream`. It uses `readWord()` to get the first word from the stream. This should be either "P6" or "P3", depending on whether the data is in binary or ASCII. It then uses `readWord()` to save the image's width and height and the maximum value of any color component. Next, it reads the color data into the `store[][]` array. The ASCII case is simple because we can use `readWord()` to read ASCII words conveniently; we read red, green, and blue words, convert them into `ints`, and pack the three into one element (one pixel) of `store[][]`. For binary data, we read an entire scan line into the byte array `row[]`, using `readFully()`; then we start a loop that packs this scan line into one row of `store[][]`. A little additional complexity is in the inner loop because we must keep track of two arrays (`row[]` and `store[][]`). We read red, green, and blue components from `row[]`, converting Java's signed bytes to unsigned data by adding 256 to any negative values; finally, we pack these components into one element of `store[][]`.

```
/* readWord returns a word of text from stream          */
/* Ignores PPM comment lines.                           */
/* word defined to be something wrapped by whitespace   */
    private String readWord (InputStream is) throws IOException {
        StringBuffer buf = new StringBuffer();
        int b;
        do {// get rid of leading whitespace
            if ((b=is.read()) == -1)
                throw new EOFException();
            if ((char)b == '#') { // read to end of line - ppm comment
                DataInputStream dis = new DataInputStream (is);
                dis.readLine();
                b = ' ';  // ensure more reading
            }
        }while (Character.isSpace ((char)b));
        do {
            buf.append ((char)(b));
            if ((b=is.read()) == -1)
```

```
                throw new EOFException();
        } while (!Character.isSpace ((char)b));  // reads first space
        return buf.toString();
    }
}
```

`readWord()` is a utility method that reads one ASCII word from an `InputStream`. A word is a sequence of characters that aren't spaces; space characters include newlines and tabs in addition to spaces. This method also throws out any comments (anything between # and the end of the line). It collects the characters into a `StringBuffer`, converting the `StringBuffer` into a `String` when it returns.

Example 12.5: PPMImageDecoder Test Program

```
import java.awt.Graphics;
import java.awt.Color;
import java.awt.image.ImageConsumer;
import java.awt.Image;
import java.awt.MediaTracker;
import java.net.URL;
import java.net.MalformedURLException;
import java.io.InputStream;
import java.io.IOException;
import java.applet.Applet;
public class ppmViewer extends Applet {
    Image image = null;
    public void init () {
        try {
            String file = getParameter ("file");
            if (file != null) {
                URL imageurl = new URL (getDocumentBase(), file);
                InputStream is = imageurl.openStream();
                PPMImageDecoder ppm = new PPMImageDecoder ();
                ppm.readImage (is);
                image = createImage (ppm);
                repaint();
            }
        } catch (MalformedURLException me) {
            System.out.println ("Bad URL");
         } catch (IOException io) {
            System.out.println ("Bad File");
        }
    }
    public void paint (Graphics g) {
        g.drawImage (image, 0, 0, this);
    }
}
```

The applet we use to test our `ImageProducer` is very simple. It creates a URL that points to an appropriate PPM file and gets an `InputStream` from that URL. It then creates an instance of our `PPMImageDecoder`; calls `readImage()` to load the image and generate pixel data; and finally, calls `createImage()` with our `ImageProducer` as an argument to create an `Image` object, which we draw in `paint()`.

PixelGrabber

The `PixelGrabber` class is a utility for converting an image into an array of pixels. This is useful in many situations. If you are writing a drawing utility that lets users create their own graphics, you probably want some way to save a drawing to a file. Likewise, if you're implementing a shared whiteboard, you'll want some way to transmit images across the Net. If you're doing some kind of image processing, you may want to read and alter individual pixels in an image. The `PixelGrabber` class is an `ImageConsumer` that can capture a subset of the current pixels of an `Image`. Once you have the pixels, you can easily save the image in a file, send it across the Net, or work with individual points in the array. To recreate the `Image` (or a modified version), you can pass the pixel array to a `MemoryImageSource`.

Prior to Java 1.1, `PixelGrabber` saves an array of pixels but doesn't save the image's width and height--that's your responsibility. You may want to put the width and height in the first two elements of the pixel array and use an offset of 2 when you store (or reproduce) the image.

Starting with Java 1.1, the grabbing process changes in several ways. You can ask the `PixelGrabber` for the image's size or color model. You can grab pixels asynchronously and abort the grabbing process before it is completed. Finally, you don't have to preallocate the pixel data array. Constructors

public PixelGrabber (ImageProducer ip, int x, int y, int width, int height, int pixels[], int offset, int scansize)

> The first `PixelGrabber` constructor creates a new `PixelGrabber` instance. The `PixelGrabber` uses `ImageProducer ip` to store the unscaled cropped rectangle at position (`x`, `y`) of size `width` x `height` into the `pixels` array, starting at `offset` within `pixels`, and each row starting at increments of `scansize` from that.
>
> As shown in Figure 12.5, the position (`x1`, `y1`) would be stored in `pixels[]` at position `(y1 - y) * scansize + (x1 - x) + offset.` Calling `grabPixels()` starts the process of writing pixels into the array.
>
> The `ColorModel` for the pixels copied into the array is always the default RGB model: that is, 32 bits per pixel, with 8 bits for alpha, red, green, and blue components.

public PixelGrabber (Image image, int x, int y, int width, int height, int pixels[], int offset, int scansize)

> This version of the `PixelGrabber` constructor gets the `ImageProducer` of the `Image image` through `getSource()`; it then calls the previous constructor to create the `PixelGrabber`.

public PixelGrabber (Image image, int x, int y, int width, int height, boolean forceRGB) ★

> This version of the constructor does not require you to preallocate the pixel array and lets you preserve the color model of the original image. If `forceRGB` is `true`, the pixels of `image` are converted to the default RGB model when grabbed. If `forceRGB` is `false` and all the pixels of image use one `ColorModel`, the original color model of `image` is preserved.
>
> As with the other constructors, the `x`, `y`, `width`, and `height` values define the bounding box to grab. However,

there's one special case to consider. Setting `width` or `height` to -1 tells the `PixelGrabber` to take the `width` and `height` from the image itself. In this case, the grabber stores all the pixels below and to the right of the point (`x`, `y`). If (`x`, `y`) is outside of the image, you get an empty array.

Once the pixels have been grabbed, you get the pixel data via the `getPixels()` method described in "Other methods." To get the `ColorModel`, see the `getColorModel()` method.

ImageConsumer interface methods

public void setDimensions (int width, int height)

In Java 1.0, the `setDimensions()` method of `PixelGrabber` ignores the `width` and `height`, since this was set by the constructor.

With Java 1.1, `setDimensions()` is called by the image producer to give it the dimensions of the original image. This is how the `PixelGrabber` finds out the image's size if the constructor specified -1 for the image's width or height.

public void setHints (int hints)

The `setHints()` method ignores the `hints`.

public void setProperties (Hashtable properties)

The `setProperties()` method ignores the `properties`.

public void setColorModel (ColorModel model)

The `setColorModel()` method ignores the `model`.

public void setPixels (int x, int y, int w, int h, ColorModel model, byte pixels[], int offset, int scansize)

The `setPixels()` method is called by the `ImageProducer` to deliver pixel data for some image. If the pixels fall within the portion of the image that the `PixelGrabber` is interested in, they are stored within the array passed to the `PixelGrabber` constructor. If necessary, the `ColorModel` is used to convert each pixel from its original representation to the default RGB representation. This method is called when each pixel coming from the image producer is represented by a byte.

public void setPixels (int x, int y, int w, int h, ColorModel model, int pixels[], int offset, int scansize)

The second `setPixels()` method is almost identical to the first; it is used when each pixel coming from the image producer is represented by an `int`.

public synchronized void imageComplete (int status)

The `imageComplete()` method uses `status` to determine if the pixels were successfully delivered. The `PixelGrabber` then notifies anyone waiting for the pixels from a `grabPixels()` call.

Grabbing methods

public synchronized boolean grabPixels (long ms) throws InterruptedException

> The `grabPixels()` method starts storing pixel data from the image. It doesn't return until all pixels have been loaded into the pixels array or until `ms` milliseconds have passed. The return value is `true` if all pixels were successfully acquired. Otherwise, it returns `false` for the abort, error, or timeout condition encountered. The exception `InterruptedException` is thrown if another thread interrupts this one while waiting for pixel data.

public boolean grabPixels () throws InterruptedException

> This `grabPixels()` method starts storing pixel data from the image. It doesn't return until all pixels have been loaded into the pixels array. The return value is `true` if all pixels were successfully acquired. It returns `false` if it encountered an abort or error condition. The exception `InterruptedException` is thrown if another thread interrupts this one while waiting for pixel data.

public synchronized void startGrabbing() ★

> The `startGrabbing()` method provides an asynchronous means of grabbing the pixels. This method returns immediately; it does not block like the `grabPixels()` methods described previously. To find out when the `PixelGrabber` has finished, call `getStatus()`.

public synchronized void abortGrabbing() ★

> The `abortGrabbing()` method allows you to stop grabbing pixel data from the image. If a thread is waiting for pixel data from a `grabPixels()` call, it is interrupted and `grabPixels()` throws an `InterruptedException`.

Other methods

public synchronized int getStatus() ★
public synchronized int status () ☆

> Call the `getStatus()` method to find out whether a `PixelGrabber` succeeded in grabbing the pixels you want. The return value is a set of `ImageObserver` flags ORed together. `ALLBITS` and `FRAMEBITS` indicate success; which of the two you get depends on how the image was created. `ABORT` and `ERROR` indicate that problems occurred while the image was being produced.
>
> `status()`is the Java 1.0 name for this method.

public synchronized int getWidth() ★

> The `getWidth()` method reports the width of the image data stored in the destination buffer. If you set width to -1 when you called the `PixelGrabber` constructor, this information will be available only after the grabber has received the information from the image producer (`setDimensions()`). If the width is not available yet, `getWidth()` returns -1.

The width of the resulting image depends on several factors. If you specified the width explicitly in the constructor, the resulting image has that width, no questions asked--even if the position at which you start grabbing is outside the image. If you specified -1 for the width, the resulting width will be the difference between the `x` position at which you start grabbing (set in the constructor) and the actual image width; for example, if you start grabbing at `x`=50 and the original image width is 100, the width of the resulting image is 50. If `x` falls outside the image, the resulting width is 0.

public synchronized int getHeight() ★

The `getHeight()` method reports the height of the image data stored in the destination buffer. If you set height to -1 when you called the `PixelGrabber` constructor, this information will be available only after the grabber has received the information from the image producer (`setDimensions()`). If the height is not available yet, `getHeight()` returns -1.

The height of the resulting image depends on several factors. If you specified the height explicitly in the constructor, the resulting image has that height, no questions asked--even if the position at which you start grabbing is outside the image. If you specified -1 for the height, the resulting height will be the difference between the `y` position at which you start grabbing (set in the constructor) and the actual image height; for example, if you start grabbing at `y`=50 and the original image height is 100, the height of the resulting image is 50. If `y` falls outside the image, the resulting height is 0.

public synchronized Object getPixels() ★

The `getPixels()` method returns an array of pixel data. If you passed a pixel array to the constructor, you get back your original array object, with the data filled in. If, however, the array was not previously allocated, you get back a new array. The size of this array depends on the image you are grabbing and the portion of that image you want. If size and image format are not known yet, this method returns `null`. If the `PixelGrabber` is still grabbing pixels, this method returns an array that may change based upon the rest of the image. The type of the array you get is either `int[]` or `byte[]`, depending on the color model of the image. To find out if the `PixelGrabber` has finished, call `getStatus()`.

public synchronized ColorModel getColorModel() ★

The `getColorModel()` method returns the color model of the image. This could be the default RGB `ColorModel` if a pixel buffer was explicitly provided, `null` if the color model is not known yet, or a varying color model until all the pixel data has been grabbed. After all the pixels have been grabbed, `getColorModel()` returns the actual color model used for the `getPixels()`array. It is best to wait until grabbing has finished before you ask for the `ColorModel`; to find out, call `getStatus()`.

Using PixelGrabber to modify an image

You can modify images by combining a `PixelGrabber` with `MemoryImageSource`. Use `getImage()` to load an image from the Net; then use `PixelGrabber` to convert the image into an array. Modify the data in the array any way you please; then use `MemoryImageSource` as an image producer to display the new image.

Example 12.6 demonstrates the use of the `PixelGrabber` and `MemoryImageSource` to rotate, flip, and mirror an image. (We could also do the rotations with a subclass of `ImageFilter`, which we will discuss next.) The output is shown in Figure 12.6. When working with an image that is loaded from a local disk or the network, remember to wait until the image is loaded before grabbing its pixels. In this example, we use a `MediaTracker` to wait for the image to load.

Example 12.6: Flip Source

```
import java.applet.*;
import java.awt.*;
import java.awt.image.*;
public class flip extends Applet {
    Image i, j, k, l;
    public void init () {
        MediaTracker mt = new MediaTracker (this);
        i = getImage (getDocumentBase(), "ora-icon.gif");
        mt.addImage (i, 0);
    try {
        mt.waitForAll();
        int width = i.getWidth(this);
        int height = i.getHeight(this);
        int pixels[] = new int [width * height];
        PixelGrabber pg = new PixelGrabber
        (i, 0, 0, width, height, pixels, 0, width);
        if (pg.grabPixels() && ((pg.status() &
            ImageObserver.ALLBITS) !=0)) {
            j = createImage (new MemoryImageSource (width, height,
                     rowFlipPixels (pixels, width, height), 0, width));
            k = createImage (new MemoryImageSource (width, height,
                 colFlipPixels (pixels, width, height), 0, width));
            l = createImage (new MemoryImageSource (height, width,
                 rot90Pixels (pixels, width, height), 0, height));
        }
    } catch (InterruptedException e) {
        e.printStackTrace();
    }
}
```

Figure 12.6: Flip output

[Graphic: Figure 12-6]

The `try` block in Example 12.6 does all the interesting work. It uses a `PixelGrabber` to grab the entire image into the array `pixels[]`. After calling `grabPixels()`, it checks the `PixelGrabber` status to make sure that the image was stored correctly. It then generates three new images based on the first by calling `createImage()` with a `MemoryImageSource` object as an argument. Instead of using the original array, the `MemoryImageSource` objects call several utility methods to manipulate the array: `rowFlipPixels()`, `colFlipPixels()`, and `rot90Pixels()`. These methods all return integer arrays.

```
public void paint (Graphics g) {
    g.drawImage (i, 10, 10, this); // regular
    if (j != null)
        g.drawImage (j, 150, 10, this); // rowFlip
    if (k != null)
        g.drawImage (k, 10, 60, this); // colFlip
    if (l != null)
        g.drawImage (l, 150, 60, this); // rot90
}
private int[] rowFlipPixels (int pixels[], int width, int height) {
    int newPixels[] = null;
    if ((width*height) == pixels.length) {
        newPixels = new int [width*height];
        int newIndex=0;
        for (int y=height-1;y>=0;y--)
            for (int x=width-1;x>=0;x--)
                newPixels[newIndex++]=pixels[y*width+x];
    }
    return newPixels;
}
```

`rowFlipPixels()` creates a mirror image of the original, flipped horizontally. It is nothing more than a nested loop that copies the original array into a new array.

```
    private int[] colFlipPixels (int pixels[], int width, int height) {
        ...
    }
private int[] rot90Pixels (int pixels[], int width, int height) {
        ...
    }
}
```

`colFlipPixels()` and `rot90Pixels()` are fundamentally similar to `rowFlipPixels()`; they just copy the original pixel array into another array, and return the result. `colFlipPixels()` generates a vertical mirror image; `rot90Pixels()` rotates the image by 90 degrees counterclockwise. Grabbing data asynchronously

To demonstrate the new methods introduced by Java 1.1 for `PixelGrabber`, the following program grabs the pixels and reports information about the original image on mouse clicks. It takes its data from the image used in Figure 12.6.

```
// Java 1.1 only
import java.applet.*;
import java.awt.*;
import java.awt.image.*;
import java.awt.event.*;
public class grab extends Applet {
    Image i;
    PixelGrabber pg;
    public void init () {
        i = getImage (getDocumentBase(), "ora-icon.gif");
        pg  = new PixelGrabber (i, 0, 0, -1, -1, false);
        pg.startGrabbing();
        enableEvents (AWTEvent.MOUSE_EVENT_MASK);
    }
    public void paint (Graphics g) {
        g.drawImage (i, 10, 10, this);
    }
    protected void processMouseEvent(MouseEvent e) {
        if (e.getID() == MouseEvent.MOUSE_CLICKED) {
            System.out.println ("Status: " + pg.getStatus());
            System.out.println ("Width:  " + pg.getWidth());
            System.out.println ("Height: " + pg.getHeight());
            System.out.println ("Pixels: " +
               (pg.getPixels() instanceof byte[] ? "bytes" : "ints"));
            System.out.println ("Model:  " + pg.getColorModel());
        }
        super.processMouseEvent (e);
    }
}
```

This applet creates a `PixelGrabber` without specifying an array, then starts grabbing pixels. The grabber allocates its own array, but we never bother to ask for it since we don't do anything with the data itself: we only report the grabber's status. (If we wanted the data, we'd call `getPixels()`.) Sample output from a single mouse click, after the image loaded, would appear something like the following:

```
Status: 27
```

```
Width:  120
Height: 38
Pixels: bytes
Model:  java.awt.image.IndexColorModel@1ed34
```

You need to convert the status value manually to the corresponding meaning by looking up the status codes in `ImageObserver`. The value 27 indicates that the 1, 2, 8, and 16 flags are set, which translates to the `WIDTH`, `HEIGHT`, `SOMEBITS`, and `FRAMEBITS` flags, respectively.

