O'REILLY

JAVA Reference Library

As of February 9, 1998, the entire online Java Reference Library reflects version 1.4 of the Java Deluxe CD product, which will be available at the end of February. This version includes the updated files for Exploring Java, Second Edition (published October 1997), plus minor revisions to the other files.

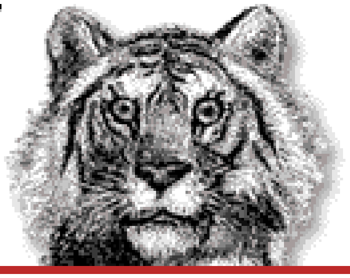
O'REILLY



JAVA IN A NUTSHELL

Java in a Nutshell
By David Flanagan; 1-56592-262-X, 628 pages.
2nd Edition, May 1997

Table of Contents

Part I: Introducing Java

Part I is an introduction to Java and Java programming. If you know how to program in C or C++, these chapters teach you everything you need to know to start programming with Java.

If you are already familiar with Java 1.0 you may want to just skip ahead to Part II, which introduces the new features of Java 1.1.

Part II: Introducing Java 1.1

The two chapters in this part introduce the new features of Java 1.1. Chapter 4 is an overview of the new APIs, and Chapter 5 explains the new language syntax. See Part III for some examples of the new features.

Part III: Programming with the Java 1.1 API

Part III contains examples of programming with the new features of Java 1.1. You can study and learn from the examples, and you should feel free to adapt them for use in your own programs. The examples shown in these chapters may be downloaded from the Internet. See http://www.ora.com/catalog/books/javanut2/. Some of the chapters in this part also contain tables and other reference material for new features in Java 1.1.

Part III of this book is "deprecated." Most of the examples from the first edition of this book do not appear here, and Part III may disappear altogether in the next edition of the book. Unfortunately, as Java continues to grow, there is less and less room for programming examples in this book. However, all of the examples from the first edition are still available on the Web page listed above.

Part IV: Java Language Reference

Part IV contains reference material on the Java language and related topics. Chapter 13 contains a number of useful summary tables of Java syntax. Chapter 14 describes the standard Java system properties and how to use them. Chapter 15 covers the syntax of the HTML tags that allow you to include Java applets in Web pages. Chapter 16 documents the command-line syntax for the Java compiler, interpreter, and other tools shipped with the JDK.

Part V: API Quick Reference

Part V is the real heart of this book: quick-reference material for the Java API. Please read the following section, *How to Use This Quick Reference*, to learn how to get the most out of this material.

Preface

Contents:

This handbook is a desktop quick reference for Java programmers; it covers version 1.1 of the Java language and API. It also includes introductory and tutorial material for C and C++ programmers who want to learn Java. It was written to sit faithfully by your keyboard for easy reference while you program. The wild success of the first edition has shown that this is exactly what Java programmers want, and I've retained the "no fluff" explanations and the to-the-point reference material in this second edition. I hope that new readers will find this book useful, and that old readers will find it even more useful than the last one!

Contents of This Book

This book is divided into five parts:

Part I: Introducing Java

> This first part of the book introduces Java and Java programming, with a particular emphasis on helping C and C++ programmers make the transition to Java. If you are already familiar with Java 1.0 programming, you can skip the three chapters in this part.

Part II: Introducing Java 1.1

This second part of the book contains two chapters that introduce the new features of the Java 1.1 API and the new language features in Java 1.1.

Part III: Programming with the Java 1.1 API

This part contains example programs that demonstrate many of the new features of Java 1.1. You may find that these examples are a good starting point for your own programs, and you should feel free to adapt them for your own use. As explained below, this example section has changed a lot since the first edition of this book.

Part IV: Java Language Reference

This part of the book contains reference material that describes the syntax of the Java language and the tools provided with the Java Development Kit (JDK), among other things.

Part V: API Quick Reference

This part is a quick reference for the Java API; it forms the bulk of the book. Please be sure to read the *How To Use This Quick Reference* material, which appears at the beginning of the part. It explains how to get the most out of the reference material.

Changes Since the First Edition

The many changes in Java 1.1 have resulted in changes to this book. The most significant change since the first edition is a direct result of the large size of Java 1.1: Java has grown too large to fit in a single book, even in quick-reference form. Thus, we need to split *Java in a Nutshell* into multiple volumes. This volume, the "original" *Java in a Nutshell* documents the most commonly used features of Java, and it is an indispensable volume for all Java programmers.

We are planning to publish a separate volume that covers the Java "Enterprise APIs," which include the database connectivity, remote method invocation, and security features of Java 1.1, as well as other forthcoming components, such as CORBA IDL support and the electronic commerce framework. And as new Java APIs are developed and released, we may consider adding new volumes to the *Java in a Nutshell* series.

While I was working on this second edition of *Java in a Nutshell*, it became clear that, even without the enterprise material, the book was becoming too long. (Too long, that is, to remain a useful quick reference, and too long to keep at an affordable price.) Something had to give. The most logical solution was to remove the example programs, which are tutorial in nature, from the book, which is a quick-reference at heart. However, we didn't want to surprise faithful readers by removing the examples altogether, so we decided to pare down the example chapters to the bare minimum. You'll notice that Part III contains examples of using the new Java 1.1 features, such as the JavaBeans API and object serialization, but it does not contain the majority of the old examples from the first edition. For now, Part III contains useful examples for experienced Java programmers who want to learn about the new features of Java 1.1. When Java 1.2 is released, though, we expect that we will have to remove the example section entirely.

Readers familiar with the first edition of *Java in a Nutshell* will notice some other changes as well. The table of contents has been rearranged to accommodate all the new material. We've used a new easier-to-read font for code listings. And we've included cross-reference material (that used to be available only in separate index chapters) directly in the quick-reference section, which should make that section substantially more useful. Be sure to read *How To Use This Quick Reference* at the beginning of the reference section to learn about these and other changes to the quick-reference format.

Related Books

O'Reilly & Associates is developing an entire series of books on Java. This series consists of introductory books, reference manuals, and advanced programming guides.

The following books on Java are currently available or due to be released soon from O'Reilly & Associates:

Exploring Java, by Patrick Niemeyer and Joshua Peck

> A comprehensive tutorial that provides a practical, hands-on approach to learning Java.

Java Language Reference, by Mark Grand

> A complete reference for the Java programming language itself.

Java AWT Reference, by John Zukowski

> A complete reference manual for the AWT-related packages in the core Java API.

Java Fundamental Classes Reference, by Mark Grand and Jonathan Knudsen

> A complete reference manual for the `java.lang`, `java.io`, `java.net`, `java.util` packages, among others, in the core Java API.

Java Virtual Machine, by Jon Meyer and Troy Downing

> A programming guide and reference manual for the Java Virtual Machine.

Java Threads, by Scott Oaks and Henry Wong

An advanced programming guide to working with threads in Java.

Java Network Programming, by Elliote Rusty Harold

A complete guide to writing sophisticated network applications.

Database Programming with JDBC and Java, by George Reese

An advanced tutorial on JDBC that presents a robust model for developing Java database programs.

Developing Java Beans, by Robert Englander

A complete guide to writing components that work with the JavaBeans API.

Look for additional advanced programming guides on such topics as distributed computing and electronic commerce from O'Reilly in the near future.

Conventions Used in This Book

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Conventions Used in This Book

Italic is used for:

- Pathnames, filenames, and program names.
- New terms where they are defined.
- Internet addresses, such as domain names and URLs.

Boldface is used for:

- Particular keys on a computer keyboard.
- Names of user interface buttons and menus.

`Constant Width` is used for:

- Anything that appears literally in a Java program, including keywords, data types, constants, method names, variables, class names, and interface names.
- Command lines and options that should be typed verbatim on the screen.
- All Java code listings.
- HTML documents, tags, and attributes.
- Method parameters, and general placeholders that indicate that an item is replaced by some actual value in your own program.
- Variable expressions in command-line options.

- Java class synopses in the quick-reference section. This very narrow font allows us to fit a lot of information on the page without a lot of distracting line breaks.
- Highlighting class, method, field, and constructor names in the quick-reference section, which makes it easier to scan the class synopses.
- Method parameter names and comments in the quick-reference section.

Request for Comments

Please help us to improve future editions of this book by reporting any errors, inaccuracies, bugs, misleading or confusing statements, and plain old typos that you find anywhere in this book. Email your bug reports and comments to us at: *bookquestions@ora.com*. (Before sending a bug report, however, you may want to check for an errata list at http://www.ora.com/catalog/books/javanut2/ to see if the bug has already been submitted.)

Please also let us know what we can do to make this book more useful to you. We take your comments seriously and will try to incorporate reasonable suggestions into future editions.

Acknowledgments

Many people helped in the creation of this book and I am grateful to them all. I am indebted to literally hundreds of readers of the first edition who wrote in with comments, suggestions, bug reports, and praise. Their many small contributions are scattered throughout the book. Also, my apologies to those who made the many good suggestions that could not be incorporated into this edition.

Paula Ferguson, a friend and colleague, edited both editions of the book. Her careful reading and always-practical suggestions made the book stronger, clearer, and more useful. She is also the one who prodded me when I started to slack off, and got me back on track when I started trying to turn *Java in a Nutshell* into *Java in a Packing Crate*.

Mike Loukides provided high-level direction and guidance for the first edition of the book. Eric Raymond and Troy Downing reviewed that first edition--they helped spot my errors and omissions, and offered good advice on making the book more useful to Java programmers.

For the second edition, John Zukowski reviewed my Java 1.1 AWT quick-reference material, and George Reese reviewed most of the remaining new material. This edition was also blessed with a "dream team" of technical reviewers from Sun. John Rose, the author of the Java Inner Classes Specification, reviewed the chapter on inner classes. Mark Reinhold, author of the character stream classes in `java.io`, reviewed my documentation of these classes. Nakul Saraiya, the designer of the new Java Reflection API, reviewed my documentation of the `java.lang.reflect` package. I am very grateful to these engineers and architects; their efforts have made this a stronger, more accurate book. Any errors that remain are of course my own.

Nicole Gipson Arigo was the production editor for this edition of the book, taking over the job from John Files, who produced the first edition. Nicole coordinated the entire production process, entered changes from edited copy, and handled the meticulous task of fixing line and page breaks in the manuscript. Madeleine Newell provided production assistance. Clairemarie Fisher O'Leary, Jane Ellin, and Sheryl Avruch performed quality control checks. Seth Maislin wrote the index. Chris Reilley created the figures, including all the detailed class hierarchy diagrams in Part V. [1] Edie Freedman designed the cover. Nancy Priest designed the interior format of the book and Lenny Muellner carefully implemented the format in *troff*, with help from Ellen Siever.

The whole production team has my thanks for once again pulling together all the pieces to create the finished product you now hold in your hands.

As always, my thanks and love to Christie.

David Flanagan
April 1997

[1] The hierarchy diagrams are loosely based on similar diagrams for Java 1.0 by Charles L. Perkins.

Request for Comments | BOOK INDEX | Getting Started with Java

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1. Getting Started with Java

Contents:

When it was introduced in late 1995, Java took the Internet by storm. Java 1.1, released in early 1997, nearly doubles the speed of the Java interpreter and includes many important new features. With the addition of APIs to support database access, remote objects, an object component model, internationalization, printing, encryption, digital signatures, and many other technologies, Java is now poised to take the rest of the programming world by storm.