12.5 ImageFilter

Image filters provide another way to modify images. An `ImageFilter` is used in conjunction with a `FilteredImageSource` object. The `ImageFilter`, which implements `ImageConsumer` (and `Cloneable`), receives data from an `ImageProducer` and modifies it; the `FilteredImageSource`, which implements `ImageProducer`, sends the modified data to the new consumer. As Figure 12.1 shows, an image filter sits between the original `ImageProducer` and the ultimate `ImageConsumer`.

The `ImageFilter` class implements a "null" filter that does nothing to the image. To modify an image, you must use a subclass of `ImageFilter`, by either writing one yourself or using a subclass provided with AWT, like the `CropImageFilter`. Another `ImageFilter` subclass provided with AWT is the `RGBImageFilter`; it is useful for filtering an image on the basis of a pixel's color. Unlike the `CropImageFilter`, `RGBImageFilter` is an abstract class, so you need to create your own subclass to use it. Java 1.1 introduces two more image filters, `AreaAveragingScaleFilter` and `ReplicateScaleFilter`. Other filters must be created by subclassing `ImageFilter` and providing the necessary methods to modify the image as necessary.

`ImageFilter`s tend to work on a pixel-by-pixel basis, so large `Image` objects can take a considerable amount of time to filter, depending on the complexity of the filtering algorithm. In the simplest case, filters generate new pixels based upon the color value and location of the original pixel. Such filters can start delivering data before they have loaded the entire image. More complex filters may use internal buffers to store an intermediate copy of the image so the filter can use adjacent pixel values to smooth or blend pixels together. These filters may need to load the entire image before they can deliver any data to the ultimate consumer.

To use an `ImageFilter`, you pass it to the `FilteredImageSource` constructor, which serves as an `ImageProducer` to pass the new pixels to their consumer. The following code runs the image *logo.jpg* through an image filter, `SomeImageFilter`, to produce a new image. The constructor for `SomeImageFilter` is called within the constructor for `FilteredImageSource`, which in turn is the only argument to `createImage()`.

```
Image image = getImage (new URL (
     "http://www.ora.com/images/logo.jpg"));
Image newOne = createImage (new FilteredImageSource (image.getSource(),
                               new SomeImageFilter()));
```

ImageFilter Methods

Variables

protected ImageConsumer consumer;

> The actual `ImageConsumer` for the image. It is initialized automatically for you by the `getFilterInstance()` method.

Constructor

public ImageFilter ()

> The only constructor for `ImageFilter` is the default one, which takes no arguments. Subclasses can provide their own constructors if they need additional information.

ImageConsumer interface methods

public void setDimensions (int width, int height)

> The `setDimensions()` method of `ImageFilter` is called when the `width` and `height` of the original image are known. It calls `consumer.setDimensions()` to tell the next consumer the dimensions of the filtered image. If you subclass `ImageFilter` and your filter changes the image's dimensions, you should override this method to compute and report the new dimensions.

public void setProperties (Hashtable properties)

> The `setProperties()` method is called to provide the image filter with the property list for the original image. The image filter adds the property `filters` to the list and passes it along to the next consumer. The value given for the `filters` property is the result of the image filter's `toString()` method; that is, the `String` representation of the current filter. If `filters` is already set, information about this `ImageFilter` is appended to the end. Subclasses of `ImageFilter` may add other properties.

public void setColorModel (ColorModel model)

> The `setColorModel()` method is called to give the `ImageFilter` the color model used for most of the pixels in the original image. It passes this color model on to the next consumer. Subclasses may override this method if they change the color model.

public void setHints (int hints)

> The `setHints()` method is called to give the `ImageFilter` hints about how the producer will deliver pixels. This method passes the same set of hints to the next consumer. Subclasses must override this method if they need to provide different hints; for example, if they are delivering pixels in a different order.

public void setPixels (int x, int y, int width, int height, ColorModel model, byte pixels[], int offset, int scansize)
public void setPixels (int x, int y, int width, int height, ColorModel model, int pixels[], int offset, int scansize)

> The `setPixels()` method receives pixel data from the `ImageProducer` and passes all the information on to the `ImageConsumer`. (`x`, `y`) is the top left corner of the bounding rectangle for the pixels. The bounding

rectangle has size `width` x `height`. The `ColorModel` for the new image is `model`. `pixels` is the byte or integer array of the pixel information, starting at `offset` (usually 0), with scan lines of size `scansize` (usually `width`).

public void imageComplete (int status)

The `imageComplete()` method receives the completion `status` from the `ImageProducer` and passes it along to the `ImageConsumer`.

If you subclass `ImageFilter`, you will probably override the `setPixels()` methods. For simple filters, you may be able to modify the pixel array and deliver the result to `consumer.setPixels()` immediately. For more complex filters, you will have to build a buffer containing the entire image; in this case, the call to `imageComplete()` will probably trigger filtering and pixel delivery.

Cloneable interface methods

public Object clone ()

The `clone()` method creates a clone of the `ImageFilter`. The `getFilterInstance()` function uses this method to create a copy of the `ImageFilter`. Cloning allows the same filter instance to be used with multiple `Image` objects.

Other methods

public ImageFilter getFilterInstance (ImageConsumer ic)

`FilteredImageSource` calls `getFilterInstance()` to register `ic` as the `ImageConsumer` for an instance of this filter; to do so, it sets the instance variable `consumer`. In effect, this method inserts the `ImageFilter` between the image's producer and the consumer. You have to override this method only if there are special requirements for the insertion process. This default implementation just calls `clone()`.

public void resendTopDownLeftRight (ImageProducer ip)

The `resendTopDownLeftRight()` method tells the `ImageProducer` `ip` to try to resend the image data in the top-down, left-to-right order. If you override this method and your `ImageFilter` has saved the image data internally, you may want your `ImageFilter` to resend the data itself, rather than asking the `ImageProducer`. Otherwise, your subclass may ignore the request or pass it along to the `ImageProducer` `ip`.

Subclassing ImageFilter: A blurring filter

When you subclass `ImageFilter`, there are very few restrictions on what you can do. We will create a few subclasses that show some of the possibilities. This `ImageFilter` generates a new pixel by averaging the pixels around it. The result is a blurred version of the original. To implement this filter, we have to save all the pixel data into a buffer; we can't start delivering pixels until the entire image is in hand. Therefore, we override `setPixels()` to build the buffer; we override `imageComplete()` to produce the new pixels and deliver them.

Before looking at the code, here are a few hints about how the filter works; it uses a few tricks that may be helpful in other situations. We need to provide two versions of `setPixels()`: one for integer arrays, and the other for byte arrays. To avoid duplicating code, both versions call a single method, `setThePixels()`, which takes an `Object` as an argument, instead of a pixel array; thus it can be called with either kind of pixel array. Within the method, we check whether the pixels argument is an instance of `byte[]` or `int[]`. The body of this method uses another trick: when it reads the `byte[]` version of the pixel array, it ANDs the value with 0xff. This prevents the byte value, which is signed, from being converted to a negative `int` when used as an argument to `cm.getRGB()`.

The logic inside of `imageComplete()` gets a bit hairy. This method does the actual filtering, after all the data has arrived. Its job is basically simple: compute an average value of the pixel and the eight pixels surrounding it (i.e., a 3x3 rectangle with the current pixel in the center). The problem lies in taking care of the edge conditions. We don't always want to average nine pixels; in fact, we may want to average as few as four. The `if` statements figure out which surrounding pixels should be included in the average. The pixels we care about are placed in `sumArray[]`, which has nine elements. We keep track of the number of elements that have been saved in the variable `sumIndex` and use a helper method, `avgPixels()`, to compute the average. The code might be a little cleaner if we used a `Vector`, which automatically counts the number of elements it contains, but it would probably be much slower.

Example 12.7 shows the code for the blurring filter.

Example 12.7: Blur Filter Source

```
import java.awt.*;
import java.awt.image.*;
public class BlurFilter extends ImageFilter {
    private int savedWidth, savedHeight, savedPixels[];
    private static ColorModel defaultCM = ColorModel.getRGBdefault();
    public void setDimensions (int width, int height) {
        savedWidth=width;
        savedHeight=height;
        savedPixels=new int [width*height];
        consumer.setDimensions (width, height);
    }
```

We override `setDimensions()` to save the original image's height and width, which we use later.

```
    public void setColorModel (ColorModel model) {
    // Change color model to model you are generating
        consumer.setColorModel (defaultCM);
    }
    public void setHints (int hintflags) {
    // Set new hints, but preserve SINGLEFRAME setting
        consumer.setHints (TOPDOWNLEFTRIGHT | COMPLETESCANLINES |
                           SINGLEPASS | (hintflags & SINGLEFRAME));
    }
```

This filter always generates pixels in the same order, so it sends the hint flags `TOPDOWNLEFTRIGHT`, `COMPLETESCANLINES`, and `SINGLEPASS` to the consumer, regardless of what the image producer says. It sends the `SINGLEFRAME` hint only if the producer has sent it.

```
    private void setThePixels (int x, int y, int width, int height,
            ColorModel cm, Object pixels, int offset, int scansize) {
        int sourceOffset = offset;
        int destinationOffset = y * savedWidth + x;
        boolean bytearray = (pixels instanceof byte[]);
        for (int yy=0;yy<height;yy++) {
            for (int xx=0;xx<width;xx++)
                if (bytearray)
                    savedPixels[destinationOffset++]=
                        cm.getRGB(((byte[])pixels)[sourceOffset++]&0xff);
                else
                    savedPixels[destinationOffset++]=
                        cm.getRGB(((int[])pixels)[sourceOffset++]);
            sourceOffset += (scansize - width);
            destinationOffset += (savedWidth - width);
        }
    }
```

`setThePixels()` saves the pixel data for the image in the array `savedPixels[]`. Both versions of `setPixels()` call this method. It doesn't pass the pixels along to the image consumer, since this filter can't process the pixels until the entire image is available.

```
public void setPixels (int x, int y, int width, int height,
       ColorModel cm, byte pixels[], int offset, int scansize) {
    setThePixels (x, y, width, height, cm, pixels, offset, scansize);
}
public void setPixels (int x, int y, int width, int height,
       ColorModel cm, int pixels[], int offset, int scansize) {
    setThePixels (x, y, width, height, cm, pixels, offset, scansize);
}
public void imageComplete (int status) {
    if ((status == IMAGEABORTED) || (status == IMAGEERROR)) {
        consumer.imageComplete (status);
        return;
    } else {
        int pixels[] = new int [savedWidth];
        int position, sumArray[], sumIndex;
        sumArray = new int [9]; // maxsize - vs. Vector for performance
        for (int yy=0;yy<savedHeight;yy++) {
            position=0;
            int start = yy * savedWidth;
            for (int xx=0;xx<savedWidth;xx++) {
                sumIndex=0;
                                                                 //  xx     yy
                sumArray[sumIndex++] = savedPixels[start+xx];  // center center
                if (yy != (savedHeight-1))                       // center bottom
                    sumArray[sumIndex++] = savedPixels[start+xx+savedWidth];
                if (yy != 0)                                   // center top
                    sumArray[sumIndex++] = savedPixels[start+xx-savedWidth];
                if (xx != (savedWidth-1))                      // right  center
                    sumArray[sumIndex++] = savedPixels[start+xx+1];
                if (xx != 0)                                   // left   center
                    sumArray[sumIndex++] = savedPixels[start+xx-1];
                if ((yy != 0) && (xx != 0))                    // left   top
                    sumArray[sumIndex++] = savedPixels[start+xx-savedWidth-1];
                if ((yy != (savedHeight-1)) && (xx != (savedWidth-1)))
                    //                                           right  bottom
                    sumArray[sumIndex++] = savedPixels[start+xx+savedWidth+1];
                if ((yy != 0) && (xx != (savedWidth-1)))       //right  top
                    sumArray[sumIndex++] = savedPixels[start+xx-savedWidth+1];
                if ((yy != (savedHeight-1)) && (xx != 0))      //left   bottom
                    sumArray[sumIndex++] = savedPixels[start+xx+savedWidth-1];
                pixels[position++] = avgPixels(sumArray, sumIndex);
            }
            consumer.setPixels (0, yy, savedWidth, 1, defaultCM,
                                pixels, 0, savedWidth);
        }
        consumer.imageComplete (status);
    }
}
```

`imageComplete()` does the actual filtering after the pixels have been delivered and saved. If the producer reports that an error occurred, this method passes the error flags to the consumer and returns. If not, it builds a new array, `pixels[]`, which contains the filtered pixels, and delivers these to the consumer.

Previously, we gave an overview of how the filtering process works. Here are some details. (`xx`, `yy`) represents the current point's `x` and `y` coordinates. The point (`xx`, `yy`) must always fall within the image; otherwise, our loops are constructed incorrectly. Therefore, we can copy (`xx`, `yy`) into the `sumArray[]` for averaging without any tests. For the point's eight neighbors, we check whether the neighbor falls in the image; if so, we add it to `sumArray[]`. For example, the point just below (`xx`, `yy`) is at the bottom center of the 3x3 rectangle of points we are averaging. We know that `xx` falls within the image; `yy` falls within the image if it doesn't equal `savedHeight-1`. We do similar tests for the other points.

Even though we're working with a rectangular image, our arrays are all one-dimensional so we have to convert a coordinate pair (`xx`, `yy`) into a single array index. To help us do the bookkeeping, we use the local variable `start` to keep track of the start of the current scan line. Then `start` + `xx` is the current point; `start` + `xx` + `savedWidth` is the point immediately below; `start` + `xx` + `savedWidth-1` is the point below and to the left; and so on.