Despite all the hype surrounding Java and the new features of Java 1.1, it's important to remember that at its core, Java is just a programming language, like many others, and its APIs are just class libraries, like those of other languages. What is interesting about Java, and thus the source of much of the hype, is that it has a number of important features that make it ideally suited for programming in the heavily networked, heterogenous world of the late 1990s. The rest of this chapter describes those interesting features of Java and demonstrates some simple Java code. Chapter 4, *What's New in Java 1.1* explores the new features that have been added to version 1.1 of the Java API.

1.1 Why Is Java Interesting?

In one of their early papers about the language, Sun described Java as follows:

> Java: A simple, object-oriented, distributed, interpreted, robust, secure, architecture neutral, portable, high-performance, multithreaded, and dynamic language.

Sun acknowledges that this is quite a string of buzzwords, but the fact is that, for the most part, they aptly describe the language. In order to understand why Java is so interesting, let's take a look at the language features behind the buzzwords.

Object-Oriented

Java is an *object-oriented* programming language. As a programmer, this means that you focus on the data in your application and methods that manipulate that data, rather than thinking strictly in terms of procedures. If you're accustomed to procedure-based programming in C, you may find that you need to change how you design your programs when you use Java. Once you see how powerful this new paradigm is, however, you'll quickly adjust to it.

In an object-oriented system, a *class* is a collection of data and methods that operate on that data. Taken together, the data and methods describe the state and behavior of an *object*. Classes are arranged in a hierarchy, so that a subclass can inherit behavior from its superclass. A class hierarchy always has a root class; this is a class with very general behavior.

Java comes with an extensive set of classes, arranged in *packages*, that you can use in your programs. For example, Java provides classes that create graphical user interface components (the `java.awt` package), classes that handle input and output (the `java.io` package), and classes that support networking functionality (the `java.net` package). The `Object` class (in the `java.lang` package) serves as the root of the Java class hierarchy.

Unlike C++, Java was designed to be object-oriented from the ground up. Most things in Java are objects; the primitive numeric, character, and boolean types are the only exceptions. Strings are represented by objects in Java, as are other important language constructs like threads. A class is the basic unit of compilation and of execution in Java; all Java programs are classes.

While Java is designed to look like C++, you'll find that Java removes many of the complexities of that language. If you are a C++ programmer, you'll want to study the object-oriented constructs in Java carefully. Although the syntax is often similar to C++, the behavior is not nearly so analogous. For a complete description of the object-oriented features of Java, see Chapter 3, *Classes and Objects in Java*.

Interpreted

Java is an an interpreted language: the Java compiler generates byte-codes for the Java Virtual Machine (JVM), rather than native machine code. To actually run a Java program, you use the Java interpreter to execute the compiled byte-codes. Because Java byte-codes are platform-independent, Java programs can run on any platform that the JVM (the interpreter and run-time system) has been ported to.

In an interpreted environment, the standard "link" phase of program development pretty much vanishes. If Java has a link phase at all, it is only the process of loading new classes into the environment, which is an incremental, lightweight process that occurs at run-time. This is in contrast with the slower and more cumbersome compile-link-run cycle of languages like C and C++.

Architecture Neutral and Portable

Because Java programs are compiled to an *architecture neutral* byte-code format, a Java application can run on any system, as long as that system implements the Java Virtual Machine. This is a particularly important for applications distributed over the Internet or other heterogenous networks. But the architecture neutral approach is useful beyond the scope of network-based applications. As an application developer in today's software market, you probably want to develop versions of your application that can run on PCs, Macs, and UNIX workstations. With multiple flavors of UNIX, Windows 95, and Windows NT on the PC, and the new PowerPC Macintosh, it is becoming increasingly difficult to produce software for all of the possible platforms. If you write your application in Java, however, it can run on all platforms.

The fact that Java is interpreted and defines a standard, architecture neutral, byte-code format is one big part of being *portable*. But Java goes even further, by making sure that there are no "implementation-dependent" aspects of the language specification. For example, Java explicitly specifies the size of each of the primitive data types, as well as its arithmetic behavior. This differs from C, for example, in which an `int` type can be 16, 32, or 64 bits long depending on the platform.

While it is technically possible to write non-portable programs in Java, it is relatively easy to avoid the few platform-dependencies that are exposed by the Java API and write truly portable or "pure" Java programs. Sun's new "100% Pure Java" program helps developers ensure (and certify) that their code is portable. Programmers need only to make simple efforts to avoid non-portable pitfalls in order to live up to Sun's trademarked motto "Write Once, Run Anywhere."

Dynamic and Distributed

Java is a *dynamic* language. Any Java class can be loaded into a running Java interpreter at any time. These dynamically loaded classes can then be dynamically instantiated. Native code libraries can also be dynamically loaded. Classes in Java are represented by the `Class` class; you can dynamically obtain information about a class at run-time. This is especially true in Java 1.1, with the addition of the Reflection API, which is introduced in Chapter 12, *Reflection*.

Java is also called a *distributed* language. This means, simply, that it provides a lot of high-level support for networking. For example, the `URL` class and OArelated classes in the `java.net` package make it almost as easy to read a remote file or resource as it is to read a local file. Similarly, in Java 1.1, the Remote Method Invocation (RMI) API allows a Java program to invoke methods of remote Java objects, as if they were local objects. (Java also provides traditional lower-level networking support, including datagrams and stream-based connections through sockets.)

The distributed nature of Java really shines when combined with its dynamic class loading capabilities. Together, these features make it possible for a Java interpreter to download and run code from across the

Internet. (As we'll see below, Java implements strong security measures to be sure that this can be done safely.) This is what happens when a Web browser downloads and runs a Java applet, for example. Scenarios can be more complicated than this, however. Imagine a multi-media word processor written in Java. When this program is asked to display some type of data that it has never encountered before, it might dynamically download a class from the network that can parse the data, and then dynamically download another class (probably a Java "bean") that can display the data within a compound document. A program like this uses distributed resources on the network to dynamically grow and adapt to the needs of its user.

Simple

Java is a *simple* language. The Java designers were trying to create a language that a programmer could learn quickly, so the number of language constructs has been kept relatively small. Another design goal was to make the language look familiar to a majority of programmers, for ease of migration. If you are a C or C++ programmer, you'll find that Java uses many of the same language constructs as C and C++.

In order to keep the language both small and familiar, the Java designers removed a number of features available in C and C++. These features are mostly ones that led to poor programming practices or were rarely used. For example, Java does not support the `goto` statement; instead, it provides labelled `break` and `continue` statements and exception handling. Java does not use header files and it eliminates the C preprocessor. Because Java is object-oriented, C constructs like `struct` and `union` have been removed. Java also eliminates the operator overloading and multiple inheritance features of C++.

Perhaps the most important simplification, however, is that Java does not use pointers. Pointers are one of the most bug-prone aspects of C and C++ programming. Since Java does not have structures, and arrays and strings are objects, there's no need for pointers. Java automatically handles the referencing and dereferencing of objects for you. Java also implements automatic garbage collection, so you don't have to worry about memory management issues. All of this frees you from having to worry about dangling pointers, invalid pointer references, and memory leaks, so you can spend your time developing the functionality of your programs.

If it sounds like Java has gutted C and C++, leaving only a shell of a programming language, hold off on that judgment for a bit. As we'll see in Chapter 2, *How Java Differs from C*, Java is actually a full-featured and very elegant language.

Robust

Java has been designed for writing highly reliable or *robust* software. Java certainly doesn't eliminate the need for software quality assurance; it's still quite possible to write buggy software in Java. However, Java does eliminate certain types of programming errors, which makes it considerably easier to write reliable software.

Java is a strongly typed language, which allows for extensive compile-time checking for potential type-mismatch problems. Java is more strongly typed than C++, which inherits a number of compile-time laxities from C, especially in the area of function declarations. Java requires explicit method declarations; it does not support C-style implicit declarations. These stringent requirements ensure that the compiler can catch method invocation errors, which leads to more reliable programs.

One of the things that makes Java simple is its lack of pointers and pointer arithmetic. This feature also increases the robustness of Java programs by abolishing an entire class of pointer-related bugs. Similarly, all accesses to arrays and strings are checked at run-time to ensure that they are in bounds, eliminating the possibility of overwriting memory and corrupting data. Casts of objects from one type to another are also checked at run-time to ensure that they are legal. Finally, and very importantly, Java's automatic garbage collection prevents memory leaks and other pernicious bugs related to memory allocation and deallocation.

Exception handling is another feature in Java that makes for more robust programs. An *exception* is a signal that some sort of exceptional condition, such as a "file not found" error, has occurred. Using the `try`/`catch`/`finally` statement, you can group all of your error handling code in one place, which greatly simplifies the task of error handling and recovery.

Secure

One of the most highly touted aspects of Java is that it's a *secure* language. This is especially important because of the distributed nature of Java. Without an assurance of security, you certainly wouldn't want to download code from a random site on the Internet and let it run on your computer. Yet this is exactly what people do with Java applets every day. Java was designed with security in mind, and provides several layers of security controls that protect against malicious code, and allow users to comfortably run untrusted programs such as applets.

At the lowest level, security goes hand-in-hand with robustness. As we've already seen, Java programs cannot forge pointers to memory, or overflow arrays, or read memory outside of the bounds of an array or string. These features are one of Java's main defenses against malicious code. By totally disallowing any direct access to memory, an entire huge, messy class of security attacks is ruled out.

The second line of defense against malicious code is the byte-code verification process that the Java interpreter performs on any untrusted code it loads. These verification steps ensure that the code is well-formed--that it doesn't overflow or underflow the stack or contain illegal byte-codes, for example. If the byte-code verification step was skipped, inadvertently corrupted or maliciously crafted byte-codes might be able to take advantage of implementation weaknesses in a Java interpreter.

Another layer of security protection is commonly referred to as the "sandbox model": untrusted code is placed in a "sandbox," where it can play safely, without doing any damage to the "real world," or full Java environment. When an applet, or other untrusted code, is running in the sandbox, there are a number of restrictions on what it can do. The most obvious of these restrictions is that it has no access whatsoever to the local file system. There are a number of other restrictions in the sandbox as well. These restrictions are enforced by a `SecurityManager` class. The model works because all of the core Java classes that perform sensitive operations, such as filesystem access, first ask permission of the currently installed `SecurityManager`. If the call is being made, directly or indirectly, by untrusted code, the security manager throws an exception, and the operation is not permitted. See Chapter 6, *Applets* for a complete list of the restrictions placed on applets running in the sandbox.

Finally, in Java 1.1, there is another possible solution to the problem of security. By attaching a digital signature to Java code, the origin of that code can be established in a cryptographically secure and unforgeable way. If you have specified that you trust a person or organization, then code that bears the digital signature of that trusted entity is trusted, even when loaded over the network, and may be run without the restrictions of the sandbox model.

Of course, security isn't a black-and-white thing. Just as a program can never be guaranteed to be 100% bug-free, no language or environment can be guaranteed 100% secure. With that said, however, Java does seem to offer a practical level of security for most applications. It anticipates and defends against most of the techniques that have historically been used to trick software into misbehaving, and it has been intensely scrutinized by security experts and hackers alike. Some security holes were found in early versions of Java, but these flaws were fixed almost as soon as they were found, and it seems reasonable to expect that any future holes will be fixed just as quickly.

High-Performance

Java is an interpreted language, so it is never going to be as fast as a compiled language like C. Java 1.0 was said to be about 20 times slower than C. Java 1.1 is nearly twice as fast as Java 1.0, however, so it might be reasonable to say that compiled C code runs ten times as fast as interpreted Java byte-codes. But before you throw up your arms in disgust, be aware that this speed is more than adequate to run interactive, GUI and network-based applications, where the application is often idle, waiting for the user to do something, or waiting for data from the network. Furthermore, the speed-critical sections of the Java run-time environment, that do things like string concatenation and comparison, are implemented with efficient native code.

As a further performance boost, many Java interpreters now include "just in time" compilers that can translate Java byte-codes into machine code for a particular CPU at run-time. The Java byte-code format was designed with these "just in time" compilers in mind, so the process of generating machine code is fairly efficient and it produces reasonably good code. In fact, Sun claims that the performance of byte-codes converted to machine code is nearly as good as native C or C++. If you are willing to sacrifice code portability to gain speed, you can also write portions of your program in C or C++ and use Java native methods to interface with this native code.

When you are considering performance, it's important to remember where Java falls in the spectrum of available programming languages. At one end of the spectrum, there are high-level, fully-interpreted scripting languages such as Tcl and the UNIX shells. These languages are great for prototyping and they are highly portable, but they are also very slow. At the other end of the spectrum, you have low-level compiled languages like C and C++. These languages offer high performance, but they suffer in terms of reliability and portability. Java falls in the middle of the spectrum. The performance of Java's interpreted byte-codes is much better than the high-level scripting languages (even Perl), but it still offers the simplicity and portability of those languages.

Multithreaded

In a GUI-based network application such as a Web browser, it's easy to imagine multiple things going on at the same time. A user could be listening to an audio clip while she is scrolling a page, and in the background the browser is downloading an image. Java is a *multithreaded* language; it provides support for multiple threads of execution (sometimes called lightweight processes) that can handle different tasks. An important benefit of multithreading is that it improves the interactive performance of graphical applications for the user.

If you have tried working with threads in C or C++, you know that it can be quite difficult. Java makes programming with threads much easier, by providing built-in language support for threads. The `java.lang` package provides a `Thread` class that supports methods to start and stop threads and set thread priorities, among other things. The Java language syntax also supports threads directly with the `synchronized` keyword. This keyword makes it extremely easy to mark sections of code or entire methods that should only be run by a single thread at a time.

While threads are "wizard-level" stuff in C and C++, their use is commonplace in Java. Because Java makes threads so easy to use, the Java class libraries require their use in a number of places. For example, any applet that performs animation does so with a thread. Similarly, Java does not support asynchronous, non-blocking I/O with notification through signals or interrupts--you must instead create a thread that blocks on every I/O channel you are interested in.

1.2 A Simple Example

By now you should have a pretty good idea of why Java is such an interesting language. So we'll stop talking about abstract concepts and look at some concrete Java code. Before we look at an interesting applet, however, we are going to pay tribute to that ubiquitous favorite, "Hello World."

Hello World

Example 1.1 shows the simplest possible Java program: "Hello World."

Example 1.1: Hello World

```
public class HelloWorld {
    public static void main(String[] args) {
        System.out.println("Hello World!");
    }
}
```

This program, like every Java program, consists of a public class definition. The class contains a method named `main()`, which is the main entry point for all Java applications--that is, the point at which the interpreter starts executing the program. The body of `main()` consists of only a single line, which prints out the message:

```
Hello World!
```

This program must be saved in a file with the same name as the public class plus a *.java* extension. To compile it, you would use *javac*: [1]

> [1] Assuming you're using Sun's Java Development Kit (JDK). If you're using a Java development environment from some other vendor, follow your vendor's instructions.

```
% javac HelloWorld.java
```

This command produces the *HelloWorld.class* file in the current directory. To run the program, you use the Java interpreter, *java*:

```
% java HelloWorld
```

Note that when you invoke the interpreter, you do not supply the *.class* extension for the file you want to run.

A Scribble Applet

Example 1.2 shows a less trivial Java program. This program is an applet, rather than a standalone Java application like the "Hello World" program above. Because this example is an applet, it has a different structure than a standalone application; notably, it does not have a `main()` method. Like all applets, this one runs inside an applet viewer or Web browser, and lets the user draw (or scribble) with the mouse, as illustrated in Figure 1.1.

Figure 1.1: A Java applet running in a Web browser

[Graphic: Figure 1-1]

One of the major changes between Java 1.0 and Java 1.1 is in the way that Java programs are notified of "events", such as mouse motion. Example 1.2 uses the Java 1.0 event model rather than the preferred Java 1.1 event model. This is because the current generation of Web browsers (as this is written) still use Java 1.0. In order for this applet to be widely usable, it is coded with the old, "deprecated" event model. [2]

[2] If you are interested in updating this program to use Java 1.1, see Chapter 7, *Events* for

information on how to use the new 1.1 event model. In addition, you need to change the call to `bounds()` in the `action()` method to a call to `getBounds()`, if you want to avoid a compilation warning about using a deprecated method.

Example 1.2: A Java Applet

```
import java.applet.*;
import java.awt.*;
public class Scribble extends Applet {
  private int last_x, last_y;                // Store the last mouse position.
  private Color current_color = Color.black; // Store the current color.
  private Button clear_button;               // The clear button.
  private Choice color_choices;              // The color dropdown list.
  // This method is called to initialize the applet.
  // Applets don't have a main() method.
  public void init() {
    // Set the background color.
    this.setBackground(Color.white);
    // Create a button and add it to the applet.  Set the button's colors.
    clear_button = new Button("Clear");
    clear_button.setForeground(Color.black);
    clear_button.setBackground(Color.lightGray);
    this.add(clear_button);
    // Create a menu of colors and add it to the applet.
    // Also set the menu's colors and add a label.
    color_choices = new Choice();
    color_choices.addItem("black");
    color_choices.addItem("red");
    color_choices.addItem("yellow");
    color_choices.addItem("green");
    color_choices.setForeground(Color.black);
    color_choices.setBackground(Color.lightGray);
    this.add(new Label("Color: "));
    this.add(color_choices);
  }
  // This method is called when the user clicks the mouse to start a scribble.
  public boolean mouseDown(Event e, int x, int y)
  {
    last_x = x; last_y = y;
    return true;
  }
  // This method is called when the user drags the mouse.
  public boolean mouseDrag(Event e, int x, int y)
  {
    Graphics g = this.getGraphics();
    g.setColor(current_color);
    g.drawLine(last_x, last_y, x, y);
    last_x = x;
    last_y = y;
    return true;
  }
  // This method is called when the user clicks the button or chooses a color.
  public boolean action(Event event, Object arg) {
    // If the Clear button was clicked on, handle it.
    if (event.target == clear_button) {
      Graphics g = this.getGraphics();
      Rectangle r = this.bounds();
      g.setColor(this.getBackground());
      g.fillRect(r.x, r.y, r.width, r.height);
      return true;
    }
    // Otherwise if a color was chosen, handle that.
    else if (event.target == color_choices) {
      if (arg.equals("black")) current_color = Color.black;
      else if (arg.equals("red")) current_color = Color.red;
      else if (arg.equals("yellow")) current_color = Color.yellow;
      else if (arg.equals("green")) current_color = Color.green;
      return true;
    }
    // Otherwise, let the superclass handle it.
    else return super.action(event, arg);
  }
}
```

Don't expect to be able to understand the entire applet at this point. It is here to give you the flavor of the language. In Chapter 2, *How Java Differs from C* and Chapter 3, *Classes and Objects in Java* we'll explain the language constructs you need to understand the example. Then, in Chapter 6, *Applets* and Chapter 7, *Events* we'll explain the applet and event-handling concepts used in this example.

The first thing you should notice when browsing through the code is that it looks reassuringly like C and C++. The `if` and `return` statements are familiar. Assignment of values to variables uses the expected syntax. Procedures (called "methods" in Java) are recognizable as such.

The second thing to notice is the object-oriented nature of the code. As you can see at the top of the example, the program consists of the definition of a public class. The name of the class we are defining is `Scribble`; it is an extension, or subclass, of the `Applet` class. (The full name of the `Applet` class is `java.applet.Applet`. One of the `import` statements at the top of the example allows us to refer to `Applet` by this shorter name.)

Classes are said to "encapsulate" data and methods. As you can see, our `Scribble` class contains both variable and method declarations. The methods are actually defined inside of the class. The methods of a class are often invoked through an instance of the class. Thus you see lines like:

```
color_choices.addItem("black");
```

This line of code invokes the `addItem()` method of the object referred to by the `color_choices` variable. If you're a C programmer, but not a C++ programmer, this syntax may take a little getting used to. We'll see lots more of it in Chapters 2 and 3. Note that `this` is a keyword, not a variable name. It refers to the current object; in this example, it refers to the `Scribble` object.

The `init()` method of an applet is called by the Web browser or applet viewer when it is starting the applet up. In our example, this method creates a **Clear** button and a menu of color choices, and then adds these GUI components to the applet.

The `mouseDown()` and `mouseDrag()` methods are called when the user clicks and drags the mouse. These are the methods that are responsible for drawing lines as the user scribbles. The `action()` method is invoked when the user clicks on the **Clear** button or selects a color from the menu of colors. The body of the method determines which of these two "events" has occurred and handles the event appropriately. Recall that these methods are part of the Java 1.0 event model. Chapter 7, *Events* explains this model and also explains the Java 1.1 event model that replaces it.

To compile this example, you'd save it in a file named *Scribble.java* and use *javac*:

```
% javac Scribble.java
```

This example is an applet, not a standalone program like our "Hello World" example. It does not have a `main()` method, and therefore cannot be run directly by the Java interpreter. Instead, we must reference it in an HTML file and run the applet in an applet viewer or Web browser. It is the applet viewer or Web browser that loads the applet class into its running Java interpreter and invokes the various methods of the applet at the appropriate times. To include the applet in a Web page, we'd use an HTML fragment like the following:

```
<APPLET code="Scribble.class" width=500 height=300>
</APPLET>
```

Example 1.3 shows a complete HTML file that we might use to display the applet. Chapter 15, *Java-Related HTML Tags* explains the HTML syntax for applets in full detail.

Example 1.3: An HTML File that Contains an Applet

```
<HTML>
<HEAD>
<TITLE>The Scribble Applet</TITLE>
</HEAD>
<BODY>
Please scribble away in the applet below.
<P>
<APPLET code="Scribble.class" width=500 height=300>
Your browser does not support Java, or Java is not enabled. Sorry!
</APPLET>
</BODY>
</HTML>
```

Suppose we save this example HTML file as *Scribble.html*. Then to run this applet, you could use Sun's *appletviewer* command like this:

```
% appletviewer Scribble.html
```

You could also display the applet by viewing the *Scribble.html* file in your Web browser, if your browser supports Java applets. Figure 1.1 showed the `Scribble` applet running in Netscape Navigator.

How Java Differs from C

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2. How Java Differs from C

Contents:

Java is a lot like C, which makes it relatively easy for C programmers to learn. But there are a number of important differences between C and Java, such as the lack of a preprocessor, the use of 16-bit Unicode characters, and the exception handling mechanism. This chapter explains those differences, so that programmers who already know C can start programming in Java right away!