`avgPixels()` is our helper method for computing the average value that we assign to the new pixel. For each pixel in the `pixels[]` array, it extracts the red, blue, green, and alpha components; averages them separately, and returns a new ARGB value.

```
    private int avgPixels (int pixels[], int size) {
        float redSum=0, greenSum=0, blueSum=0, alphaSum=0;
        for (int i=0;i<size;i++)
```

```
            try {
                int pixel = pixels[i];
                redSum   += defaultCM.getRed   (pixel);
                greenSum += defaultCM.getGreen (pixel);
                blueSum  += defaultCM.getBlue  (pixel);
                alphaSum += defaultCM.getAlpha (pixel);
            } catch (ArrayIndexOutOfBoundsException e) {
                System.out.println ("Ooops");
            }
        int redAvg   = (int)(redSum   / size);
        int greenAvg = (int)(greenSum / size);
        int blueAvg  = (int)(blueSum  / size);
        int alphaAvg = (int)(alphaSum / size);
        return ((0xff << 24) | (redAvg << 16) |
                (greenAvg << 8)  | (blueAvg << 0));
    }
}
```

Producing many images from one: dynamic ImageFilter

The `ImageFilter` framework is flexible enough to allow you to return a sequence of images based on an original. You can send back one frame at a time, calling the following when you are finished with each frame:

```
consumer.imageComplete(ImageConsumer.SINGLEFRAMEDONE);
```

After you have generated all the frames, you can tell the consumer that the sequence is finished with the `STATICIMAGEDONE` constant. In fact, this is exactly what the new animation capabilities of `MemoryImageSource` use.

In Example 12.8, the `DynamicFilter` lets the consumer display an image. After the image has been displayed, the filter gradually overwrites the image with a specified color by sending additional image frames. The end result is a solid colored rectangle. Not too exciting, but it's easy to imagine interesting extensions: you could use this technique to implement a fade from one image into another. The key points to understand are:

- This filter does not override `setPixels()`, so it is extremely fast. In this case, we want the original image to reach the consumer, and there is no reason to save the image in a buffer.

- Filtering takes place in the image-fetching thread, so it is safe to put the filter-processing thread to sleep if the image is coming from disk. If the image is in memory, filtering should not sleep because there will be a noticeable performance lag in your program if it does. The `DynamicFilter` class has a delay parameter to its constructor that lets you control this behavior.

- This subclass overrides `setDimensions()` to save the image's dimensions for its own use. It needs to override `setHints()` because it sends pixels to the consumer in a nonstandard order: it sends the original image, then goes back and starts sending overlays. Likewise, this subclass overrides `resendTopDownLeftRight()` to do nothing because there is no way the original `ImageProducer` can replace all the changes with the original `Image`.

- `imageComplete()` is where all the fun happens. Take a special look at the status flags that are returned.

Example 12.8: DynamicFilter Source

```
import java.awt.*;
import java.awt.image.*;
public class DynamicFilter extends ImageFilter {
    Color overlapColor;
    int   delay;
    int   imageWidth;
    int   imageHeight;
    int   iterations;
    DynamicFilter (int delay, int iterations, Color color) {
        this.delay      = delay;
        this.iterations = iterations;
        overlapColor    = color;
    }
    public void setDimensions (int width, int height) {
        imageWidth  = width;
        imageHeight = height;
        consumer.setDimensions (width, height);
    }
    public void setHints (int hints) {
        consumer.setHints (ImageConsumer.RANDOMPIXELORDER);
    }
    public void resendTopDownLeftRight (ImageProducer ip) {
    }
    public void imageComplete (int status) {
        if ((status == IMAGEERROR) || (status == IMAGEABORTED)) {
            consumer.imageComplete (status);
            return;
        } else {
            int xWidth = imageWidth / iterations;
            if (xWidth <= 0)
                xWidth = 1;
            int newPixels[] = new int [xWidth*imageHeight];
            int iColor = overlapColor.getRGB();
            for (int x=0;x<(xWidth*imageHeight);x++)
                newPixels[x] = iColor;
            int t=0;
            for (;t<(imageWidth-xWidth);t+=xWidth) {
                consumer.setPixels(t, 0, xWidth, imageHeight,
                        ColorModel.getRGBdefault(), newPixels, 0, xWidth);
                consumer.imageComplete (ImageConsumer.SINGLEFRAMEDONE);
                try {
                    Thread.sleep (delay);
                } catch (InterruptedException e) {
                    e.printStackTrace();
                }
            }
            int left = imageWidth-t;
            if (left > 0) {
                consumer.setPixels(imageWidth-left, 0, left, imageHeight,
                        ColorModel.getRGBdefault(), newPixels, 0, xWidth);
                consumer.imageComplete (ImageConsumer.SINGLEFRAMEDONE);
            }
            consumer.imageComplete (STATICIMAGEDONE);
        }
    }
}
```

The `DynamicFilter` relies on the default `setPixels()` method to send the original image to the consumer. When the original image has been transferred, the image producer calls this filter's `imageComplete()` method, which does the real work. Instead of relaying the completion status to the consumer, `imageComplete()` starts generating its own data: solid rectangles that are all in the `overlapColor` specified in the constructor. It sends these rectangles to the consumer by calling `consumer.setPixels()`. After each rectangle, it calls `consumer.imageComplete()` with the `SINGLEFRAMEDONE` flag, meaning that it has just finished one frame of a multi-frame sequence. When the rectangles have completely covered the image, the method `imageComplete()` finally notifies the consumer that the entire image sequence has been transferred by sending the `STATICIMAGEDONE` flag.

The following code is a simple applet that uses this image filter to produce a new image:

```
import java.applet.*;
import java.awt.*;
import java.awt.image.*;
public class DynamicImages extends Applet {
    Image i, j;
    public void init () {
        i = getImage (getDocumentBase(), "rosey.jpg");
        j = createImage (new FilteredImageSource (i.getSource(),
                        new DynamicFilter(250, 10, Color.red)));
    }
    public void paint (Graphics g) {
        g.drawImage (j, 10, 10, this);
    }
}
```

One final curiosity: the `DynamicFilter` doesn't make any assumptions about the color model used for the original image. It sends its overlays with the default RGB color model. Therefore, this is one case in which an `ImageConsumer` may see calls to `setPixels()` that use different color models.

RGBImageFilter

`RGBImageFilter` is an abstract subclass of `ImageFilter` that provides a shortcut for building the most common kind of image filters: filters that independently modify the pixels of an existing image, based only on the pixel's position and color. Because `RGBImageFilter` is an abstract class, you must subclass it before you can do anything. The only method your subclass must provide is `filterRGB()`, which produces a new pixel value based on the original pixel and its location. A handful of additional methods are in this class; most of them provide the behind-the-scenes framework for funneling each pixel through the `filterRGB()` method.

If the filtering algorithm you are using does not rely on pixel position (i.e., the new pixel is based only on the old pixel's color), AWT can apply an optimization for images that use an `IndexColorModel`: rather than filtering individual pixels, it can filter the image's color map. In order to tell AWT that this optimization is okay, add a constructor to the class definition that sets the `canFilterIndexColorModel` variable to `true`. If `canFilterIndexColorModel` is `false` (the default) and an `IndexColorModel` image is sent through the filter, nothing happens to the image. Variables

protected boolean canFilterIndexColorModel

> Setting the `canFilterIndexColorModel` variable permits the `ImageFilter` to filter `IndexColorModel` images. The default value is `false`. When this variable is `false`, `IndexColorModel` images are not filtered. When this variable is `true`, the `ImageFilter` filters the colormap instead of the individual pixel values.

protected ColorModel newmodel

> The `newmodel` variable is used to store the new `ColorModel` when `canFilterIndexColorModel` is `true` and the `ColorModel` actually is of type `IndexColorModel`. Normally, you do not need to access this variable, even in subclasses.

protected ColorModel origmodel

> The `origmodel` variable stores the original color model when filtering an `IndexColorModel`. Normally, you do not need to access this variable, even in subclasses.

Constructors

public RGBImageFilter ()--called by subclass

> The only constructor for `RGBImageFilter` is the implied constructor with no parameters. In most subclasses of `RGBImageFilter`, the constructor has to initialize only the `canFilterIndexColorModel` variable.

ImageConsumer interface methods

public void setColorModel (ColorModel model)

> The `setColorModel()` method changes the `ColorModel` of the filter to `model`. If `canFilterIndexColorModel` is `true` and `model` is of type `IndexColorModel`, a filtered version of `model` is used instead.

public void setPixels (int x, int y, int w, int h, ColorModel model, byte pixels[], int off, int scansize) *public void setPixels (int x, int y, int w, int h, ColorModel model, int pixels[], int off, int scansize)*

> If necessary, the `setPixels()` method converts the `pixels` buffer to the default RGB `ColorModel` and then filters them with `filterRGBPixels()`. If `model` has already been converted, this method just passes the pixels along to the consumer's `setPixels()`.

Other methods

The only method you care about here is `filterRGB()`. All subclasses of RGBImageFilter *must* override this method. It is very difficult to imagine situations in which you would override (or even call) the other methods in this group. They are helper methods that funnel pixels through `filterRGB()`.

public void substituteColorModel (ColorModel oldModel, ColorModel newModel)

> `substituteColorModel()` is a helper method for `setColorModel()`. It initializes the protected variables of `RGBImageFilter`. The `origmodel` variable is set to `oldModel` and the `newmodel` variable is set to `newModel`.

public IndexColorModel filterIndexColorModel (IndexColorModel icm)

> `filterIndexColorModel()` is another helper method for `setColorModel()`. It runs the entire color table of `icm` through `filterRGB()` and returns the filtered `ColorModel` for use by `setColorModel()`.

public void filterRGBPixels (int x, int y, int width, int height, int pixels[], int off, int scansize)

> `filterRGBPixels()` is a helper method for `setPixels()`. It filters each element of the `pixels` buffer through `filterRGB()`, converting pixels to the default RGB `ColorModel` first. This method changes the values in the `pixels` array.

public abstract int filterRGB (int x, int y, int rgb)

> `filterRGB()` is the one method that `RGBImageFilter` subclasses must implement. The method takes the `rgb` pixel value at position (`x`, `y`) and returns the converted pixel value in the default RGB `ColorModel`. Coordinates of (-1, -1) signify that a color table entry is being filtered instead of a pixel.

A transparent image filter that extends RGBImageFilter

Creating your own `RGBImageFilter` is fairly easy. One of the more common applications for an `RGBImageFilter` is to make images transparent by setting the alpha component of each pixel. To do so, we extend the abstract `RGBImageFilter` class. The filter in Example 12.9 makes the entire image translucent, based on a percentage passed to the class constructor. Filtering is independent of position, so the constructor can set the `canFilterIndexColorModel` variable. A constructor with no arguments uses a default alpha value of 0.75.

Example 12.9: TransparentImageFilter Source

```
import java.awt.image.*;
class TransparentImageFilter extends RGBImageFilter {
    float alphaPercent;
    public TransparentImageFilter () {
        this (0.75f);
    }
    public TransparentImageFilter (float aPercent)
            throws IllegalArgumentException {
        if ((aPercent < 0.0) || (aPercent > 1.0))
            throw new IllegalArgumentException();
        alphaPercent = aPercent;
        canFilterIndexColorModel = true;
    }
    public int filterRGB (int x, int y, int rgb) {
        int a = (rgb >> 24) & 0xff;
        a *= alphaPercent;
        return ((rgb & 0x00ffffff) | (a << 24));
    }
}
```

CropImageFilter

The `CropImageFilter` is an `ImageFilter` that crops an image to a rectangular region. When used with `FilteredImageSource`, it produces a new image that consists of a portion of the original image. The cropped region must be completely within the original image. It is never necessary to subclass this class. Also, using the 10 or 11 argument version of `Graphics.drawImage()` introduced in Java 1.1 precludes the need to use this filter, unless you need to save the resulting cropped image.

If you crop an image and then send the result through a second `ImageFilter`, the pixel array received by the filter will be the size of the original `Image`, with the `offset` and `scansize` set accordingly. The `width` and `height` are set to the cropped values; the result is a smaller `Image` with the same amount of data. `CropImageFilter` keeps the full pixel array around, partially empty. Constructors

public CropImageFilter (int x, int y, int width, int height) ★

> The constructor for `CropImageFilter` specifies the rectangular area of the old image that makes up the new image. The (`x`, `y`) coordinates specify the top left corner for the cropped image; `width` and `height` must be positive or the resulting image will be empty. If the (`x`, `y`) coordinates are outside the original image area, the resulting image is empty. If (`x`, `y`) starts within the image but the rectangular area of size `width` x `height` goes beyond the original image, the part that extends outside will be black. (Remember the color black has pixel values of 0 for red, green, and blue.)

ImageConsumer interface methods

public void setProperties (Hashtable properties) ★

> The `setProperties()` method adds the `croprect` image property to the properties list. The bounding

Rectangle, specified by the (x, y) coordinates and width x height size, is associated with this property. After updating properties, this method sets the properties list of the consumer.

public void setDimensions (int width, int height) ★

The setDimensions() method of CropImageFilter ignores the width and height parameters to the function call. Instead, it relies on the size parameters in the constructor.

public void setPixels (int x, int y, int w, int h, ColorModel model, byte pixels[], int offset, int scansize) ★
public void setPixels (int x, int y, int w, int h, ColorModel model, int pixels[], int offset, int scansize) ★

These setPixels() methods check to see what portion of the pixels array falls within the cropped area and pass those pixels along.

Cropping an image with CropImageFilter

Example 12.10 uses a CropImageFilter to extract the center third of a larger image. No subclassing is needed; the CropImageFilter is complete in itself. The output is displayed in Figure 12.7.

Example 12.10: Crop Applet Source

```
import java.applet.*;
import java.awt.*;
import java.awt.image.*;
public class Crop extends Applet {
    Image i, j;
    public void init () {
        MediaTracker mt = new MediaTracker (this);
        i = getImage (getDocumentBase(), "rosey.jpg");
        mt.addImage (i, 0);
        try {
            mt.waitForAll();
            int width        = i.getWidth(this);
            int height       = i. getHeight(this);
            j = createImage (new FilteredImageSource (i.getSource(),
                                new CropImageFilter (width/3, height/3,
                                                     width/3, height/3)));
        } catch (InterruptedException e) {
            e.printStackTrace();
        }
    }
    public void paint (Graphics g) {
        g.drawImage (i, 10, 10, this);                  // regular
        if (j != null) {
            g.drawImage (j, 10, 90, this);             // cropped
        }
    }
}
```

Figure 12.7: Image cropping example output.

[Graphic: Figure 12-7]

TIP:

You can use `CropImageFilter` to help improve your animation performance or just the general download time of images. Without `CropImageFilter`, you can use `Graphics.clipRect()` to clip each image of an image strip when drawing. Instead of clipping each `Image` (each time), you can use `CropImageFilter` to create a new `Image` for each cell of the strip. Or for times when an image strip is inappropriate, you can put all your images within one image file (in any order whatsoever), and use `CropImageFilter` to get each out as an `Image` .

ReplicateScaleFilter

Back in Chapter 2, *Simple Graphics* we introduced you to the `getScaledInstance()` method. This method uses a new image filter that is provided with Java 1.1. The `ReplicateScaleFilter` and its subclass, `AreaAveragingScaleFilter`, allow you to scale images before calling `drawImage()`. This can greatly speed your programs because you don't have to wait for the call to `drawImage()` before performing scaling.

The `ReplicateScaleFilter` is an `ImageFilter` that scales by duplicating or removing rows and columns. When used with `FilteredImageSource`, it produces a new image that is a scaled version of the original. As you can guess, `ReplicateScaleFilter` is very fast, but the results aren't particularly pleasing aesthetically. It is great if you want to magnify a checkerboard but not that useful if you want to scale an image of your Aunt Polly. Its subclass, `AreaAveragingScaleFilter`, implements a more time-consuming algorithm that is more suitable when image quality is a concern. Constructor

public ReplicateScaleFilter (int width, int height)

> The constructor for `ReplicateScaleFilter` specifies the size of the resulting image. If either parameter is -1, the resulting image maintains the same aspect ratio as the original image.

ImageConsumer interface methods

public void setProperties (Hashtable properties)

The `setProperties()` method adds the `rescale` image property to the properties list. The value of the rescale property is a quoted string showing the image's new width and height, in the form `` `<width>x<height>` ``, where the width and height are taken from the constructor. After updating `properties`, this method sets the properties list of the consumer.

public void setDimensions (int width, int height)

The `setDimensions()` method of `ReplicateScaleFilter` passes the new width and height from the constructor along to the consumer. If either of the constructor's parameters are negative, the size is recalculated proportionally. If both are negative, the size becomes `width` x `height`.

public void setPixels (int x, int y, int w, int h, ColorModel model, int pixels[], int offset, int scansize)
public void setPixels (int x, int y, int w, int h, ColorModel model, byte pixels[], int offset, int scansize)

The `setPixels()` method of `ReplicateScaleFilter` checks to see which rows and columns of `pixels` to pass along.

AreaAveragingScaleFilter

The `AreaAveragingScaleFilter` subclasses `ReplicateScaleFilter` to provide a better scaling algorithm. Instead of just dropping or adding rows and columns, `AreaAveragingScaleFilter` tries to blend pixel values when creating new rows and columns. The filter works by replicating rows and columns to generate an image that is a multiple of the original size. Then the image is resized back down by an algorithm that blends the pixels around each destination pixel. AreaAveragingScaleFilter methods

Because this filter subclasses `ReplicateScaleFilter`, the only methods it includes are those that override methods of `ReplicateScaleFilter`. Constructors

public AreaAveragingScaleFilter (int width, int height) ★

The constructor for `AreaAveragingScaleFilter` specifies the size of the resulting image. If either parameter is -1, the resulting image maintains the same aspect ratio as the original image.

ImageConsumer interface methods

public void setHints (int hints) ★

The `setHints()` method of `AreaAveragingScaleFilter` checks to see if some optimizations can be performed based upon the value of the `hints` parameter. If they can't, the image filter has to cache the pixel data until it receives the entire image.

public void setPixels (int x, int y, int w, int h, ColorModel model, byte pixels[], int offset, int scansize) ★
public void setPixels (int x, int y, int w, int h, ColorModel model, int pixels[], int offset, int scansize) ★

The `setPixels()` method of `AreaAveragingScaleFilter` accumulates the pixels or passes them along based upon the available hints. If `setPixels()` accumulates the pixels, this filter passes them along to the consumer when appropriate.

Cascading Filters

It is often a good idea to perform complex filtering operations by using several filters in a chain. This technique requires the system to perform several passes through the image array, so it may be slower than using a single complex filter; however, cascading filters yield code that is easier to understand and quicker to write--particularly if you already have a collection of image filters from other projects.

For example, assume you want to make a color image transparent and then render the image in black and white. The easy way to do this task is to apply a filter that converts color to a gray value and then apply the `TransparentImageFilter` we developed in Example 12.9. Using this strategy, we have to develop only one very simple filter. Example 12.11 shows the source for the `GrayImageFilter`; Example 12.12 shows the applet that applies the two filters in a daisy chain.

Example 12.11: GrayImageFilter Source

```
import java.awt.image.*;
public class GrayImageFilter extends RGBImageFilter {
    public GrayImageFilter () {
        canFilterIndexColorModel = true;
    }
    public int filterRGB (int x, int y, int rgb) {
        int gray  = (((rgb & 0xff0000) >> 16) +
                     ((rgb & 0x00ff00) >> 8) +
                     (rgb & 0x0000ff)) / 3;
        return (0xff000000 | (gray << 16) | (gray <<  8) |  gray);
    }
}
```

Example 12.12: DrawingImages Source

```
import java.applet.*;
import java.awt.*;
import java.awt.image.*;
public class DrawingImages extends Applet {
    Image i, j, k, l;
    public void init () {
        i = getImage (getDocumentBase(), "rosey.jpg");
        GrayImageFilter gif = new GrayImageFilter ();
        j = createImage (new FilteredImageSource (i.getSource(), gif));
        TransparentImageFilter tf = new TransparentImageFilter (.5f);
        k = createImage (new FilteredImageSource (j.getSource(), tf));
        l = createImage (new FilteredImageSource (i.getSource(), tf));
    }
    public void paint (Graphics g) {
        g.drawImage (i, 10, 10, this);                  // regular
        g.drawImage (j, 270, 10, this);                 // gray
        g.drawImage (k, 10, 110, Color.red, this);      // gray - transparent
        g.drawImage (l, 270, 110, Color.red, this);     // transparent
    }
}
```

Granted, neither the `GrayImageFilter` or the `TransparentImageFilter` are very complex, but consider the savings you would get if you wanted to blur an image, crop it, and then render the result in grayscale. Writing a filter that does all three is not a task for the faint of heart; remember, you can't subclass `RGBImageFilter` or `CropImageFilter` because the result does not depend purely on each pixel's color and position. However, you can solve the problem easily by cascading the filters developed in this chapter.

PREVIOUS ImageConsumer | HOME BOOK INDEX | NEXT AWT Exceptions and Errors

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

13.2 IllegalComponentStateException

`IllegalComponentStateException` is a subclass of `IllegalStateException`; both are new to Java 1.1. This exception is used when you try to do something with a `Component` that is not yet appropriate. With the standard AWT components, this can happen only in three instances:

- If you call `setCaretPosition()` to set the cursor position of a text component before the component's peer exists.
- If you call `getLocale()` to get the locale of a component that does not have one and is not in a container that has one.
- If you call `getLocationOnScreen()` for a component that is not showing.

In these cases, the operation isn't fundamentally illegal; you are just trying to perform it before the component is ready. When you create your own components, you should consider using this exception for similar cases.

Since `IllegalComponentStateException` is a subclass of `Run-TimeException`, you do not have to enclose method calls that might throw this exception within `try/catch` blocks. However, catching this exception isn't a bad idea, since it should be fairly easy to correct the problem and retry the operation.

IllegalComponentStateException Method

Constructor

public IllegalComponentStateException () ★

The first constructor creates an `IllegalComponentStateException` instance with no detail message.

public IllegalComponentStateException (String message) ★

This constructor creates an `IllegalComponentStateException` with a detail message of `message`. This message can be retrieved using `getMessage()`, which it inherits from `Exception` (and is required by the `Throwable` interface).

IllegalComponentStateException Example

The following code throws an `IllegalComponentStateException`. The `Exception` occurs because the `TextField` peer does not exist when `setCaretPosition()` is called. `setCaretPosition()` throws an `IllegalComponentStateException`, and the next statement never executes.

```
import java.awt.TextField;
public class illegal {
    public static void main (String[] args) {
        new TextField().setCaretPosition (24);
        System.out.println ("Never gets here");
    }
}
```

AWTException BOOK INDEX AWTError

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

13.3 AWTError

AWTError is a subclass of Error that is used when a serious run-time error has occurred within AWT. For example, an AWTError is thrown if the default Toolkit cannot be initialized or if you try to create a FileDialog within Netscape Navigator (since that program does not permit local file system access). When an AWTError is thrown and not caught, the virtual machine stops your program. You may throw this Error to indicate a serious run-time problem in any subclass of the AWT classes. Using AWTError is slightly preferable to creating your own Error because you don't have to provide another class file. Since it is part of Java, AWTError is guaranteed to exist on the run-time platform.

Methods are not required to declare that they throw AWTError. If you throw an error that is not caught, it will eventually propagate to the top level of the system.

AWTError Method

Constructor

public AWTError (String message)

> The sole constructor creates an AWTError with a detail message of message. This message can be retrieved using getMessage(), which it inherits from Error (and is required by the Throwable interface). If you do not want a detailed message, message may be null.

Throwing an AWTError

The code in Example 13.1 throws an AWTError if it is executed with this command:

```
java -Dawt.toolkit=foo throwme
```

The error occurs because the Java interpreter tries to use the toolkit foo, which does not exist (assuming that class `foo` does not exist in your `CLASSPATH`). Therefore, `getDefaultToolkit()` throws an `AWTError`, and the next statement never executes.

Example 13.1: The throwme class

```
import java.awt.Toolkit;
public class throwme {
    public static void main (String[] args) {
        System.out.println (Toolkit.getDefaultToolkit());
        System.out.println ("Never Gets Here");
    }
}
```

IllegalComponentStateException | BOOK INDEX | And Then There Were Applets

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

14.2 AudioClip Interface

Once an audio file is loaded into memory with `getAudioClip()`, you use the `AudioClip` interface to work with it. Methods

Three methods define the `AudioClip` interface. The class that implements these methods depends on the run-time environment; the class is probably `sun.applet.AppletAudioClip` or `netscape.applet.AppletAudioClip`.

If you play an audio clip anywhere within your `Applet`, you should call the `AudioClip` `stop()` method within the `stop()` method of the applet. This ensures that the audio file will stop playing when the user leaves your web page. Stopping audio clips is a must if you call `loop()` to play the sound continuously; if you don't stop an audio clip, the user will have to exit the browser to get the sound to stop playing.

Applets can play audio clips simultaneously. Based upon the user's actions, you may want to play a sound file in the background continuously, while playing other files.

void play ()

> The `play()` method plays the audio clip once from the beginning.

void loop ()

> The `loop()` method plays the audio clip continuously. When it gets to the end-of-file marker, it resets itself to the beginning.

void stop ()

> The `stop()` method stops the applet from playing the audio clip.

Using an AudioClip

The applet in Example 14.2 loads three audio files in the `init()` method. The `start()` method plays Dino barking in the background as a continuous loop. Whenever the browser calls `paint()`, Fred yells "Wilma," and when you click the mouse anywhere, the call to `mouseDown()` plays Fred yelling, "Yabba-Dabba-Doo." If you try real hard, all three can play at once. Before playing any audio clip, the applet makes sure that the clip is not null--that is, that the clip loaded correctly. `stop()` stops all clips from playing; you should make sure that applets stop all audio clips before the viewer leaves the web page.

Example 14.2: AudioClip Usage

```
import java.net.*;
import java.awt.*;
import java.applet.*;
public class AudioTestExample extends Applet{
    AudioClip audio1, audio2, audio3;
    public void init () {
        audio1 = getAudioClip (getCodeBase(), "audio/flintstones.au");
        audio2 = getAudioClip (getCodeBase(), "audio/dino.au");
        audio3 = getAudioClip (getCodeBase(), "audio/wilma.au");
    }
    public boolean mouseDown (Event e, int x, int y) {
        if (audio1 != null)
            audio1.play();
        return true;
    }
    public void start () {
        if (audio2 != null)
            audio2.loop();
    }
    public void paint (Graphics g) {
        if (audio3 != null)
            audio3.play();
    }
    public void stop () {
        if (audio1 != null)
            audio1.stop();
        if (audio2 != null)
            audio2.stop();
        if (audio3 != null)
```

```
            audio3.stop();
    }
}
```

What's a Java Applet? BOOK INDEX AppletContext Interface

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

14.3 AppletContext Interface

The `AppletContext` interface provides the means to control the browser environment where the applet is running. Methods

Some of these methods are so frequently used that they are also provided within the `Applet` class.

public abstract AudioClip getAudioClip (URL url)

> The `getAudioClip()` method loads the audio file located at `url`. `url` must be a complete and valid URL. Upon success, `getAudioClip()` returns an instance of a class that implements the `AudioClip` interface. You can then call methods in the `AudioClip` interface (see AudioClip Interface) to play the clip. If an error occurs during loading (e.g., because the file was not found or the URL was invalid), `getAudioClip()` returns `null`.

public abstract Image getImage (URL url)

> The `getImage()` method loads the image file located at `url`. `url` must be a complete and valid URL. The method returns a system-specific object that subclasses `Image` and returns immediately. The `Image` is not loaded until needed. A call to `prepareImage()`, `MediaTracker`, or `drawImage()` forces loading to start.

public abstract Applet getApplet (String name)

> The `getApplet()` method fetches the `Applet` from the current HTML page named `name`, which can be the applet's class name or the name provided in the `NAME` parameter of the `<APPLET>` tag. `getApplet()` returns `null` if the applet does not exist in the current context. This method allows you to call methods of other applets within the same context, loaded by the same `ClassLoader`. For example:

```
MyApplet who = (MyApplet)getAppletContext().getApplet("hey");
who.method();
```

TIP:

Netscape Navigator 3.0 restricts which applets can communicate with each other. Internet Explorer seems to have a similar restriction. For applets to communicate, they must:

- Have the same `CODEBASE`.
- Have the same or no `ARCHIVES` tag.
- Have `MAYSCRIPT` tags and appear in the same frame; alternatively, neither applet may have a `MAYSCRIPT` tag.

If these conditions are not met and you try to cast the return value of `getApplet()` or `getApplets()` to the appropriate class, either the cast will throw a `ClassCastException`; or nothing will happen, and the method will not continue beyond the point of the failure.

public abstract Enumeration getApplets ()

The `getApplets()` method gathers all the `Applets` in the current context, loaded by the same `ClassLoader`, into a collection and returns the `Enumeration`. You can then cycle through them to perform some operation collectively. For example:

```
Enumeration e = getAppletContext().getApplets();
while (e.hasMoreElements()) {
    Object o = e.nextElement();
    if (o instance of MyApplet) {
        MyApplet a = (Object)o;
        a.MyAppletMethod();
    }
}
```

TIP:

If you want communication between applets on one page, be aware that there is no guarantee which applet will start first. Communications must be synchronized by using a controlling class or continual polling.

public abstract void showDocument (URL url)

The `showDocument()` method shows `url` in the current browser window. The browser may ignore the request if it so desires.

public abstract void showDocument (URL url, String frame)

The `showDocument()` method shows `url` in a browser window specified by `frame`. Different `frame` values and the results are shown in Table 14.1. The browser may ignore the request, as *appletviewer* does.

```
try {
    URL u = new URL (getDocumentBase(), (String) file);
    getAppletContext().showDocument (u, "_blank");
} catch (Exception e) {
}
```

Table 14.1: Target Values

Target String	**Results**
`_blank`	Show `url` new browser window with no name.
`_parent`	Show `url` in the parent frame of the current window.
`_self`	Replace current `url` with `url` (i.e., display in the current window).
`_top`	Show `url` in top-most frame.
`name`	Show `url` in new browser window named `name`.

public abstract void showStatus (String message)

The `showStatus()` method displays `message` on the browser's status line, if it has one. How to display this string is up to the browser, and the browser can overwrite it whenever it wants. You should use `showStatus()` only for messages that the user can afford to miss.