This chapter also points out similarities and differences between Java and C++. C++ programmers should beware, though: While Java borrows a lot of terminology and even syntax from C++, the analogies between Java and C++ are not nearly as strong as those between Java and C. C++ programmers should be careful not to be lulled into a false sense of familiarity with Java just because the languages share a number of keywords.

One of the main areas in which Java differs from C, of course, is that Java is an object-oriented language and has mechanisms to define classes and create objects that are instances of those classes. Java's object-oriented features are a topic for a chapter of their own, and they'll be explained in detail in Chapter 3, *Classes and Objects in Java*.

2.1 Program Structure and Environment

A program in Java consists of one or more class definitions, each of which has been compiled into its own *.class* file of Java Virtual Machine object code. One of these classes must define a method `main()`, which is where the program starts running. [1]

> [1] *Method* is an object-oriented term for a procedure or function. You'll see it used throughout this book.

To invoke a Java program, you run the Java interpreter, *java*, and specify the name of the class that contains the `main()` method. You should omit the *.class* extension when doing this. Note that a Java applet is not an application--it is a Java class that is loaded and run by an already running Java application such as a Web browser or applet viewer.

The `main()` method that the Java interpreter invokes to start a Java program must have the following prototype:

```
public static void main(String args[])
```

The Java interpreter runs until the `main()` method returns, or until the interpreter reaches the end of `main()`. If no threads have been created by the program, the interpreter exits. Otherwise, the interpreter continues running until the last thread terminates.

Command-Line Arguments

The single argument to `main()` is an array of strings, conventionally named `args` or `argv`. The length of this array (which would be passed as the `argc` argument in C) is available as `argv.length`, as is the case with any Java array. The elements of the array are the arguments, if any, that appeared on the interpreter command line after the class name. Note that the first element of the array is *not* the name of the class, as a C programmer might expect it to be. Example 2.1 shows how you could write a UNIX-style *echo* command (a program that simply prints out its arguments) in Java.

Example 2.1: An Echo Program in Java

```
public class echo {
    public static void main(String argv[]) {
        for(int i=0; i < argv.length; i++)
```

```
            System.out.print(argv[i] + " ");
        System.out.print("\n");
        System.exit(0);
    }
}
```

Program Exit Value

Note that `main()` must be declared to return `void`. Thus you cannot return a value from your Java program with a `return` statement in `main()`. If you need to return a value, call `System.exit()` with the desired integer value, as we've done in Example 2.1. Note that the handling and interpretation of this exit value are, of course, operating-system dependent. `System.exit()` causes the Java interpreter to exit immediately, whether or not other threads are running.

Environment

The Java API does not allow a Java program to read operating system environment variables because they are platform-dependent. However, Java defines a similar, platform-independent mechanism, known as the system properties list, for associating textual values with names.

A Java program can look up the value of a named property with the `System.getProperty()` method:

```
String homedir = System.getProperty("user.home");
String debug = System.getProperty("myapp.debug");
```

The Java interpreter automatically defines a number of standard system properties when it starts up. You can insert additional property definitions into the list by specifying the `-D` option to the interpreter:

```
% java -Dmyapp.debug=true myapp
```

See Chapter 14, *System Properties* for more information on system properties.

The Name Space: Packages, Classes, and Members

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.2 The Name Space: Packages, Classes, and Members

As a language that is designed to support dynamic loading of modules over the entire Internet, Java takes special care to avoid name space conflicts. Global variables are simply not part of the language. Neither are "global" functions or procedures, for that matter.

No Global Variables

In Java, every field and method is declared within a class and forms part of that class. Also, every class is part of a *package* (in Java 1.1, classes can also be declared within other classes). The fields and methods (and classes in 1.1) of a class are known as the *members* of a class. Every Java field or method may be referred to by its fully qualified name, which consists of the package name, the class name, and the member name (i.e., the field or the method name), all separated by periods. Package names are themselves usually composed of multiple period-separated components. Thus, the fully qualified name for a method might be:

```
david.games.tetris.SoundEffects.play()
```

Java Filenames and Directory Structure

A file of Java source code has the extension *.java*. It consists of an optional `package` statement followed by any number of `import` statements followed by one or more class or interface definitions. (The `package` and `import` statements will be introduced shortly.) If more than one class or interface is defined in a Java source file, only one of them may be declared `public` (i.e., made available outside of the package), and the source file must have the same name as that public class or interface, plus the *.java* extension.

Each class or interface definition in a *.java* file is compiled into a separate file. These files of compiled Java byte-codes are known as "class files," and must have the same name as the class or interface they define, with the extension *.class* appended. For example, the class `SoundEffects` would be stored in the file *SoundEffects.class*.

Class files are stored in a directory that has the same components as the package name. If the fully qualified name of a class is `david.games.tetris.SoundEffects`, for example, the full path of the class file must be *david/games/tetris/SoundEffects.class*. This filename is interpreted relative to the Java "class path," described below. [2]

> [2] We'll use UNIX-style directory specifications in this book. If you are a Windows programmer, simply change all the forward slashes in filenames to backward slashes. Similarly, in path specifications, change colons to semicolons.

Packages of the Java API

The Java 1.1 API consists of the classes and interfaces defined in the twenty-three packages listed in Table 2.1.

Table 2.1: The Packages of the Java API

Package name	**Contents**
java.applet	Applet classes
java.awt	Graphics, window, and GUI classes
java.awt.datatransfer	Data transfer (e.g., cut-and-paste) classes
java.awt.event	Event processing classes and interfaces
java.awt.image	Image processing classes
java.awt.peer	GUI interfaces for platform independence
java.beans	JavaBeans component model API
java.io	Various types of input and output classes
java.lang	Core language classes
java.lang.reflect	Reflection API classes
java.math	Arbitrary precision arithmetic
java.net	Networking classes
java.rmi	Remote Method Invocation classes
java.rmi.dgc	RMI-related classes
java.rmi.registry	RMI-related classes
java.rmi.server	RMI-related classes

java.security	Security classes
java.security.acl	Security-related classes
java.security.interfaces	Security-related classes
java.sql	JDBC SQL API for database access
java.text	Internationalization classes
java.util	Various useful data types
java.util.zip	Compression and decompression classes

The Java Class Path

The Java interpreter knows where its standard system classes are installed, and loads them from that location as needed. By default, it looks up user-defined classes in or relative to the current directory. You can set the `CLASSPATH` environment variable to tell the interpreter where to look for user-defined classes. The interpreter always appends the location of its system classes to the end of the path specified by this environment variable. The entries in a class path specification should be directories or ZIP files that contain the classes. The directories in a class path specification should be colon-separated on a UNIX system, and semicolon-separated on a Windows system. For example, on a UNIX system, you might use:

```
setenv CLASSPATH .:/home/david/classes:/usr/local/javatools/classes.zip
```

On a Windows system you could use:

```
setenv CLASSPATH .;C:\david\classes;D:\local\javatools\classes.zip
```

This tells Java to search in and beneath the specified directories for non-system classes. Note that the current directory (`.`) is included in these paths.

You can also specify a class path to the Java interpreter with the `-classpath` command-line argument. Setting this option overides any path specified in the `CLASSPATH` environment variable. Note that the interpreter does not append the location of the system classes to the end of this path, so you must be sure to specify those system classes yourself. Finally, note that the Java compiler also recognizes and honors class paths specified with the `CLASSPATH` environment variable and the `-classpath` command-line argument.

Globally Unique Package Names

The Java designers have proposed an Internet-wide unique package naming scheme that is based on the Internet domain name of the organization at which the package is developed.

Figure 2.1 shows some fully qualified names, which include package, class, and field components.

Figure 2.1: Fully qualified names in Java

[Graphic: Figure 2-1]

Some organizations are following this naming scheme, and producing classes with names like `com.sybase.jdbc.SybDriver`. Another trend that is developing, however, is for companies to simply use their company name as the first component of their package names, and produce classes like `netscape.javascript.JSObject`.

The top-level package names `java` and `sun` are reserved for use by Sun, of course. Developers should not define new classes within these packages.

The package Statement

The `package` statement must appear as the first statement (i.e., the first text other than comments and whitespace) in a file of Java source code, if it appears at all. It specifies which package the code in the file is part of. Java code that is part of a particular package has access to all classes (`public` and non-`public`) in the package, and to all non-`private` methods and fields in all those classes. When Java code is part of a named package, the compiled class file must be placed at the appropriate position in the `CLASSPATH` directory hierarchy before it can be accessed by the Java interpreter or other utilities.

If the `package` statement is omitted from a file, the code in that file is part of an unnamed default package. This is convenient for small test programs, or during development, because it means that the code can be interpreted from the current directory.

The import Statement

The `import` statement makes Java classes available to the current class under an abbreviated name. Public Java classes are always available by their fully qualified names, assuming that the appropriate class file can be found (and is readable) relative to the `CLASSPATH` environment variable. `import` doesn't actually make the class available or "read it in"; it simply saves you typing and makes your code more legible.

Any number of `import` statements may appear in a Java program. They must appear, however, after the optional `package` statement at the top of the file, and before the first class or interface definition in the file.

There are two forms of the `import` statement:

```
import package.class ;
import package.* ;
```

The first form allows the specified class in the specified package to be known by its class name alone. Thus, this `import` statement allows you to type `Hashtable` instead of `java.util.Hashtable`:

```
import java.util.Hashtable;
```

The second form of the `import` statement makes all classes in a package available by their class name. For example, the following `import` statement is implicit (you need not specify it yourself) in every Java program:

```
import java.lang.*;
```

It makes the core classes of the language available by their unqualified class names. If two packages imported with this form of the statement contain classes with the same name, it is an error to use either of those ambiguous classes without using its fully qualified name.

Access to Packages, Classes, and Class Members

Java has the following rules about access to packages, classes, and class members. (Class members are the variables, methods, and, in Java 1.1, nested classes defined within a class). Note that the `public`, `private`, and `protected` keywords used in these rules will be explained in more detail in the next chapter.

- A package is accessible if the appropriate files and directories are accessible (e.g., if local files have appropriate read permissions, or if they can be downloaded via the network).

- All classes and interfaces in a package are accessible to all other classes and interfaces in the same package. It is not possible to define classes in Java that are visible only within a single file of source code.
- A class declared `public` in one package is accessible within another package, assuming that the package itself is accessible. A non-`public` class is not accessible outside of its package.
- Members of a class are accessible from a different class within the same package, as long as they are not declared `private`. `private` members are accessible only within their own class.
- Af member of a class `A` is accessible from a class `B` in a different package if `A` is `public` and the member is `public`, or if `A` is `public`, the member is `protected`, and `B` is a subclass of `A`.
- All members of a class are always accessible from within that class.

Local Variables

The name space rules we've been describing apply to packages, classes, and the members within classes. Java also supports local variables, declared within method definitions. These local variables behave just like local variables in C--they do not have globally unique hierarchical names, nor do they have access modifiers like `public` and `private`. Local variables are quite different from class fields.

Comments

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.3 Comments

Java supports three types of comments:

- A standard C-style comment that begins with `/*` and continues until the next `*/`. As in most implementations of C, this style of comment cannot be nested.
- A C++-style comment that begins with `//` and continues until the end of the line.
- A special "doc comment" that begins with `/**` and continues until the next `*/`. These comments may not be nested. Doc comments are specially processed by the *javadoc* program to produce simple online documentation from the Java source code. See Chapter 13, *Java Syntax* for more information on the doc comment syntax, and Chapter 16, *JDK Tools* for more information on the *javadoc* program.