PREVIOUS | HOME | NEXT
AudioClip Interface | BOOK INDEX | AppletStub Interface

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

14.4 AppletStub Interface

The `AppletStub` interface provides a way to get information from the run-time browser environment. The `Applet` class provides methods with similar names that call these methods. Methods

public abstract boolean isActive ()

> The `isActive()` method returns the current state of the applet. While an applet is initializing, it is not active, and calls to `isActive()` return `false`. The system marks the applet active just prior to calling `start()`; after this point, calls to `isActive()` return `true`.

public abstract URL getDocumentBase ()

> The `getDocumentBase()` method returns the complete URL of the HTML file that loaded the applet. This method can be used with the `getImage()` or `getAudioClip()` methods to load an image or audio file relative to the HTML file.

public abstract URL getCodeBase ()

> The `getCodeBase()` method returns the complete URL of the *.class* file that contains the applet. This method can be used with the `getImage()` method or the `getAudioClip()` method to load an image or audio file relative to the *.class* file.

public abstract String getParameter (String name)

> The `getParameter()` method allows you to get parameters from `<PARAM>` tags within the `<APPLET>` tag of the HTML file that loaded the applet. The `name` parameter of `getParameter()` must match the name string of the `<PARAM>` tag; `name` is case insensitive. The return value of `getParameter()` is the value associated with `name`; it is always a `String` regardless of the type of data in the tag. If `name` is not found within the `<PARAM>` tags

of the `<APPLET>`, `getParameter()` returns `null`.

public abstract AppletContext getAppletContext ()

The `getAppletContext()` method returns the current `AppletContext` of the applet. This is part of the stub that is set by the system when `setStub()` is called.

public abstract void appletResize (int width, int height)

The `appletResize()` method is called by the resize method of the `Applet` class. The method changes the size of the applet space to `width` x `height`. The browser must support changing the applet space; if it doesn't, the size remains unchanged.

PREVIOUS AppletContext Interface | HOME BOOK INDEX | NEXT Audio in Applications

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

14.5 Audio in Applications

The rest of this chapter describes how to use audio in your applications. Because the audio support discussed so far has been provided by the browser, applications that don't run in the context of a browser must use a different set of classes to work with audio. These classes are within the `sun.audio` package. Although the `sun.*` package hierarchy is not necessarily included by other vendors, the `sun.audio` classes discussed here are provided with Netscape Navigator 2.0/3.0 and Internet Explorer 3.0. Therefore, you can use these classes within applets, too. This section ends by developing a `SunAudioClip` class that has an interface similar to the applet's audio interface; you can use it to minimize coding differences between applets and applications.

AudioData

The `AudioData` class holds a clip of 8000 Hz µLaw audio data. This data can be used to construct an `AudioDataStream` or `ContinuousAudioDataStream`, which can then be played with the `AudioPlayer`. Constructor

public AudioData (byte buffer[])

> The `AudioData` constructor accepts a byte array `buffer` and creates an instance of `AudioData`. The buffer should contain 8000 Hz µLaw audio data.

Methods

There are no methods for `AudioData`.

AudioStream

`AudioStream` subclasses `FilterInputStream`, which extends `InputStream`. Using an `InputStream` lets you move back and forth (rewind and fast forward) within an audio file, in addition to playing the audio data from start to finish. Constructors

public AudioStream (InputStream in) throws IOException

> The `AudioStream` constructor has `InputStream in` as its parameter and can throw `IOException` on error. In the following code, we get an input stream by opening a *.au* file. Another common way to construct an `AudioStream` is to use the stream associated with a URL through the URL's `openStream()` method.

```
FileInputStream fis = new FileInputStream ("/usr/openwin/demo/sounds/1.au");
AudioStream audiostream = new AudioStream (fis);
```

or:

```
AudioStream audiostream = new AudioStream (savedUrl.openStream());
```

If you are constructing the audio data yourself, you would use a `ByteArrayInputStream`. Whatever the source of the data, the input stream should provide data in Sun's *.au* format.

Methods

public int read (byte buffer[], int offset, int length) throws IOException

The `read()` method for `AudioStream` reads an array of bytes into `buffer`. `offset` is the first element of `buffer` that is used. `length` is the maximum number of bytes to read. This method blocks until some input is available. `read()` returns the actual number of bytes read. If the end of stream is encountered and no bytes were read, `read()` returns -1. Ordinarily, you `read()` an `AudioStream` only if you want to modify the audio data in some way.

public int getLength()

The `getLength()` method returns the length of the audio data contained within the `AudioStream`, excluding any header information in the file.

public AudioData getData () throws IOException

The `getData()` method of `AudioStream` is the most important and most frequently used. It reads the data from the input stream and creates an `AudioData` instance. As the following code shows, you can create an `AudioStream` and get the `AudioData` with one statement.

```
AudioData audiodata = new AudioStream (aUrl.openStream()).getData();
```

AudioDataStream

Constructors

public AudioDataStream (AudioData data)

This constructor creates an `AudioDataStream` from an `AudioData` object `data`. The resulting `AudioDataStream` is a subclass of `ByteArrayInputStream` and can be played by the `AudioPlayer.start()` method.

Methods

There are no methods for `AudioDataStream`.

ContinuousAudioDataStream

Constructors

public ContinuousAudioDataStream (AudioData data)

> This constructor creates a continuous stream of audio from `data`. The resulting `ContinuousAudioDataStream` is a subclass of `AudioDataStream` and, therefore, of `ByteArrayInputStream`. It can be played by `AudioPlayer.start()`; whenever the player reaches the end of the continuous audio data stream, it restarts from the beginning.

Methods

public int read ()

> This `read()` method of `ContinuousAudioDataStream` overrides the `read()` method in `ByteArrayInputStream` to rewind back to the beginning of the stream when end-of-file is reached. This method is used by the system when it reads the `InputStream`; it is rarely called directly. `read()` never returns -1 since it loops back to the beginning on end-of-file.

public int read (byte buffer[], int offset, int length)

> This `read()` method of `ContinuousAudioDataStream` overrides the `read()` method in `ByteArrayInputStream` to rewind back to the beginning of the stream when end-of-file is reached. This method is used by the system when it reads the `InputStream`; it is rarely called directly. `read()` returns the actual number of bytes read. `read()` never returns -1 since it loops back to the beginning on end-of-file.

AudioStreamSequence

Constructors

public AudioStreamSequence (Enumeration e)

> The constructor for `AudioStreamSequence` accepts an `Enumeration e`(normally the elements of a `Vector` of `AudioStream`s) as its sole parameter. The constructor converts the sequence of audio streams into a single stream to be played in order. An example follows:

```
Vector v = new Vector ();
v.addElement (new AudioStream (url1.openStream ());
v.addElement (new AudioStream (url2.openStream ());
AudioStreamSequence audiostream = new AudioStreamSequence (v.elements ());
```

Methods

public int read ()

> This `read()` method of `AudioStreamSequence` overrides the `read()` method in `InputStream` to start

the next stream when end-of-file is reached. This method is used by the system when it reads the `InputStream` and is rarely called directly. If the end of all streams is encountered and no bytes were read, `read()` returns -1. Otherwise, `read()` returns the character read.

public int read (byte buffer[], int offset, int length)

This `read()` method of `AudioStreamSequence` overrides the `read()` method in `InputStream` to start the next stream when end-of-file is reached. This method is used by the system when it reads the `InputStream` and is rarely called directly. `read()` returns the actual number of bytes read. If the end of all streams is encountered and no bytes were read, `read()` returns -1.

AudioPlayer

The `AudioPlayer` class is the workhorse of the `sun.audio` package. It is used to play all the streams that were created with the other classes. There is no constructor for `AudioPlayer`; it just extends `Thread` and provides `start()` and `stop()` methods. Variable

public final static AudioPlayer player

`player` is the default audio player. This audio player is initialized automatically when the class is loaded; you do not have to initialize it (in fact, you can't because it is final) or call the constructor yourself.

Methods

public synchronized void start (InputStream in)

The `start()` method starts a thread that plays the `InputStream in`. Stream `in` continues to play until there is no more data or it is stopped. If `in` is a `ContinuousAudioDataStream`, the playing continues until `stop()` (described next) is called.

public synchronized void stop (InputStream in)

The `stop()` method stops the player from playing `InputStream in`. Nothing happens if the stream `in` is no longer playing or was never started.

SunAudioClip Class Definition

The class in Example 14.3 is all you need to play audio files in applications. It implements the `java.applet.AudioClip` interface, so the methods and functionality will be familiar. The test program in `main()` demonstrates how to use the class. Although the class itself can be used in applets, provided your users have the `sun.audio` package available, it is geared towards application users.

Example 14.3: The SunAudioClip Class

```
import java.net.URL;
import java.io.FileInputStream;
import sun.audio.*;
```

```
public class SunAudioClip implements java.applet.AudioClip {
    private AudioData audiodata;
    private AudioDataStream audiostream;
    private ContinuousAudioDataStream continuousaudiostream;
    static int length;
    public SunAudioClip (URL url) throws java.io.IOException {
        audiodata = new AudioStream (url.openStream()).getData();
        audiostream = null;
        continuousaudiostream = null;
    }
    public SunAudioClip (String filename) throws java.io.IOException {
        FileInputStream fis = new FileInputStream (filename);
        AudioStream audioStream = new AudioStream (fis);
        audiodata = audioStream.getData();
        audiostream = null;
        continuousaudiostream = null;
    }
    public void play () {
        audiostream = new AudioDataStream (audiodata);
        AudioPlayer.player.start (audiostream);
    }
    public void loop () {
        continuousaudiostream = new ContinuousAudioDataStream (audiodata);
        AudioPlayer.player.start (continuousaudiostream);
    }
    public void stop () {
        if (audiostream != null)
            AudioPlayer.player.stop (audiostream);
        if (continuousaudiostream != null)
            AudioPlayer.player.stop (continuousaudiostream);
    }
    public static void main (String args[]) throws Exception {
        URL url1 = new URL ("http://localhost:8080/audio/1.au");
        URL url2 = new URL ("http://localhost:8080/audio/2.au");
        SunAudioClip sac1 = new SunAudioClip (url1);
        SunAudioClip sac2 = new SunAudioClip (url2);
        SunAudioClip sac3 = new SunAudioClip ("1.au");
        sac1.play ();
        sac2.loop ();
        sac3.play ();
        try {// Delay for loop
            Thread.sleep (2000);
        } catch (InterruptedException ie) {}
        sac2.stop();
    }
}
```

16.3 ClipboardOwner Interface

Classes that need to place objects on a clipboard must implement the `ClipboardOwner` interface. An object becomes the clipboard owner by placing something on a `Clipboard` and remains owner as long as that object stays on the clipboard; it loses ownership when someone else writes to the clipboard. The `ClipboardOwner` interface provides a way to receive notification when you lose ownership--that is, when the object you placed on the clipboard is replaced by something else. Methods

public abstract void lostOwnership(Clipboard clipboard, Transferable contents) ★

> The `lostOwnership()` method tells the owner of `contents` that it is no longer on the given `clipboard`. It is usually implemented as an empty stub but is available for situations in which you have to know.

16.4 Clipboard

The `Clipboard` class is a repository for a `Transferable` object and can be used for cut, copy, and paste operations. You can work with a private clipboard by creating your own instance of `Clipboard`, or you can work with the system clipboard by asking the `Toolkit` for it:

```
Toolkit.getDefaultToolkit().getSystemClipboard()
```

When working with the system clipboard, native applications have access to information created within Java programs and vice versa. Access to the system clipboard is controlled by the `SecurityManager` and is restricted within applets.

Clipboard Methods

Variables

protected ClipboardOwner owner ★

> The `owner` instance variable represents the current owner of `contents`. When something new is placed on the clipboard, the previous owner is notified by a call to the `lostOwnership()` method. The owner usually ignores this notification. However, the clipboard's `contents` are passed back to `owner` in case some special processing or comparison needs to be done.

protected Transferable contents ★

> The `contents` instance variable is the object currently on the clipboard; it was placed on the clipboard by `owner`. To retrieve the current contents, use the `getContents()` method.

Constructors

public Clipboard(String name) ★

The constructor for `Clipboard` allows you to create a private clipboard named `name`. This clipboard is not accessible outside of your program and has no security constraints placed upon it.

Miscellaneous methods

public String getName() ★

The `getName()` method fetches the clipboard's name. For private clipboards, this is the name given in the constructor. The name of the system clipboard is "System".

public synchronized Transferable getContents(Object requester) ★

The `getContents()` method allows you to retrieve the current contents of the clipboard. This is the method you would call when the user selects Paste from a menu.

Once you have the `Transferable` data, you try to get the data in whatever flavor you want by calling the `Transferable.getTransferData()` method, possibly after calling `Transferable.isDataFlavorSupported()`. The `requester` represents the object that is requesting the clipboard's contents; it is usually just `this`, since the current object is making the request.

public synchronized void setContents(Transferable contents, ClipboardOwner owner) ★

The `setContents()` method changes the contents of the clipboard to `contents` and changes the clipboard's owner to `owner`. You would call this method when the user selects Cut or Copy from a menu. The `owner` parameter represents the object that owns `contents`. This object must implement the `ClipboardOwner` interface; it will be notified by a call to `lostOwnership()` when something else is placed on the clipboard.

16.5 StringSelection

`StringSelection` is a convenience class that can be used for copy and paste operations on Unicode text strings (`String`). It implements both the `ClipboardOwner` and `Transferable` interfaces, so it can be used both as the contents of the clipboard and as its owner. For example, if `s` is a `StringSelection`, you can call `Clipboard.setContents(s,s)`. `StringSelection` supports both `stringFlavor` and `plainTextFlavor` and doesn't do anything when it loses clipboard ownership.

StringSelection Methods

Constructors

public StringSelection(String data) ★

> The constructor creates an instance of `StringSelection` containing `data`. You can use this object to place the data on a clipboard.

Miscellaneous methods

public DataFlavor[] getTransferDataFlavors() ★

> The `getTransferDataFlavors()` method returns a two-element `DataFlavor` array consisting of `DataFlavor.stringFlavor` and `DataFlavor.plainTextFlavor`. This means that you can paste a `StringSelection` as either a Java `String` or as plain text (i.e., the MIME type `plain/text`).

public boolean isDataFlavorSupported(DataFlavor flavor) ★

> The `isDataFlavorSupported()` method is returns `true` if `flavor` is either

`DataFlavor.stringFlavor` or `DataFlavor.plainTextFlavor`; it returns `false` for any other flavor.

public Object getTransferData(DataFlavor flavor) throws UnsupportedFlavorException, IOException ★

The `getTransferData()` method returns an object from which you can get the data on the clipboard; the object's type is determined by the `flavor` parameter. This method returns a `String` containing the data on the clipboard if `flavor` is `DataFlavor.stringFlavor`; it returns a `StringBufferInputStream` from which you can read the data on the clipboard if you ask for `DataFlavor.plainTextFlavor`. Otherwise, `getTransferData()` throws an `UnsupportedFlavorException`.

public void lostOwnership(Clipboard clipboard, Transferable contents) ★

The `lostOwnership()` method of `StringSelection` is an empty stub; it does nothing when you lose ownership. If you want to know when you've lost ownership of string data placed on the clipboard, write a subclass of `StringSelection` and override this method.

16.7 Reading and Writing the Clipboard

Now that you know about the different `java.awt.datatransfer` classes required to use the clipboard, let's put them all together in an example. Example 16.1 creates a `TextField` for input (copying), a read-only `TextArea` for output (pasting), and a couple of buttons to control its operation. Figure 16.1 shows the program's user interface. When the user clicks on the Copy button or presses Return in the `TextField`, the text in the `TextField` is copied to the `Clipboard`. When the user clicks on the Paste button, the contents of the clipboard are drawn in the `TextArea`. Since the clipboard is not private, you can copy or paste from anywhere on your desktop, not just this program.

Example 16.1: Using the System Clipboard

```
// Java 1.1 only
import java.io.*;
import java.awt.*;
import java.awt.datatransfer.*;
public class ClipMe extends Frame {
    TextField tf;
    TextArea ta;
    Button copy, paste;
    Clipboard clipboard = null;
    ClipMe() {
        super ("Clipping Example");
        add (tf = new TextField("Welcome"), "North");
        add (ta = new TextArea(), "Center");
        ta.setEditable(false);
        Panel p = new Panel();
        p.add (copy = new Button ("Copy"));
        p.add (paste = new Button ("Paste"));
        add (p, "South");
        setSize (250, 250);
    }
    public static void main (String args[]) {
        new ClipMe().show();
    }
    public boolean handleEvent (Event e) {
        if (e.id == Event.WINDOW_DESTROY) {
            System.exit(0);
            return true;  // never gets here
        }
        return super.handleEvent (e);
    }
    public boolean action (Event e, Object o) {
        if (clipboard == null)
            clipboard = getToolkit().getSystemClipboard();
        if ((e.target == tf) || (e.target == copy)) {
            StringSelection data;
            data = new StringSelection (tf.getText());
            clipboard.setContents (data, data);
        } else if (e.target == paste) {
            Transferable clipData = clipboard.getContents(this);
            String s;
            try {
                s = (String)(clipData.getTransferData(
                       DataFlavor.stringFlavor));
            } catch (Exception ee) {
                s = ee.toString();
            }
            ta.setText(s);
        }
        return true;
    }
}
```

Figure 16.1: Using the system clipboard

[Graphic: Figure 16-1]

We won't say anything about how the display is set up; that should be familiar. All the interesting stuff happens in the `action` method, which is called in response to a button click. We check which button the user clicked; if the user clicked the Copy button, we read the text field `tf` and use it to create a new `StringSelection` named `data`. If the user clicked the Paste button, we retrieve the data from the clipboard by calling `getContents()`. This gives us an object about which (strictly speaking) we know nothing, except that it implements `Transferable`. In this case, we're pretty sure that we're getting text from the clipboard, so we call `getTransferData()` and ask for the data in the `stringFlavor` form. We catch the exception that might occur if we're wrong about the data flavor. This program has no way of placing anything but text on the clipboard, but there's no guarantee that the user didn't cut some other kind of object from a native application.

Once we have our `String`, we call the `setText()` method of the `TextArea` to tell it about the new string, and we are finished.

18.2 Package diagrams

The following figures provide a visual representation of the relationships between the classes in the AWT packages.

`java.awt`, as the mother of all AWT packages, is better represented by two diagrams, one for the graphics classes and one for the component and layout classes.

Figure 18.1: Component and Layout classes of the java.awt package.