Since C-style comments do not nest, it is a good idea to use C++-style `//` comments for most of your short comments within method bodies. This allows you to use `/* */` comments to comment out large blocks of code when you need to do that during development. This is especially important because, as you will see, Java does not support a preprocessor that allows you to use `#if 0` to comment out a block.

2.4 No Preprocessor

Java does not include any kind of preprocessor like the C *cpp* preprocessor. It may seem hard to imagine programming without `#define`, `#include`, and `#ifdef`, but in fact, Java really does not require these constructs.

Defining Constants

Any variable declared `final` in Java is a constant--its value must be specified with an initializer when it is declared, and that value may never be changed. The Java equivalent of a C `#define`'ed constant is a `static final` variable declared within a class definition. If the compiler can compute the value of such a `static final` variable at compile-time, it uses the computed value to pre-compute other compile-time constants that refer to the value. The variable `java.lang.Math.PI` is an example of such a constant. It is declared like this:

```
public final class Math {
    ...
    public static final double PI = 3.14159.....;
    ...
}
```

Note two things about this example. First, the C convention of using CAPITAL letters for constants is also a Java convention. Second, note the advantage Java constants have over C preprocessor constants: Java constants have globally unique hierarchic names, while constants defined with the C preprocessor always run the risk of a name collision. Also, Java constants are strongly typed and allow better type-checking by the compiler than C preprocessor constants.

Defining Macros

The C preprocessor allows you to define macros--a construct that looks like a function invocation but that is actually replaced directly with C code, saving the overhead of a function call. Java has no equivalent to this sort of macro, but compiler technology has advanced to a point where macros are rarely necessary any more. A good Java compiler should automatically be able to "inline" short Java methods where appropriate.

Including Files

Java does not have a `#include` directive, but it does not need one. Java defines a mapping of fully qualified class names (like `java.lang.Math`) to a directory and file structure (like *java/lang/Math.class*). This means that when the Java compiler needs to read in a specified class file, it knows exactly where to find it and does not need a special directive to tell it where to look.

Furthermore, Java does not make the distinction between *declaring* a variable or procedure and *defining* it that C does. This means that there is no need for C-style header files or function prototypes--a single Java object file serves as the interface definition and implementation for a class.

Java does have an `import` statement, which is superficially similar to the C preprocessor `#include` directive. What this statement does, however, is tell the compiler that the current file is using the specified classes, or classes from the specified package, and allows us to refer to those classes with abbreviated names. For example, since the compiler implicitly `import`s all the classes of the `java.lang` package, we can refer to the constant `java.lang.Math.PI` by the shorter name `Math.PI`.

Conditional Compilation

Java does not have any form of the C `#ifdef` or `#if` directives to perform conditional compilation. In theory, conditional compilation is not necessary in Java since it is a platform-independent language, and thus there are no platform dependencies that require the technique. In practice, however, conditional compilation is still often useful in Java--to provide slightly different user interfaces on different platforms, for example, or to support optional inclusion of debugging code in programs.

While Java does not define explicit constructs for conditional compilation, a good Java compiler (such as Sun's *javac*) performs conditional compilation implicitly--that is, it does not compile code if it can prove that the code will never be executed. Generally, this means that code within an `if` statement testing an expression that is always `false` is not included. Thus, placing code within an `if (false)` block is equivalent to surrounding it with `#if 0` and `#endif` in C.

Conditional compilation also works with constants, which, as we saw above, are `static final` variables. A class might define the constant like this:

```
private static final boolean DEBUG = false;
```

With such a constant defined, any code within an `if (DEBUG)` block is not actually compiled into the class file. To activate debugging for the class, it is only necessary to change the value of the constant to `true` and recompile the class.

Unicode and Character Escapes

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.5 Unicode and Character Escapes

Java characters, strings, and identifiers (e.g., variable, method, and class names) are composed of 16-bit Unicode characters. This makes Java programs relatively easy to internationalize for non-English-speaking users. It also makes the language easier to work with for non-English-speaking programmers--a Thai programmer could use the Thai alphabet for class and method names in her Java code.

If two-byte characters seem confusing or intimidating to you, fear not. The Unicode character set is compatible with ASCII and the first 256 characters (0x0000 to 0x00FF) are identical to the ISO8859-1 (Latin-1) characters 0x00 to 0xFF. Furthermore, the Java language design and the Java `String` API make the character representation entirely transparent to you. If you are using only Latin-1 characters, there is no way that you can even distinguish a Java 16-bit character from the 8-bit characters you are familiar with. For more information on Unicode, see Chapter 11, *Internationalization*.

Most platforms cannot display all 38,885 currently defined Unicode characters, so Java programs may be written (and Java output may appear) with special Unicode escape sequences. Anywhere within a Java program (not only within character and string literals), a Unicode character may be represented with the Unicode escape sequence `\u`*`xxxx`*, where *`xxxx`* is a sequence of four hexadecimal digits.

Java also supports all of the standard C character escape sequences, such as `\n`, `\t`, and `\`*`xxx`* (where `\`*`xxx`*is three octal digits). Note, however, that Java does not support line continuation with `\` at the end of a line. Long strings must either be specified on a single long line, or they must be created from shorter strings using the string concatenation (`+`) operator. (Note that the concatenation of two constant strings is done at compile-time rather than at run-time, so using the `+` operator in this way is not inefficient.)

There are two important differences between Unicode escapes and C-style escape characters. First, as we've noted, Unicode escapes can appear anywhere within a Java program, while the other escape characters can appear only in character and string constants.

The second, and more subtle, difference is that Unicode `\u` escape sequences are processed before the other escape characters, and thus the two types of escape sequences can have very different semantics. A

Unicode escape is simply an alternative way to represent a character that may not be displayable on certain (non-Unicode) systems. Some of the character escapes, however, represent special characters in a way that prevents the usual interpretation of those characters by the compiler. The following examples make this difference clear. Note that `\u0022` and `\u005c` are the Unicode escapes for the double-quote character and the backslash character.

```
// \" represents a " character, and prevents the normal
// interpretation of that character by the compiler.
// This is a string consisting of a double-quote character.
String quote = "\"";
// We can't represent the same string with a single Unicode escape.
// \u0022 has exactly the same meaning to the compiler as ".
// The string below turns into """: an empty string followed
// by an unterminated string, which yields a compilation error.
String quote = "\u0022";
// Here we represent both characters of an \" escape as
// Unicode escapes. This turns into "\"", and is the same
// string as in our first example.
String quote = "\u005c\u0022";
```

2.6 Primitive Data Types

Java adds `byte` and `boolean` primitive types to the standard set of C types. In addition, it strictly defines the size and signedness of its types. In C, an `int` may be 16, 32, or 64 bits, and a `char` may act signed or unsigned depending on the platform. Not so in Java. In C, an uninitialized local variable usually has garbage as its value. In Java, all variables have guaranteed default values, though the compiler may warn you in places where you rely, accidentally or not, on these default values. Table 2.2 lists Java's primitive data types. The subsections below provide details about these types.

Table 2.2: Java Primitive Data Types

				Min Value
Type	**Contains**	**Default**	**Size**	**Max Value**
boolean	`true` or `false`	`false`	1 bit	N.A.
				N.A.
char	Unicode character	`\u0000`	16 bits	`\u0000`
				`\uFFFF`
byte	signed integer	0	8 bits	-128
				127
short	signed integer	0	16 bits	-32768
				32767
int	signed integer	0	32 bits	-2147483648
				2147483647
long	signed integer	0	64 bits	-9223372036854775808
				9223372036854775807
float	IEEE 754	0.0	32 bits	+/-3.40282347E+38
	floating-point			+/-1.40239846E-45

double	IEEE 754	0.0	64 bits	+/-1.79769313486231570E+308
	floating-point			+/-4.94065645841246544E-324

The boolean Type

`boolean` values are not integers, may not be treated as integers, and may never be cast to or from any other type. To perform C-style conversions between a `boolean` value `b` and an `int i`, use the following code:

```
b = (i != 0);   // integer-to-boolean: non-0 -> true; 0 -> false;
i = (b)?1:0;    // boolean-to-integer: true -> 1; false -> 0;
```

The char Type

`char` values represent characters. Character literals may appear in a Java program between single quotes. For example:

```
char c = 'A';
```

All of the standard C character escapes, as well as Unicode escapes, are also supported in character literals. For example:

```
char newline = '\n', apostrophe = '\", delete = '\377', aleph='\u05D0';
```

Values of type `char` do not have a sign. If a `char` is cast to a `byte` or a `short`, a negative value may result.

The `char` type in Java holds a two-byte Unicode character. While this may seem intimidating to those not familiar with Unicode and the techniques of program internationalization, it is in fact totally transparent. Java does not provide a way to compute the size of a variable, nor does it allow any sort of pointer arithmetic. What this means is that if you are only using ASCII or Latin-1 characters, there is no way to distinguish a Java `char` from a C `char`.

Integral Types

The integral types in Java are `byte`, `short`, `char`, `int`, and `long`. Literals for these types are written just as they are in C. All integral types, other than `char`, are signed. There is no `unsigned` keyword as there is in C. It is not legal to write `long int` or `short int` as it is in C. A `long` constant may be distinguished from other integral constants by appending the character `l` or `L` to it.

Integer division by zero or modulo zero causes an `ArithmeticException` to be thrown. [3]

[3] Exceptions signal errors in Java. Exception handling is described later in this chapter.

Floating-Point Types

The floating-point types in Java are `float` and `double`. Literals for these types are written just as they are in C. Literals may be specified to be of type `float` by appending an `f` or `F` to the value; they may be specified to be of type `double` by appending a `d` or `D`.

`float` and `double` types have special values that may be the result of certain floating-point operations: positive infinity, negative infinity, negative zero and not-a-number. The `java.lang.Float` and `java.lang.Double` classes define some of these values as constants: `POSITIVE_INFINITY`, `NEGATIVE_INFINITY`, and `NaN`.

`NaN` is unordered--comparing it to any other number, including itself, yields `false`. Use `Float.isNaN()` or `Double.isNaN()` to test for `NaN`. Negative zero compares equal to regular zero (positive zero), but the two zeros may be distinguished by division: one divided by negative zero yields negative infinity; one divided by positive zero yields positive infinity.

Floating-point arithmetic never causes exceptions, even in the case of division by zero.

String Literals

Strings in Java are not a primitive type, but are instances of the `String` class. However, because they are so commonly used, string literals may appear between quotes in Java programs, just as they do in C. When the compiler encounters such a string literal, it automatically creates the necessary `String` object.

2.7 Reference Data Types

The non-primitive data types in Java are objects and arrays. These non-primitive types are often called "reference types" because they are handled "by reference"--in other words, the address of the object or array is stored in a variable, passed to methods, and so on. By comparison, primitive types are handled "by value"--the actual primitive values are stored in variables and passed to methods.

In C, you can manipulate a value by reference by taking its address with the & operator, and you can "dereference" an address with the `*` and `->` operators. These operators do not exist in Java: primitive types are always passed by value; arrays and objects are always passed by reference.