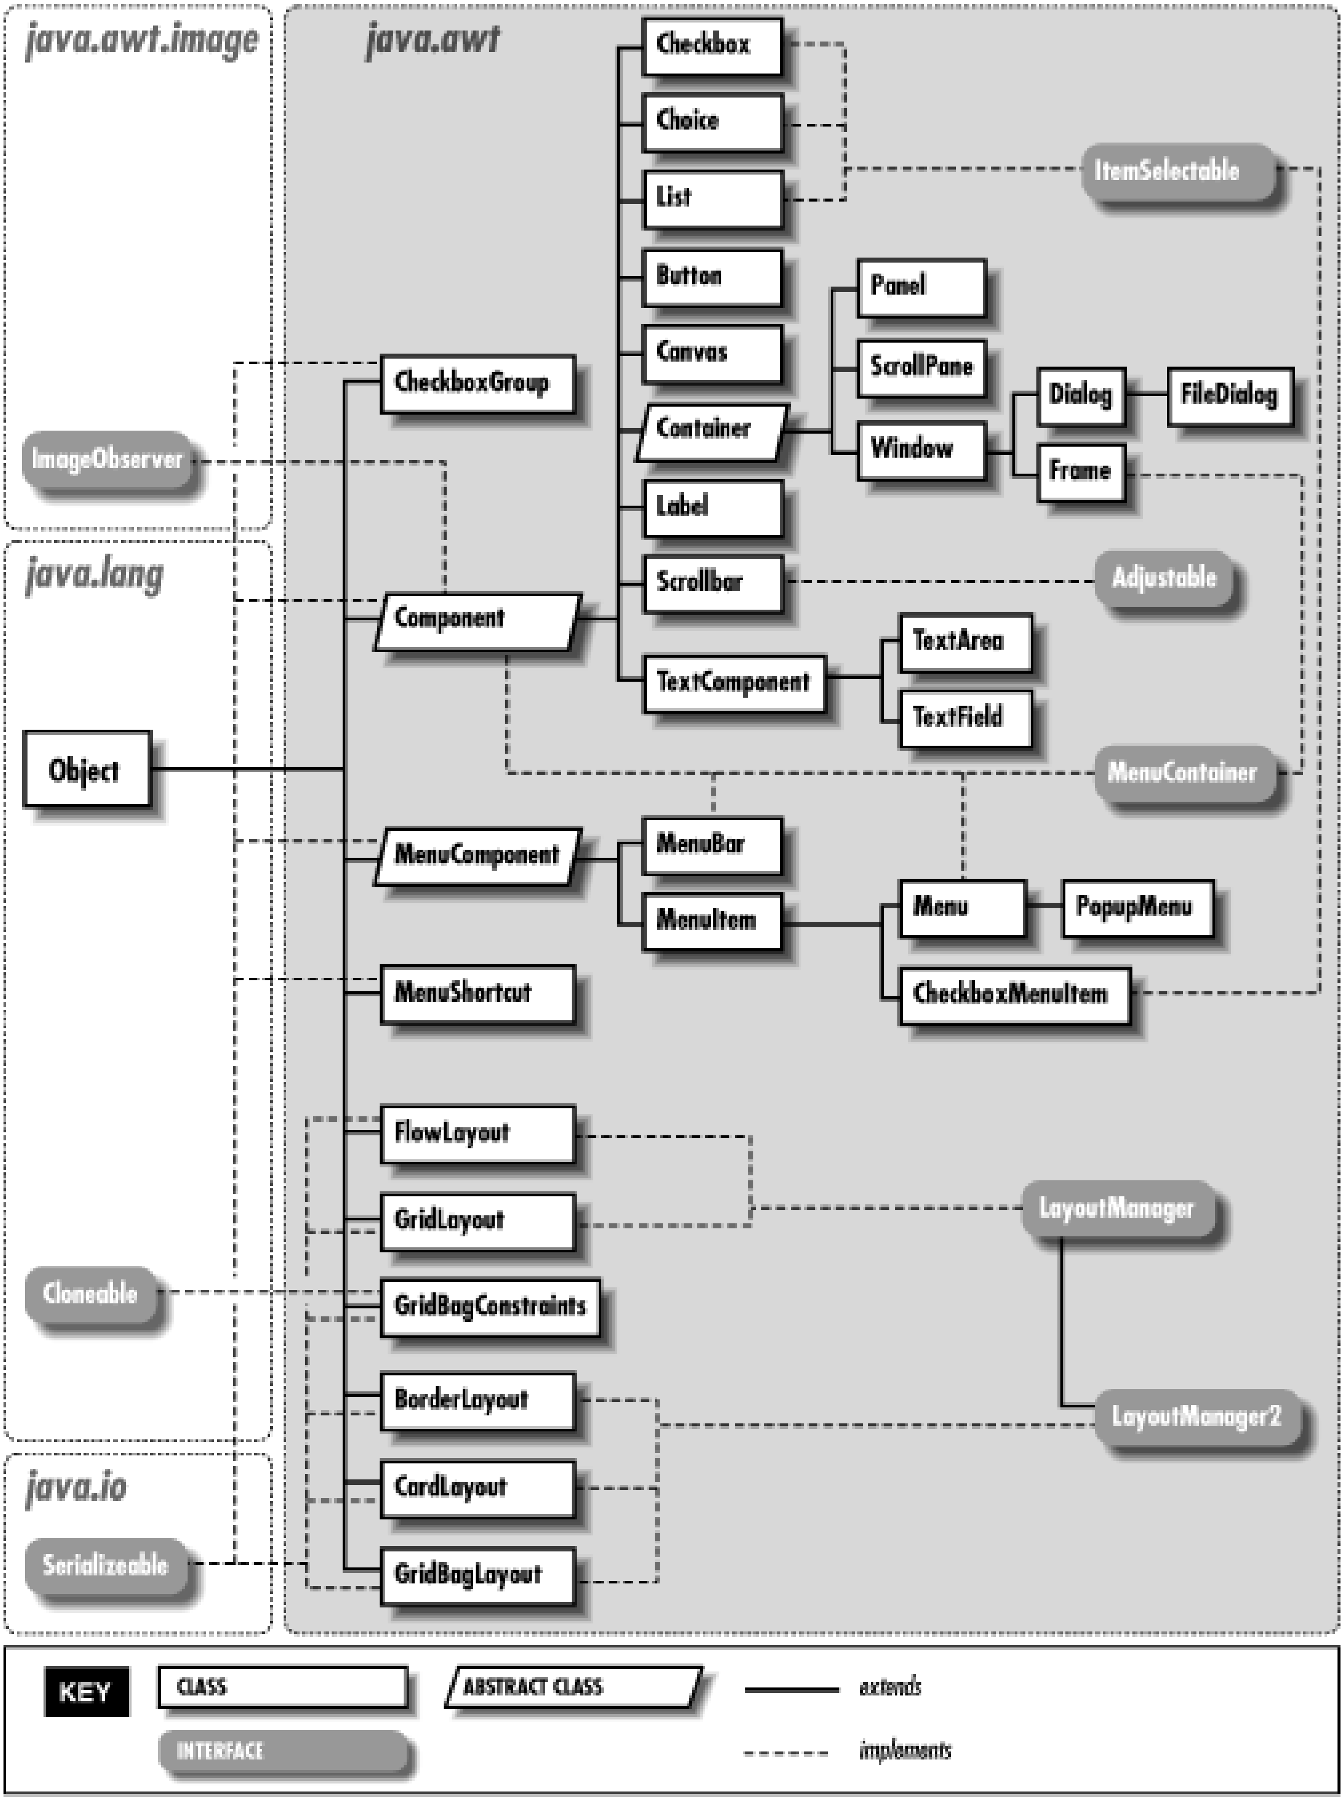

Figure 18.2: Graphics classes of java.awt package

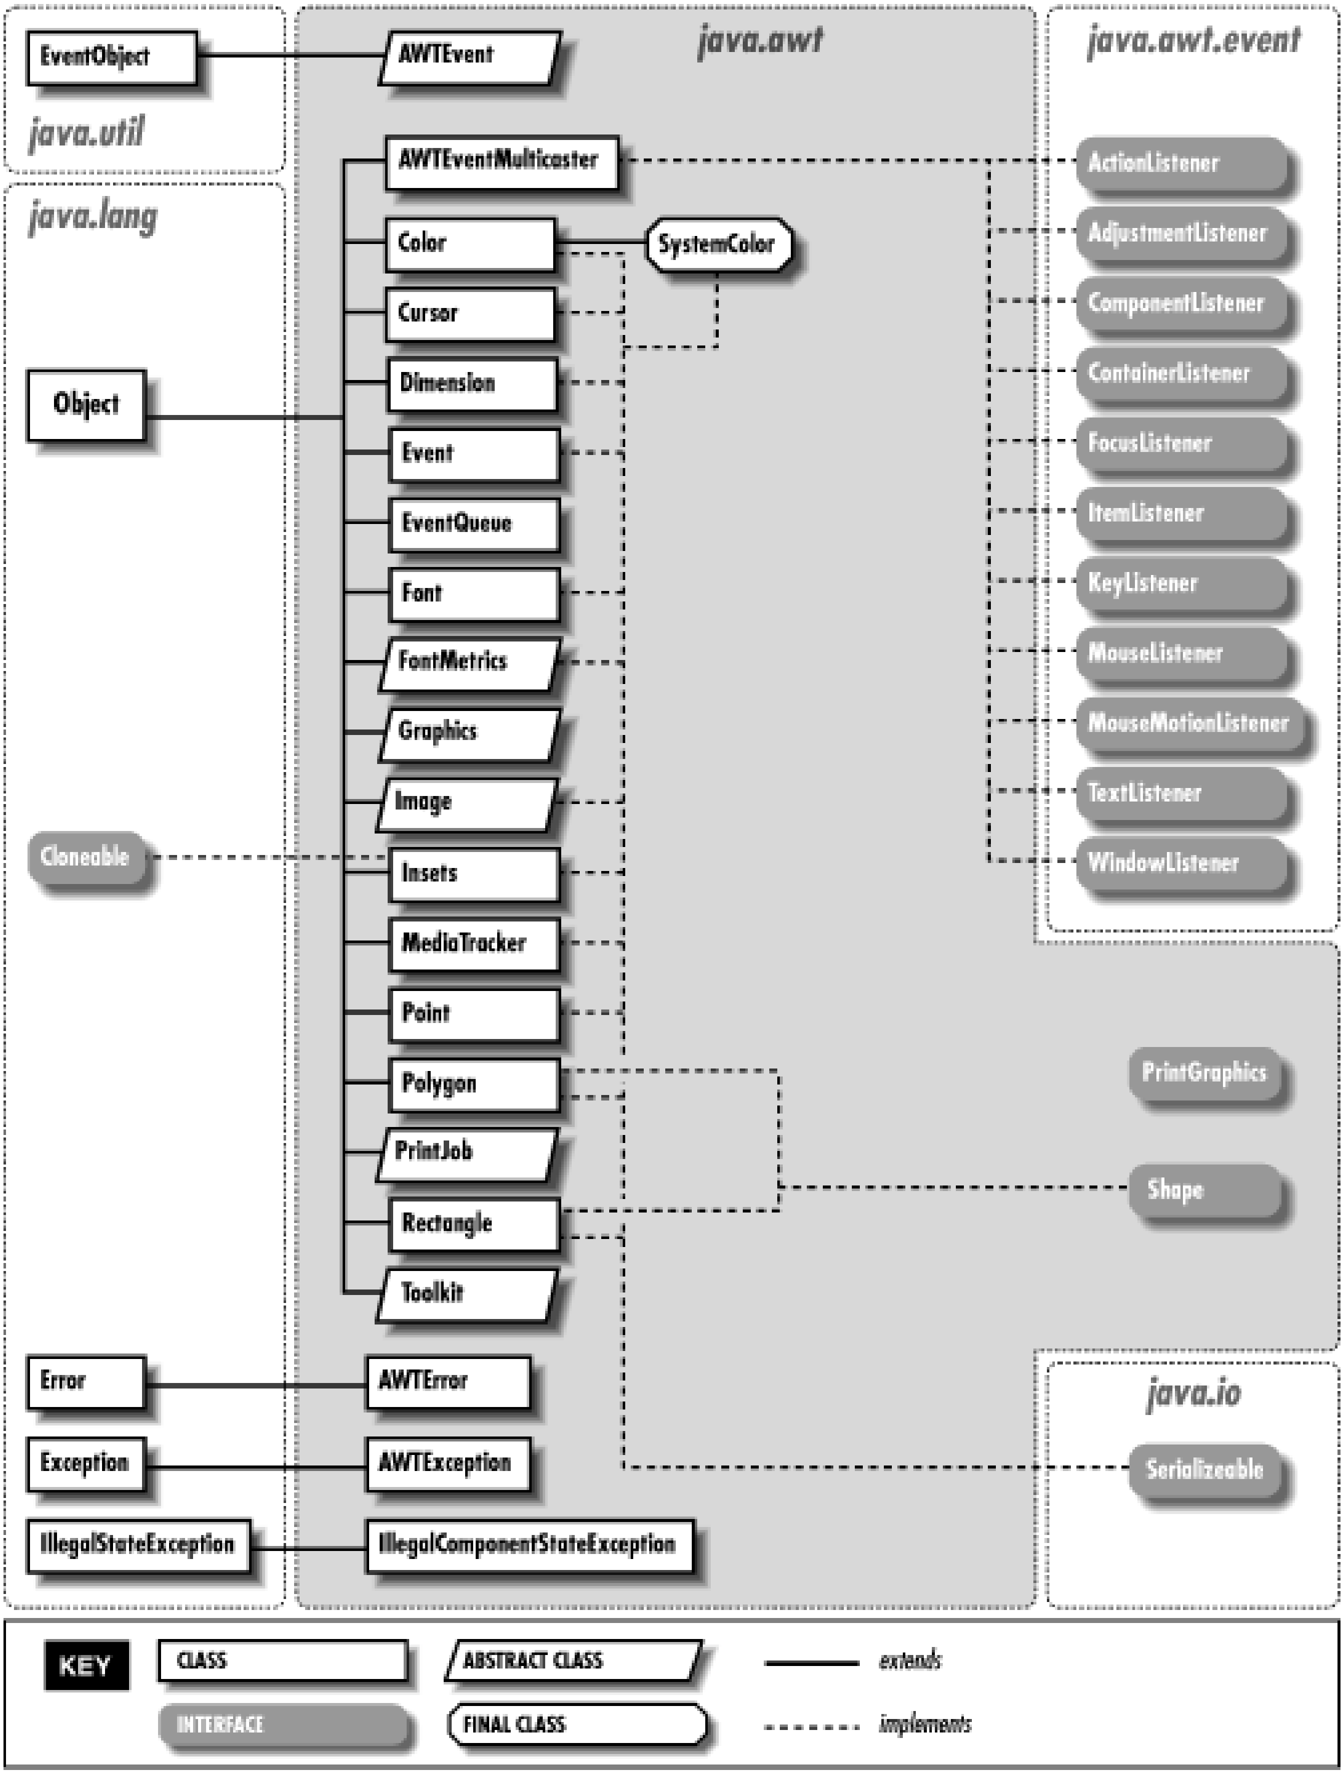

Figure 18.3: The java.awt.image package

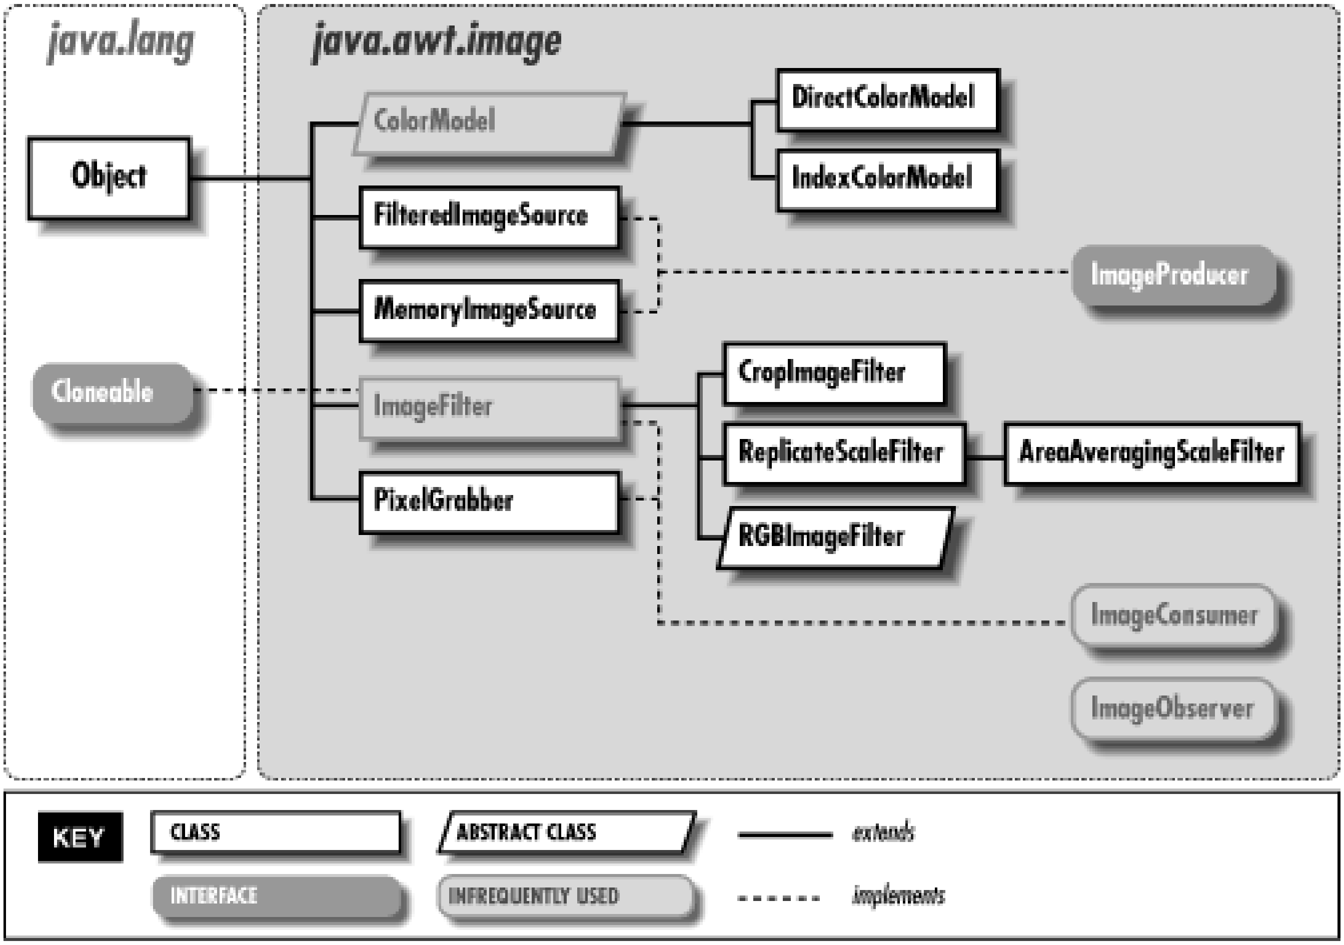

Figure 18.4: The java.awt.datatransfer package

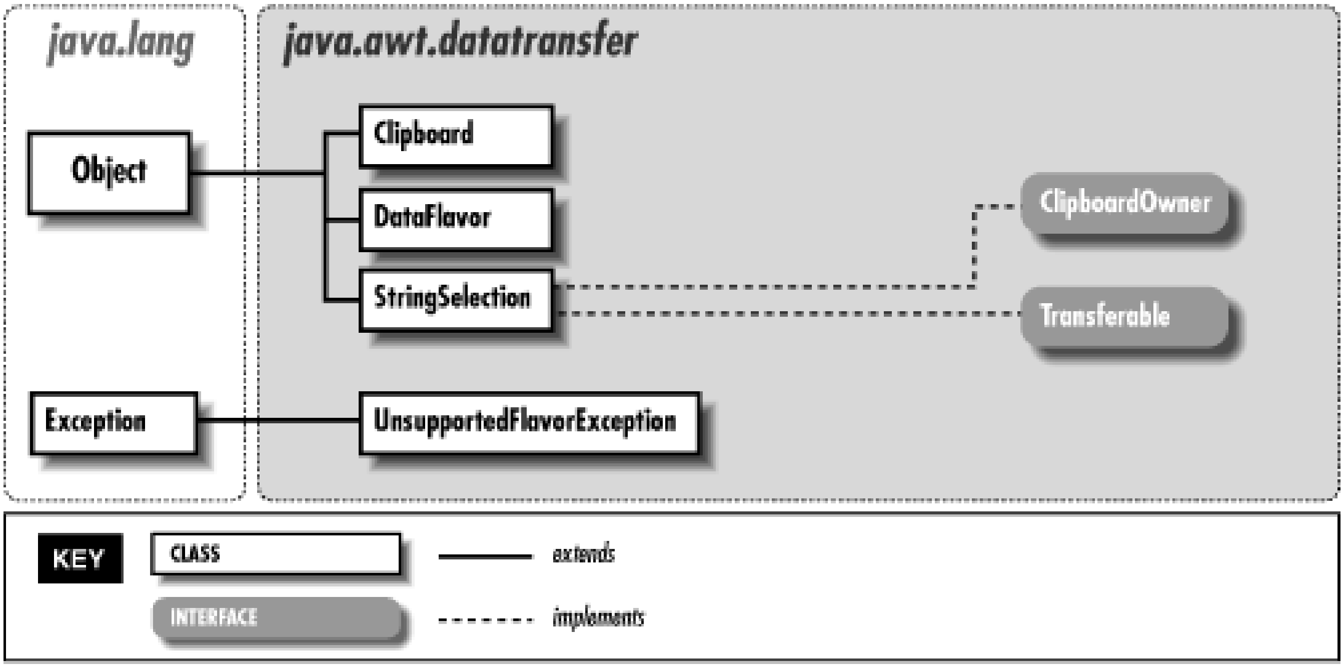

Figure 18.5: The java.awt.event package

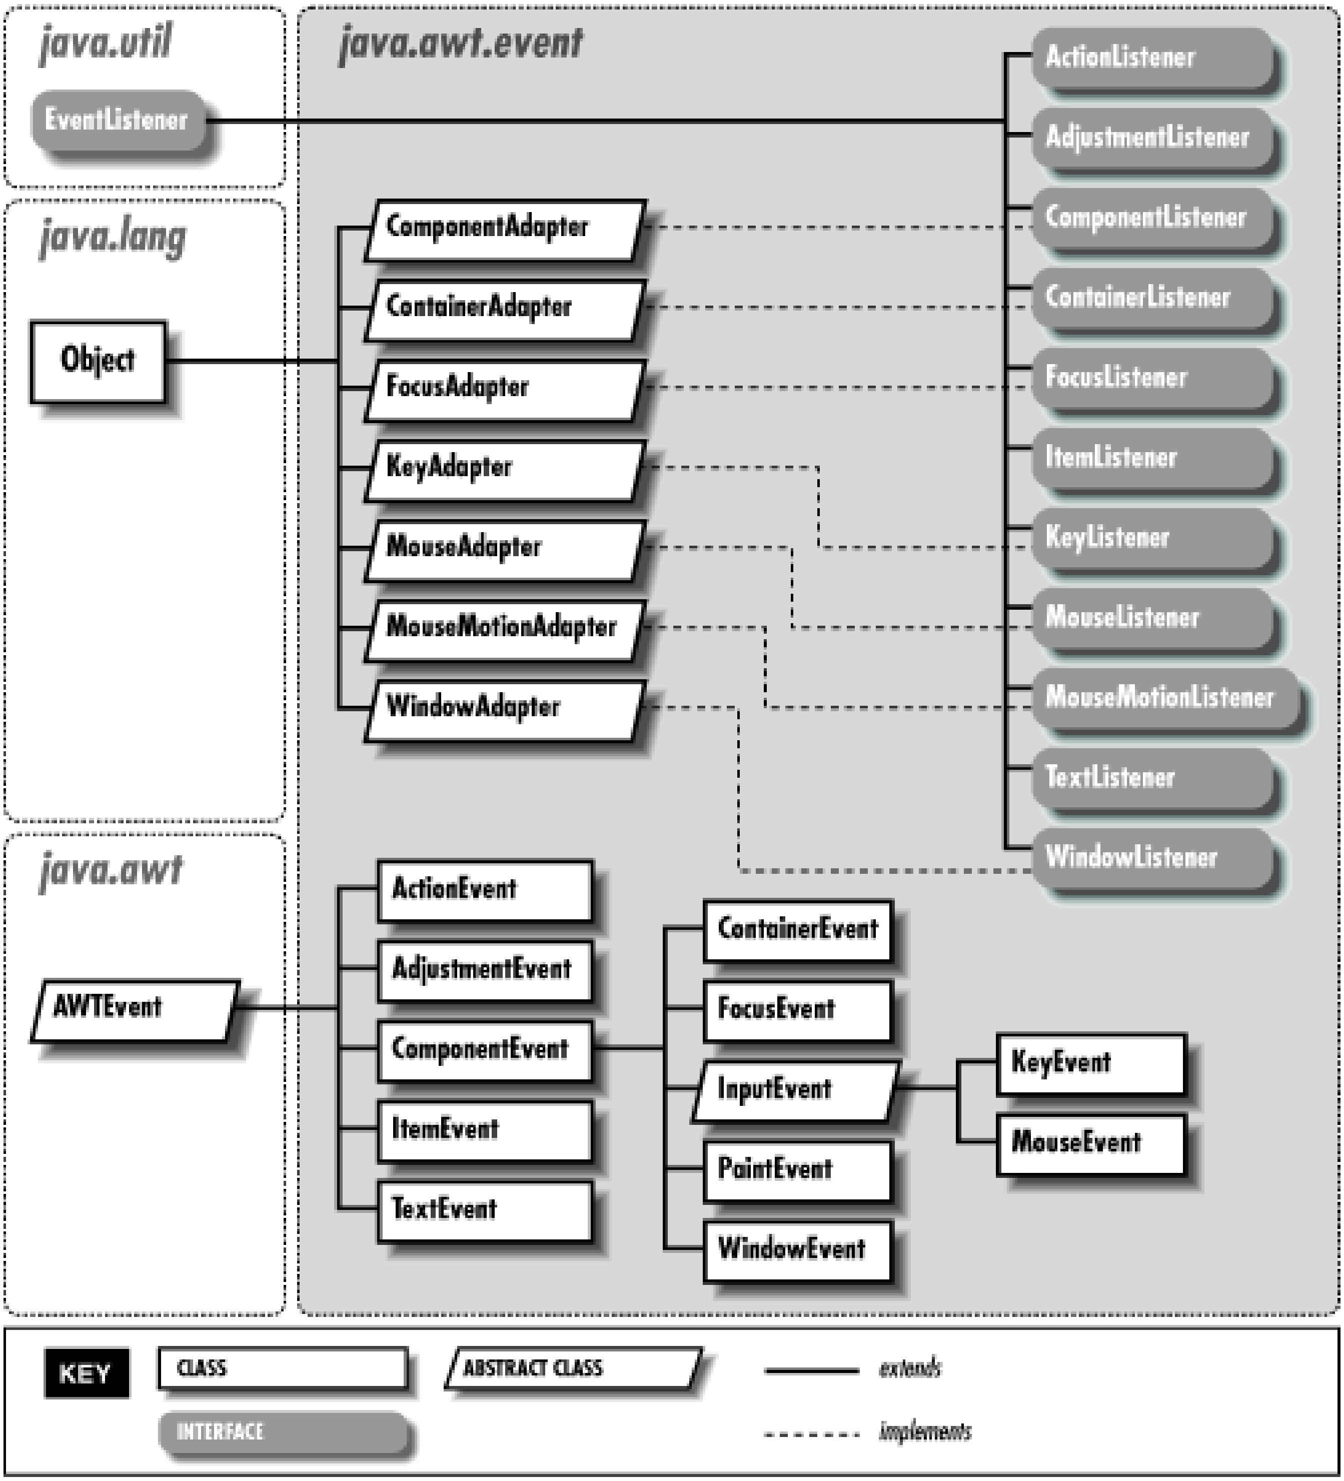

Figure 18.6: The java.awt.peer package

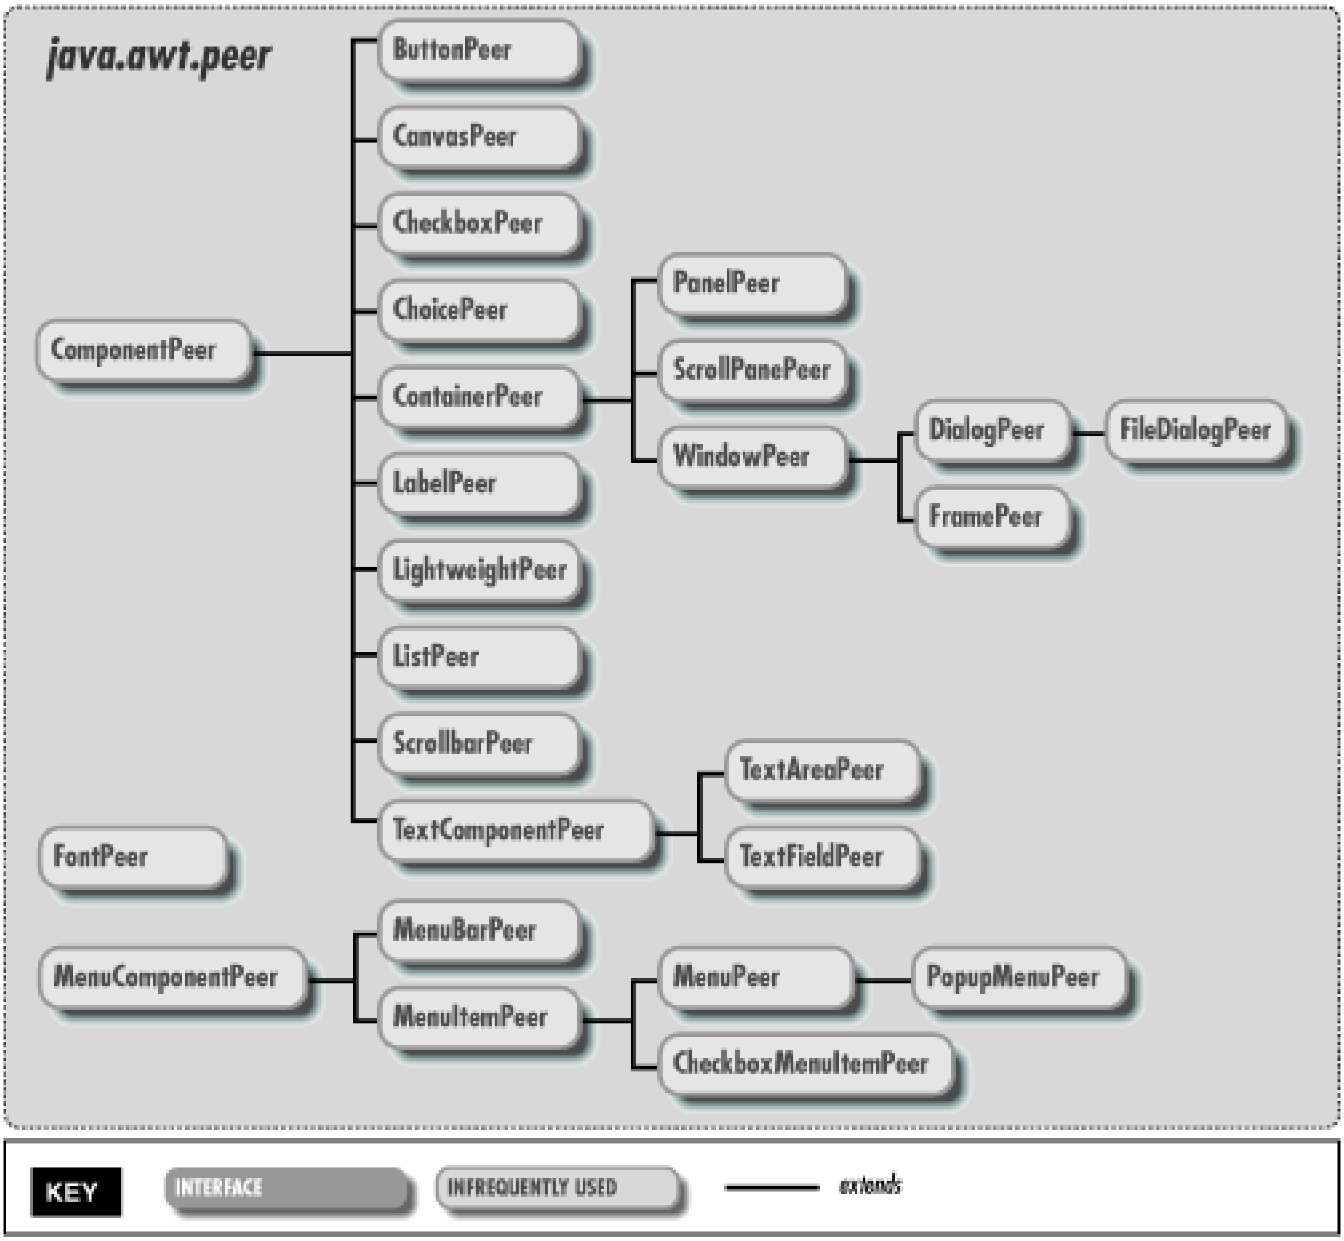

Figure 18.7: The java.applet package

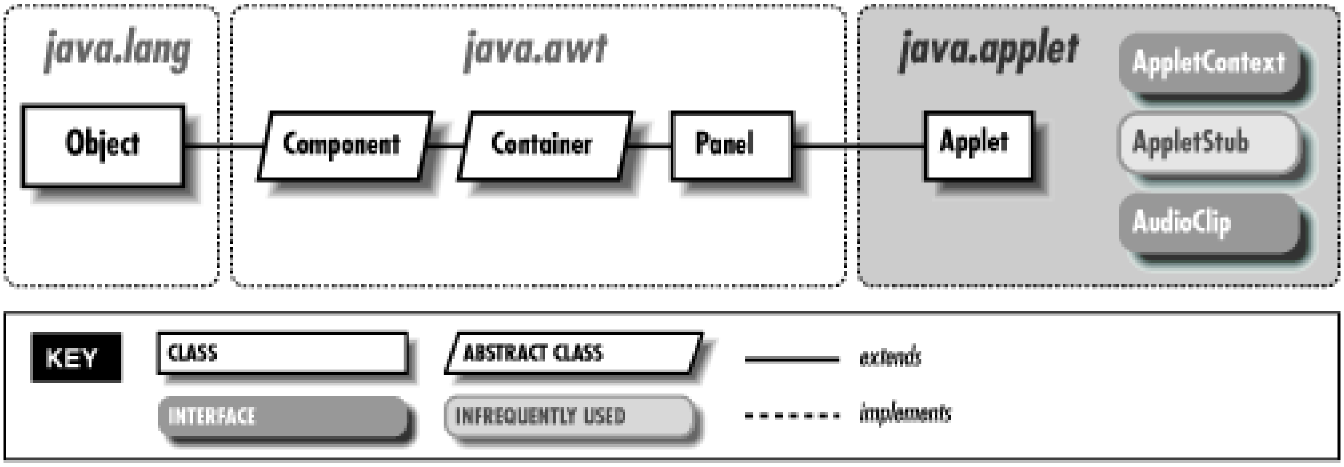
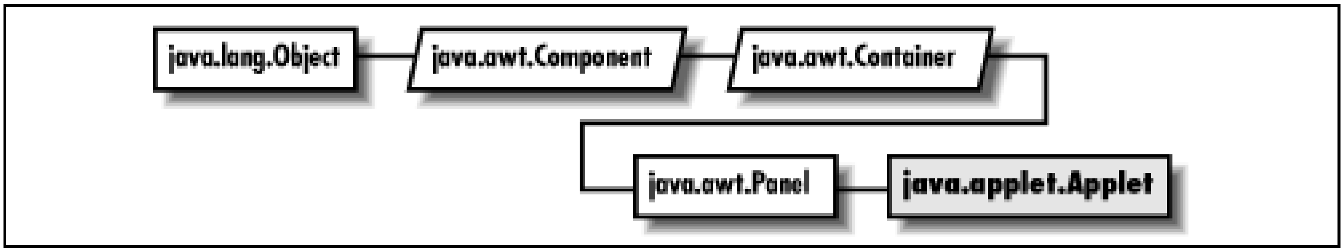


Applet

Name

Applet



Description

The `Applet` class provides the framework for delivering Java programs within web pages.

Class Definition

```
public class java.applet.Applet
    extends java.awt.Panel {
  // Constructors
  public Applet();
  // Instance Methods
  public void destroy();
  public AppletContext getAppletContext();
  public String getAppletInfo();
  public AudioClip getAudioClip (URL url);
  public AudioClip getAudioClip (URL url, String filename);
  public URL getCodeBase();
  public URL getDocumentBase();
  public Image getImage (URL url);
  public Image getImage (URL url, String filename);
  public Locale getLocale(); ★
  public String getParameter (String name);
  public String[][] getParameterInfo();
  public void init();
  public boolean isActive();
  public void play (URL url);
  public void play (URL url, String filename);
  public void resize (int width, int height);
  public void resize (Dimension dim);
  public final void setStub (AppletStub stub);
  public void showStatus (String message);
  public void start();
  public void stop();
}
```

Constructors

Applet

public Applet()

Description

> Constructs an `Applet` object.

Instance Methods

destroy

public void destroy()

Description

> Called when the browser determines that it doesn't need to keep the applet around anymore.

getAppletContext

public AppletContext getAppletContext()

Returns

The current `AppletContext` of the applet.

getAppletInfo

public String getAppletInfo()

Returns

A short information string about the applet to be shown to the user.

getAudioClip

public AudioClip getAudioClip (URL url)

Parameters

url

`URL` of an audio file.

Returns

Object that implements the `AudioClip` interface for playing audio files.

Description

Fetches an audio file to play with the `AudioClip` interface.

public AudioClip getAudioClip (URL url , String filename)

Parameters

url

Base `URL` of an audio file.

filename

Specific file, relative to `url`, that contains an audio file.

Returns

Object that implements `AudioClip` interface for playing audio file.

Description

Fetches an audio file to play with the `AudioClip` interface.

getCodeBase

public URL getCodeBase()

Returns

The complete `URL` of the *.class* file that contains the applet.

getDocumentBase

public URL getDocumentBase()

Returns

The complete `URL` of the *.html* file that loaded the applet.

getImage

public Image getImage (URL url)

Parameters

url

`URL` of an image file.

Returns

`Image` to be displayed.

Description

Initiates the image loading process for the file located at the specified location.

public Image getImage (URL url, String filename)

Parameters

url

Base `URL` of an image file.

filename

Specific file, relative to `url`, that contains an image file.

Returns

Image to be displayed.

Description

Initiates the image loading process for the file located at the specified location.

getLocale

public Locale getLocale() ★

Returns

`Applet`'s locale.

Overrides

`Component.getLocale()`

Description

Used for internationalization support.

getParameter

public String getParameter (String name)

Parameters

name

Name of parameter to get.

Returns

The value associated with the given parameter in the HTML file, or `null`.

Description

Allows you to get parameters from within the `<APPLET>` tag of the *.html* file that loaded the applet.

getParameterInfo

public String[][] getParameterInfo()

Returns

Overridden to provide a series of three-string arrays that describes the parameters this applet reads.

init

public void init()

Description

Called by the system when the applet is first loaded.

isActive

public boolean isActive()

Returns

> `true` if the applet is active, `false` otherwise.

play

public void play (URL url)

Parameters

> *url*
>
> > `URL` of an audio file .

Description

> Plays an audio file once.

public void play (URL url, String filename)

Parameters

> *url*
>
> > Base `URL` of an audio file .
>
> *filename*
>
> > Specific file, relative to `url`, that contains an audio file.

Description

> Plays an audio file once.

resize

public void resize(int width, int height)

Parameters

width

New width for the `Applet`.

height

New height for the `Applet`.

Description

Changes the size of the applet.

public void resize (Dimension dim)

Parameters

dim

New dimensions for the applet.

Description

Changes the size of the applet.

setStub

public final void setStub (AppletStub stub)

Parameters

stub

Platform specific stubfor environment.

Description

Called by the system to setup `AppletStub`.

showStatus

public void showStatus (String message)

Parameters

message

Message to display to user.

Description

Displays a message on the status line of the browser.

start

public void start()

Description

Called by the system every time the applet is displayed.

stop

public void stop()

Description

Called by the system when it wants the applet to stop execution; typically, every time the user leaves the page that includes the applet.

AppletContext

Name

AppletContext

Description

`AppletContext` is an interface that provides the means to control the browser environment in which the applet is running.

Interface Definition

```
public abstract interface java.applet.AppletContext {
  // Interface Methods
  public abstract Applet getApplet (String name);
  public abstract Enumeration getApplets();
  public abstract AudioClip getAudioClip (URL url);
  public abstract Image getImage (URL url);
  public abstract void showDocument (URL url);
  public abstract void showDocument (URL url, String frame);
  public abstract void showStatus (String message);
}
```

Interface Methods

getApplet

public abstract Applet getApplet (String name)

Parameters

name

Name of applet to locate.

Returns

`Applet` fetched.

Description

Gets a reference to another executing applet.

getApplets

public abstract Enumeration getApplets()

Returns

List of applets executing.

Description

Gets references to all executing applets.

getAudioClip

public abstract AudioClip getAudioClip (URL url)

Parameters

url

Location of an audio file.

Returns

`AudioClip` fetched.

Description

Loads an audio file.

getImage

public abstract Image getImage (URL url)

Parameters

url

Location of an image file.

Returns

Image fetched.

Description

Loads an image file.

showDocument

public abstract void showDocument (URL url)

Parameters

url

New web page to display.

Description

Changes the displayed web page.

public abstract void showDocument (URL url, String frame)

Parameters

url

New web page to display.

frame

Name of the frame in which to display the new page.

Description

Displays a web page in another frame.

showStatus

public abstract void showStatus (String message)

Parameters

message

Message to display.

Description

Displays a message on the status line of the browser.

`Applet`, `AudioClip`, `Enumeration`, `Image`, `Object`, `String`, `URL`

AppletStub

Name

AppletStub

[Graphic: Figure from the text]

Description

`AppletStub` is an interface that provides the means to get information from the run-time browser environment.

Interface Definition

```
public abstract interface java.applet.AppletStub {
  // Interface Methods
  public abstract void appletResize (int width, int height);
  public abstract AppletContext getAppletContext();
  public abstract URL getCodeBase();
  public abstract URL getDocumentBase();
  public abstract String getParameter (String name);
  public abstract boolean isActive();
}
```

Interface Methods

appletResize

public abstract void appletResize (int width, int height)

Parameters

width

Requested new width for applet.

height

Requested new height for applet.

Description

Changes the size of the applet.

getAppletContext

public abstract AppletContext getAppletContext()

Returns

Current `AppletContext` of the applet.

getCodeBase

public abstract URL getCodeBase()

Returns

Complete `URL` for the applet's .*class* file.

getDocumentBase

public abstract URL getDocumentBase()

Returns

Complete `URL` for the applet's *.html* file.

getParameter

public abstract String getParameter (String name)

Parameters

name

Name of a `<PARAM>` tag.

Returns

Value associated with the parameter.

Description

Gets a parameter value from the `<PARAM>` tag(s) of the applet.

isActive

public abstract boolean isActive()

Returns

`true` if the applet is active, `false` otherwise

Description

Returns current state of the applet.

See Also

`AppletContext`, `Object`, `String`, `URL`

AudioClip

Name

AudioClip

Description

`AudioClip` is an interface for playing audio files.

Interface Definition

```
public abstract interface java.applet.AudioClip {
  // Interface Methods
  public abstract void loop();
  public abstract void play();
  public abstract void stop();
}
```

Interface Methods

loop

public abstract void loop()

Description

Plays an audio clip continuously.

play

public abstract void play()

Description

Plays an audio clip once from the beginning.

stop

public abstract void stop()

Description

Stops playing an audio clip.