Because objects are passed by reference, two different variables may refer to the same object:

```
Button p, q;
p = new Button();           // p refers to a Button object.
q = p;                      // q refers to the same Button.
p.setLabel("Ok");           // A change to the object through p...
String s = q.getLabel();    // ...is also visible through q.
                            // s now contains "Ok."
```

This is not true of primitive types, however:

```
int i = 3;                  // i contains the value 3.
int j = i;                  // j contains a copy of the value in i.
i = 2;                      // Changing i doesn't change j.
                            // Now, i == 2 and j == 3.
```

Terminology: Pass by Reference

The statement that Java manipulates objects "by reference" causes confusion for some programmers, because there are several different meanings of "by reference" in common use. Regardless of what we call it, it is important to understand what Java does. Java works with references to objects. A Java variable holds only a reference to an object, not the object itself. When an object is passed to a method, only a reference to the object is actually passed, not the entire object. It is in this sense that Java manipulates objects "by reference."

Some people use the term "pass by reference" to mean that a reference to a variable is passed to a method. Java does not do this. For example, it is *not* possible to write a working `swap()` function like the following in Java:

```
public void swap(Object a, Object b) {
  Object temp = a;
  a = b;
  b = temp;
}
```

The method parameters `a` and `b` contain references to objects, not addresses of variables. Thus, while this `swap()` function does compile and run, it has no effect except on its own local variables and arguments.

To solve this terminology problem, perhaps we should say that Java manipulates objects "by reference," but it passes object references to methods "by value."

Copying Objects

Because reference types are not passed by value, assigning one object to another in Java does not copy the value of the object. It merely assigns a reference to the object. Consider the following code:

```
Button a = new Button("Okay");
Button b = new Button("Cancel");
a = b;
```

After these lines are executed, the variable `a` contains a reference to the object that `b` refers to. The object that `a` used to refer to is lost.

To copy the data of one object into another object, use the `clone()` method:

```
Vector b = new Vector;
c = b.clone();
```

After these lines run, the variable `c` refers to an object that is a duplicate of the object referred to by `b`. Note that not all types support the `clone()` method. Only classes that implement the `Cloneable` interface may be cloned. For more information on cloning objects, look up `java.lang.Cloneable` and `java.lang.Object.clone()` in Chapter 25, *The java.lang Package*.

Arrays are also reference types, and assigning an array simply copies a reference to the array. To actually copy the values stored in an array, you must assign each of the values individually or use the `System.arraycopy()` method.

Checking Objects for Equality

Another implication of passing objects by reference is that the `==` operator tests whether two variables refer to the same object, not whether two objects contain the same values. To actually test whether two separate objects are the same, you must use a specially written method for that object type (just as you might use `strcmp()` to compare C strings for equality). In Java, a number of classes define an `equals()` method that you can use to perform this test.

Java Has No Pointers

The referencing and dereferencing of objects is handled for you automatically by Java. Java does not allow you to manipulate pointers or memory addresses of any kind:

- It does not allow you to cast object or array references into integers or vice-versa.
- It does not allow you to do pointer arithmetic.
- It does not allow you to compute the size in bytes of any primitive type or object.

There are two reasons for these restrictions:

- Pointers are a notorious source of bugs. Eliminating them simplifies the language and eliminates many potential bugs.
- Pointers and pointer arithmetic could be used to sidestep Java's run-time checks and security mechanisms. Removing pointers allows Java to provide the security guarantees that it does.

To a C programmer, the lack of pointers and pointer arithmetic may seem an odious restriction in Java. But once you get used to the Java object-oriented programming model, it no longer seems like a serious restriction at all. The lack of pointers does mean that you probably can't do things like write UNIX device drivers in Java (at least not without using native methods written in C). But big deal--most of us never have to do this kind of low-level programming anyway.

null

The default value for variables of all reference types is `null`. `null` is a reserved value that indicates "an absence of reference"--i.e., that a variable does not refer to any object or array.

In Java, `null` is a reserved keyword, unlike `NULL` in C, where it is just a constant defined to be 0. `null` is an exception to the strong typing rules of Java--it may be assigned to any variable of reference type (i.e., any variable which has a class, interface, or array as its type).

`null` can't be cast to any primitive type, including integral types and `boolean`. It shouldn't be considered equal to zero (although it may be implemented this way).

Reference Type Summary

The distinction between primitive types passed by value, and objects and arrays passed by reference is a crucial one in Java. Be sure you understand the following:

- All objects and arrays are handled by reference in Java. (Those object references are passed-by-value to methods, however.)
- The = and == operators assign and test references to objects. Use `clone()` and `equals()` to actually copy or test the objects themselves.
- The necessary referencing and dereferencing of objects and arrays is handled automatically by Java.
- A reference type can never be cast to a primitive type.
- A primitive type can never be cast to a reference type.
- There is no pointer arithmetic in Java.
- There is no `sizeof` operator in Java.
- `null` is a special value that means "no object" or indicates an absence of reference.

2.8 Objects

Now that you know objects are passed by reference, we should discuss how they are created, used, and destroyed. The following subsections provide a very brief overview of objects. Chapter 3, *Classes and Objects in Java* explains classes and objects in much greater detail.

Creating Objects

Declaring a variable to hold an object does not create the object itself; the variable only holds the reference to the object. To actually create an object, you must use the `new` keyword. This is followed by the object's class (i.e., its type) and an optional argument list in parentheses. These arguments are passed to the constructor method for the class, which serves to initialize internal fields in the new object. For example:

```
java.awt.Button b = new java.awt.Button();
ComplexNumber c = new ComplexNumber(1.0, 1.414);
```

There are actually two other ways to create an object. First, you can create a `String` object simply by enclosing characters in double quotes:

```
String s = "This is a test";
```

Because strings are used so frequently, the Java compiler provides this technique as a shortcut. Another way to create objects is by calling the `newInstance()` method of a `Class` object. This technique is generally used only when dynamically loading classes, so we won't discuss it here. In Java 1.1, objects can also be created by "de-serializing" them--i.e., recreating an object that had its state saved through "serialization."

The memory for newly created objects is dynamically allocated. Creating an object with `new` in Java is like calling `malloc()` in C to allocate memory for an instance of a `struct`. It is also, of course, a lot like using the `new` operator in C++. (Below, we'll see where this analogy to `malloc()` in C and `new` in

C++ breaks down.)

Accessing Objects

As you've probably noticed in various example code fragments by now, the way you access the fields of an object is with a dot:

```
ComplexNumber c = new ComplexNumber();
c.x = 1.0;
c.y = -1.414;
```

This syntax is reminiscent of accessing the fields of a `struct` in C. Recall, though, that Java objects are always accessed by reference, and that Java performs any necessary dereferencing for you. Thus, the dot in Java is more like `->` in C. Java hides the fact that there is a reference here in an attempt to make your programming easier. The other difference between C and Java when accessing objects is that in Java you refer to an object's methods with the same syntax used for fields:

```
ComplexNumber c = new ComplexNumber(1.0, -1.414);
double magnitude = c.magnitude();
```

Garbage Collection

Objects in Java are created with the `new` keyword, but there is no corresponding `old` or `delete` keyword or `free()` method to get rid of them when they are no longer needed. If creating an object with `new` is like calling `malloc()` in C or using `new` in C++, then it would seem that Java is full of memory leaks, because we never call `free()` or use the `delete` operator.

In fact, this isn't the case. Java uses a technique called *garbage collection* to automatically detect objects that are no longer being used (an object is no longer in use when there are no more references to it) and to free them. This means that in our programs, we never need to worry about freeing memory or destroying objects--the garbage collector takes care of that.

If you are a C or C++ programmer, it may take some getting used to to just let allocated objects go without worrying about reclaiming their memory. Once you get used to it, however, you'll begin to appreciate what a nice feature this is. We'll discuss garbage collection in more detail in the next chapter.

2.9 Arrays

Most of what we learned in the previous sections about reference types and objects applies equally well to arrays in Java:

- Arrays are manipulated by reference.
- They are dynamically created with `new`.
- They are automatically garbage collected when no longer referred to.

The following subsections explain these and other details.

Creating and Destroying Arrays

There are two ways to create arrays in Java. The first uses `new`, and specifies how large the array should be:

```
byte octet_buffer[] = new byte[1024];
Button buttons[] = new Button[10];
```

Since creating an array does not create the objects that are stored in the array, there is no constructor to call, and the argument list is omitted with this form of the `new` keyword. The elements of an array created in this way are initialized to the default value for their type. The elements of an array of `int` are initialized to `0`, for example, and the elements of an array of objects are initialized to `null`. This last point is important to remember: creating an array of objects only allocates storage for object references, not objects themselves. The objects that will be referred to by the elements of the array must be created separately.

The second way to create an array is with an initializer, which looks just like it does in C:

```
int lookup_table[] = {1, 2, 4, 8, 16, 32, 64, 128};
```

This syntax dynamically creates an array and initializes its elements to the specified values. The elements specified in an array initializer may be arbitrary expressions. This is different than in C, where they must be constant expressions.

In Java 1.1, arrays may also be created and initialized "anonymously" by combining the `new` syntax with the initializer syntax. It looks like this:

```
Menu m = createMenu("File", new String[] { "Open...", "Save", "Quit" });
```

Arrays are automatically garbage collected, just like objects are.

Multidimensional Arrays

Java also supports multidimensional arrays. These are implemented as arrays-of-arrays, as they are in C. You specify a variable as a multidimensional array type simply by appending the appropriate number of `[]` pairs after it. You allocate a multidimensional array with `new` by specifying the appropriate number of elements (between square brackets) for each dimension. For example:

```
byte TwoDimArray[][] = new byte[256][16];
```

This statement does three things:

- Declares a variable named `TwoDimArray`. This variable has type `byte[][]` (array-of-array-of-`byte`).

- Dynamically allocates an array with 256 elements. The type of this newly allocated array is `byte[][]`, so it can be assigned to the variable we declared. Each element of this new array is of type `byte[]`--a single-dimensional array of `byte`.

- Dynamically allocates 256 arrays of bytes, each of which holds 16 bytes, and stores a reference to these 256 `byte[]` arrays into the 256 elements of the `byte[][]` array allocated in the second step. The 16 bytes in each of these 256 arrays are initialized to their default value of `0`.

When allocating a multidimensional array, you do not have to specify the number of elements that are contained in each dimension. For example:

```
int threeD[][][] = new int[10][][];
```

This expression allocates an array that contains ten elements, each of type `int[][]`. It is a single-dimensional allocation, although when the array elements are properly initialized to meaningful values, the array will be multidimensional. The rule for this sort of array allocation is that the first *n* dimensions (where *n* is at least one) must have the number of elements specified, and these dimensions may be followed by *m* additional dimensions with no dimension size specified. The following is legal:

```
String lots_of_strings[][][][] = new String[5][3][][];
```

This is not:

```
double temperature_data[][][] = new double[100][][10];  // illegal
```

Multidimensional arrays can also be allocated and initialized with nested initializers. For example, you might declare the following multidimensional array of strings for use by the `getParameterInfo()` method of an applet:

```
String param_info[][] = {
    {"foreground", "Color",  "foreground color"},
    {"background", "Color",  "background color"},
    {"message",    "String", "the banner to display"}
};
```

Note that since Java implements multidimensional arrays as arrays-of-arrays, multidimensional arrays need not be "rectangular." For example, this is how you could create and initialize a "triangular array":

```
short triangle[][] = new short[10][];       // A single-dimensional array.
for(int i = 0; i < triangle.length; i++) {  // For each element of that array
    triangle[i] = new short[i+1];           // Allocate a new array.
    for(int j=0; j < i+1; j++)              // For each element of new array
        triangle[i][j] = (short) i + j;     // Initialize it to a value.
}
```

You can also declare and initialize non-rectangular arrays with nested initializers:

```
static int[][] twodim = {{1, 2}, {3, 4, 5}, {5, 6, 7, 8}};
```

To simulate multiple dimensions within a single-dimensional array, you'd use code just as you would in C:

```
final int rows = 600;
final int columns = 800;
byte pixels[] = new byte[rows*columns];
// access element [i,j] like this:
byte b = pixels[i + j*columns];
```

Accessing Array Elements

Array access in Java is just like array access in C--you access an element of an array by putting an integer-valued expression between square brackets after the name of the array.

```
int a[] = new int[100];
a[0] = 0;
for(int i = 1; i < a.length; i++) a[i] = i + a[i-1];
```

Notice how we computed the number of elements of the array in this example--by accessing the `length` field of the array. This is the only field that arrays support. Note that it is a constant (`final`) field--any attempt to store a value into the `length` field of an array will fail.

In all Java array references, the index is checked to make sure it is not too small (less than zero) or too big (greater than or equal to the array length). If the index is out of bounds, an `ArrayIndexOutOfBoundsException` is thrown. [4] This is another way that Java works to prevent bugs (and security problems).

[4] The discussion of exceptions and exception handling is still to come.

Are Arrays Objects?

It is useful to consider arrays to be a separate kind of reference type from objects. In some ways, though, arrays behave just like objects. As we saw, arrays use the object syntax `.length` to refer to their length. Arrays may also be assigned to variables of type `Object`, and the methods of the `Object` class may be invoked for arrays. (`Object` is the root class in Java, which means that all objects can be assigned to a variable of type `Object` and all objects can invoke the methods of `Object`.)

The evidence suggests that arrays are, in fact, objects. Java defines enough special syntax for arrays, however, that it is still most useful to consider them a different kind of reference type than objects.

Declaring Array Variables and Arguments

In C, you declare an array variable or array function argument by placing square brackets next to the variable name:

```
void reverse(char strbuf[], int buffer_size)  {
    char buffer[500];
        ...
}
```

In Java, you would have to declare `buffer` as an array variable, and then allocate the array itself with `new`, but otherwise you could use the same syntax, with the array brackets after the variable or argument name.

However, Java also allows you to put the array brackets after the type name instead. So you could rewrite this code fragment to look something like this:

```
void reverse(char[] strbuf, int buffer_size) {
    char[] buffer = new char[500];
        ...
}
```

In a lot of ways, this new array syntax is easier to read and easier to understand. (It doesn't work in C, by the way, because pointers make C's type declaration syntax a real mess.) The only problem with this new syntax is that if you get in the habit of using it, it will make it harder for you when you (hopefully only occasionally!) have to switch back and program in C.

Java even allows you to mix the declaration styles, which is something you may find occasionally useful (or frequently confusing!) for certain data structures or algorithms. For example:

```
// row and column are arrays of byte.
// matrix is an array of an array of bytes.
byte[] row, column, matrix[];
// This method takes an array of bytes and an
// array of arrays of bytes.
public void dot_product(byte[] column, byte[] matrix[]) { ... }
```

A final point to note about array declarations is that (as we've seen throughout this section) the size of an array is not part of its type as it is in C. Thus, you can declare a variable to be of type `String[]`, for example, and assign any array of `String` objects to it, regardless of the length of the array:

```
String[] strings;           // this variable can refer to any String array
strings = new String[10];   // one that contains 10 Strings
strings = new String[20];   // or one that contains 20.
```

Objects | BOOK INDEX | Strings

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.10 Strings

Strings in Java are *not* null-terminated arrays of characters as they are in C. Instead, they are instances of the `java.lang.String` class. Java strings are unusual, in that the compiler treats them almost as if they were primitive types--for example, it automatically creates a `String` object when it encounters a double-quoted constant in the program. And, the language defines an operator that operates on `String` objects--the `+` operator for string concatenation.

An important feature of `String` objects is that they are immutable--i.e., there are no methods defined that allow you to change the contents of a `String`. If you need to modify the contents of a `String`, you have to create a `StringBuffer` object from the `String` object, modify the contents of the `StringBuffer`, and then create a new `String` from the contents of the `StringBuffer`.

Note that it is moot to ask whether Java strings are terminated with a NUL character (`\u0000`) or not. Java performs run-time bounds checking on all array and string accesses, so there is no way to examine the value of any internal terminator character that appears after the last character of the string.

Both the `String` and `StringBuffer` classes are documented in Chapter 25, *The java.lang Package*, and you'll find a complete set of methods for string handling and manipulation there. Some of the more important `String` methods are: `length()`, `charAt()`, `equals()`, `compareTo()`, `indexOf()`, `lastIndexOf()`, and `substring()`.

2.11 Operators

Java supports almost all of the standard C operators. These standard operators have the same precedence and associativity in Java as they do in C. They are listed in Table 2.3 and also in quick reference form in Chapter 13, *Java Syntax*.

Table 2.3: Java Operators

Prec.	Operator	Operand Type(s)	Assoc.	Operation Performed
1	++	arithmetic	R	pre-or-post increment
				(unary)
	--	arithmetic	R	pre-or-post decrement (unary)
	+, -	arithmetic	R	unary plus, unary minus
	~	integral	R	bitwise complement (unary)
	!	boolean	R	logical complement (unary)
	(*type*)	any	R	cast
2	*, /, %	arithmetic	L	multiplication, division, remainder
3	+, -	arithmetic	L	addition, subtraction
	+	string	L	string concatenation
4	<<	integral	L	left shift
	>>	integral	L	right shift with sign extension
	>>>	integral	L	right shift with zero extension
5	<, <=	arithmetic	L	less than, less than or equal
	>, >=	arithmetic	L	greater than, greater than or equal
	instanceof	object, type	L	type comparison
6	==	primitive	L	equal (have identical

				values)
	!=	primitive	L	not equal (have different values)
	==	object	L	equal (refer to same object)
	!=	object	L	not equal (refer to different objects)
7	&	integral	L	bitwise AND
	&	boolean	L	boolean AND
8	^	integral	L	bitwise XOR
	^	boolean	L	boolean XOR
9	|	integral	L	bitwise OR
	|	boolean	L	boolean OR
10	&&	boolean	L	conditional AND
11	||	boolean	L	conditional OR
12	?:	boolean, any, any	R	conditional (ternary) operator
13	=	variable, any	R	assignment
	*=, /=, %=, +=, -=, <<=, >>=, >>>=, &=, ^=, |=	variable, any	R	assignment with operation

Note the following Java operator differences from C. Java does not support the comma operator for combining two expressions into one (although the `for` statement simulates this operator in a useful way). Since Java does not allow you to manipulate pointers directly, it does not support the reference and dereference operators `*`, `->`, and `&`, nor the `sizeof` operator. Further, Java doesn't consider `[]` (array access) and `.` (field access) to be operators, as C does.

Java also adds some new operators:

The `+` operator applied to `String` values concatenates them. [5] If only one operand of `+` is a `String`, the other one is converted to a string. The conversion is done automatically for primitive types, and by calling the `toString()` method of non-primitive types. This `String` `+` operator has the same precedence as the arithmetic `+` operator. The `+=` operator works as you would expect for `String` values.

> [5] To C++ programmers, this looks like operator overloading. In fact, Java does not support operator overloading--the language designers decided (after much debate) that overloaded operators were a neat idea, but that code that relied on them became hard to read and understand.

The `instanceof` operator returns `true` if the object `o` on its left-hand side is an instance of the class

C or implements the interface I specified on its right-hand side. It also returns true if o is an instance of a subclass of C or is an instance of a subclass of some class that implements I. instanceof returns false if o is not an instance of C or does not implement I. It also returns false if the value on its left is null. If instanceof returns true, it means that o is *assignable to* variables of type C or I. The instanceof operator has the same precedence as the <, <=, >, and >= operators.

Because all integral types in Java are signed values, the Java >> operator is defined to do a right shift with sign extension. The >>> operator treats the value to be shifted as an unsigned number and shifts the bits right with zero extension. The >>>= operator works as you would expect.

& and |

> When & and | are applied to integral types in Java, they perform the expected bitwise AND and OR operations. Java makes a strong distinction between integral types and the boolean type, however. Thus, if these operators are applied to boolean types, they perform logical AND and logical OR operations. These logical AND and logical OR operators always evaluate both of their operands, even when the result of the operation is determined after evaluating only the left operand. This is useful when the operands are expressions with side effects (such as method calls) and you always want the side effects to occur. However, when you do not want the right operand evaluated if it is not necessary, you can use the && and || operators, which perform "short-circuited" logical AND and logical OR operations just as in C. The &= and |= operators perform a bitwise or logical operation depending on the type of the operands, as you would expect.

2.12 Statements

Many of Java's control statements are similar or identical to C statements. This section lists and, where necessary, explains Java's statements. Note that the topic of exceptions and the try/catch/finally statement is substantial enough that it is covered later in a section of its own.

The if/else, while, and do/while Statements

The if, else, do, and while statements are exactly the same in Java as they are in C. The only substantial difference arises because the Java boolean type cannot be cast to other types. In Java, the values 0 and null are not the same as false, and non-zero and non-null values are not the same as true.

The conditional expression that is expected by the if, the while, and the do/while statements must be of boolean type in Java. Specifying an integer type or a reference type won't do. Thus, the following C code is not legal in Java:

```
int i = 10;
while(i--) {
    Object o = get_object();
    if (o) {
        do { ... } while(j);
    }
}
```

In Java, you must make the condition you are testing for clear by explictly testing your value against 0 or null. Use code like the following:

```
int i = 10;
while(i-- > 0) {
    Object o = get_object();
    if (o != null) {
        do { ... } while(j != 0);
    }
}
```

The switch Statement

The `switch` statement is the same in Java as it is in C. You may use `byte`, `char`, `short`, `int`, or `long` types as the values of the `case` labels, and you may also specify a `default` label just as you do in C.

The for Loop

The `for` statement is perhaps the most useful looping construct available in Java. There are only two differences between the Java `for` loop and the C `for` loop. The first difference is that although Java does not support the C comma operator (which allows multiple expressions to be joined into a single expression), the Java `for` loop simulates it by allowing multiple comma-separated expressions to appear in the initialization and increment sections, but not the test section, of the loop. For example:

```
int i;
String s;
for(i=0, s = "testing";             // Initialize variables.
    (i < 10) && (s.length() >= 1);  // Test for continuation.
    i++, s = s.substring(1))        // Increment variables.
{
    System.out.println(s);          // Loop body.
}
```

As you can see, this "difference" between the Java and C `for` loops is really a similarity.

The second difference is the addition of the C++ ability to declare local loop variables in the initialization section of the loop:

```
for(int i = 0; i < my_array.length; i++)
    System.out.println("a[" + i + "] = " + my_array[i]);
```

Variables declared in this way have the `for` loop as their scope. In other words, they are only valid within the body of the `for` loop and within the initialization, test, and increment expressions of the loop. Although variables declared in `for` loops have their own scope, the Java compiler won't let you declare a loop variable that has the same name as an already existing variable or parameter.

Note that because variable declaration syntax also uses the comma, the Java syntax allows you to either specify multiple comma-separated initialization expressions or to declare and initialize multiple comma-separated variables of the same type. You may not mix variable declarations with other, non-declaration expressions. For example, the following `for` loop declares and initializes two variables that are valid only within the `for` loop.

```
for(int i=0, j=10; i < j; i++, j--) System.out.println("k = " + i*j);
```

Labelled break and continue Statements

The `break` and `continue` statements, used alone, behave the same in Java as they do in C. However, in Java, they may optionally be followed by a label that specifies an enclosing loop (for `continue`) or any enclosing statement (for `break`). The labelled forms of these statements allow you to "break" and "continue" any specified statement or loop within a method definition, not only the nearest enclosing statements or loop.

The `break` statement, without a label, transfers control out of ("breaks out of" or terminates) the nearest enclosing `for`, `while`, `do` or `switch` statement, exactly as in C. If the `break` keyword is followed by an identifier that is the label of an arbitrary enclosing statement, execution transfers out of that enclosing statement. After the `break` statement is executed, any required `finally` clauses are executed, and control resumes at the statement following the terminated statement. (The `finally` clause and the `try` statement it is associated with are exception handling constructs and are explained in the next section.) For example:

```
test: if (check(i)) {
    try {
        for(int j=0; j < 10; j++) {
            if (j > i) break;           // Terminate just this loop.
            if (a[i][j] == null)
                break test;             // Do the finally clause and
        }                               // terminate the if statement.
    }
    finally { cleanup(a, i, j); }
}
```

Without a label, the `continue` statement works exactly as in C: It stops the iteration in progress and causes execution to resume after the last statement in the `while`, `do`, or `for` loop, just before the loop iteration is to begin again. If the `continue` keyword is followed by an identifier that is the label of an enclosing loop, execution skips to the end of that loop instead. If there are any `finally` clauses between the `continue` statement and the end of the appropriate loop, these clauses are executed before control is transferred to the end of the loop.

The following code fragment illustrates how the `continue` statement works in its labelled and unlabelled forms.

```
big_loop: while(!done) {
    if (test(a,b) == 0) continue;       // Control goes to point 2.
    try {
        for(int i=0; i < 10; i++) {
            if (a[i] == null)
                continue;               // Control goes to point 1.
            else if (b[i] == null)
                continue big_loop;      // Control goes to point 2,
                                        // after executing the finally block.
            doit(a[i],b[i]);
           // Point 1.  Increment and start loop again with the test.
        }
    }
    finally { cleanup(a,b); }
    // Point 2.  Start loop again with the (!done) test.
}
```

Note the non-intuitive feature of the labelled `continue` statement: The loop label must appear at the top of the loop, but `continue` causes execution to transfer to the very bottom of the loop.

No goto Statement

`goto` is a reserved word in Java, but the `goto` statement is not currently part of the language. Labelled `break` and `continue` statements replace some important and legitimate uses of `goto`, and the `try`/`catch`/`finally` statement replaces the others.

The synchronized Statement

Since Java is a multithreaded system, care must often be taken to prevent multiple threads from modifying objects simultaneously in a way that might leave the object's state corrupted. Sections of code that must not be executed simultaneously are known as "critical sections." Java provides the `synchronized` statement to protect these critical sections. The syntax is:

```
synchronized (expression) statement
```

`expression` is an expression that must resolve to an object or an array. The *`statement`* is the code of the critical section, which is usually a block of statements (within `{` and `}`). The *`synchronized`* statement attempts to acquire an exclusive lock for the object or array specified by `expression`. It does not execute the critical section of code until it can obtain this lock, and in this way, ensures that no other threads can be executing the section at the same time.

Note that you do not have to use the `synchronized` statement unless your program creates multiple threads that share data. If only one thread ever accesses a data structure, there is no need to protect it with `synchronized`. When you do have to use it, it might be in code like the following:

```
public static void SortIntArray(int[] a) {
    // Sort the array a. This is synchronized so that some other
    // thread can't change elements of the array while we're sorting it.
    // At least not other threads that protect their changes to the
    // array with synchronized.
    synchronized (a) {
        // Do the array sort here.
    }
}
```

The `synchronized` keyword is more often used as a method modifier in Java. When applied to a method, it indicates that the entire method is a critical section. For a `synchronized` class method (a static method), Java obtains an exclusive lock on the class before executing the method. For a `synchronized` instance method, Java obtains an exclusive lock on the class instance. (Class methods and instance methods are discussed in the next chapter.)

The package and import Statements

The `package` statement, as we saw earlier in the chapter, specifies the package that the classes in a file of Java source code are part of. If it appears, it must be the first statement of a Java file. The `import` statement, which we also saw earlier, allows us to refer to classes by abbreviated names. `import` statements must appear after the `package` statement, if any, and before any other statements in a Java file. For example:

```
package games.tetris;
import java.applet.*;
import java.awt.*;
```

Operators | BOOK INDEX | Exceptions and Exception Handling

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.13 Exceptions and Exception Handling

Exception handing is a significant new feature of Java. [6] There are a number of new terms associated with exception handling. First, an *exception* is a signal that indicates that some sort of exceptional condition (such as an error) has occurred. To *throw* an exception is to signal an exceptional condition. To *catch* an exception is to handle it--to take whatever actions are necessary to recover from it.

[6] It is similar to, but not quite the same as, exception handling in C++.

Exceptions propagate up through the lexical block structure of a Java method, and then up the method call stack. If an exception is not caught by the block of code that throws it, it propagates to the next higher enclosing block of code. If it is not caught there, it propagates up again. If it is not caught anywhere in the method, it propagates to the invoking method, where it again propagates through the block structure. If an exception is never caught, it propagates all the way to the `main()` method from which the program started, and causes the Java interpreter to print an error message and a stack trace and exit.

As we'll see in the subsections below, exceptions make error handling (and "exceptional condition" handling) more regular and logical by allowing you to group all your exception handling code into one place. Instead of worrying about all of the things that can go wrong with each line of your code, you can concentrate on the algorithm at hand and place all your error handling code (that is, your exception catching code) in a single place.

Exception Objects

An exception in Java is an object that is an instance of some subclass of `java.lang.Throwable`. `Throwable` has two standard subclasses: `java.lang.Error` and `java.lang.Exception`. [7] Exceptions that are subclasses of `Error` generally indicate linkage problems related to dynamic loading, or virtual machine problems such as running out of memory. They should almost always be considered unrecoverable, and should not be caught. While the distinction is not always clear, exceptions that are subclasses of `Exception` indicate conditions that may be caught and recovered from. They include such exceptions as `java.io.EOFException`, which signals the end of a file, and `java.lang.ArrayAccessOutOfBounds`, which indicates that a program has tried to read past the end of an array.

[7] We'll use the term "exception" to refer to any subclass of `Throwable`, whether it is actually an `Exception` or an `Error`.

Since exceptions are objects, they can contain data and define methods. The `Throwable` object, at the top of the exception class hierarchy, includes a `String` message in its definition and this field is inherited by all exception classes. This field is used to store a human-readable error message that describes the exceptional condition. It is set when the exception object is created by passing an argument to the constructor method. The message can be read from the exception with the `Throwable.getMessage()` method. Most exceptions contain only this single message, but a few add other data. The `java.io.InterruptedIOException`, for example, adds the following field:

```
public int bytesTransferred;
```

This field specifies how much of the I/O was complete before the exceptional condition occurred.

Exception Handling

The `try`/`catch`/`finally` statement is Java's exception handling mechanism. `try` establishes a block of code that is to have its exceptions and abnormal exits (through `break`, `continue`, `return`, or exception propagation) handled. The `try` block is followed by zero or more `catch` clauses that catch and handle specified types of exceptions. The `catch` clauses are optionally followed by a `finally` block that contains "clean-up" code. The statements of a `finally` block are guaranteed to be executed, regardless of how the code in the `try` block exits. A detailed example of the `try`/`catch`/`finally` syntax is shown in Example 2.2.

Example 2.2: The try/catch/finally Statement

```
try {
        // Normally this code runs from the top of the block to the bottom
        // without problems.  But it sometimes may raise exceptions or
        // exit the block via a break, continue, or return statement.
}
catch (SomeException e1) {
        // Handle an exception object e1 of type SomeException
        // or of a subclass of that type.
}
catch (AnotherException e2) {
        // Handle an exception object e2 of type AnotherException
        // or of a subclass of that type.
}
finally {
        // Always execute this code, after we leave the try clause,
        // regardless of whether we leave it:
        //    1) Normally, after reaching the bottom of the block.
        //    2) With an exception that is handled by a catch.
        //    3) With an exception that is not handled.
        //    4) Because of a break, continue, or return statement.
}
```

try

The try clause simply establishes a block of code that is to have its exceptions and abnormal exits (through break, continue, return, or exception propagation) handled. The try clause by itself doesn't do anything interesting; it is the catch and finally clauses that do the exception handling and clean-up operations.

catch

A try block may be followed by zero or more catch clauses that specify code to handle various types of exceptions. catch clauses have an unusual syntax: each is declared with an argument, much like a method argument. This argument must be of type Throwable or a subclass. When an exception occurs, the first catch clause that has an argument of the appropriate type is invoked. The type of the argument must match the type of the exception object, or it must be a superclass of the exception. This catch argument is valid only within the catch block, and refers to the actual exception object that was thrown.

The code within a catch block should take whatever action is necessary to cope with the exceptional condition. If the exception was a java.io.FileNotFoundException exception, for example, you might handle it by asking the user to check his or her spelling and try again. Note that it is not required to have a catch clause for every possible exception--in some cases the correct response is to allow the exception to propagate up and be caught by the invoking method. In other cases, such as a programming error signaled by NullPointerException, the correct response is to not catch the exception at all, but to allow it to propagate and to have the Java interpreter exit with a stack trace and an error message.

finally

The finally clause is generally used to clean up (close files, release resources, etc.) after the try clause. What is useful about the finally clause is that the code in a finally block is guaranteed to be executed, if any portion of the try block is executed, regardless of how the code in the try block completes. In the normal case, control reaches the end of the try block and then proceeds to the finally block, which performs any necessary cleanup.

If control leaves the try block because of a return, continue, or break statement, the contents of the finally block are executed before control transfers to its new destination.

If an exception occurs in the try block and there is a local catch block to handle the exception, control transfers first to the catch block, and then to the finally block. If there is not a local catch block to handle the exception, control transfers first to the finally block, and then propagates up to the nearest catch clause that can handle the exception.

Note that if a finally block itself transfers control with a return, continue, or break statement, or by raising an exception, the pending control transfer is abandoned, and this new transfer is processed.

Also note that `try` and `finally` can be used together without exceptions or any `catch` clauses. In this case, the `finally` block is simply cleanup code that is guaranteed to be executed regardless of any `break`, `continue`, or `return` statements within the `try` clause.

Declaring Exceptions

Java requires that any method that can cause a "normal exception" to occur must either catch the exception or specify the type of the exception with a `throws` clause in the method declaration. [8] Such a `throws` clause might look like these:

[8] C++ programmers should note that Java uses `throws` where C++ uses `throw`.

```
public void open_file() throws IOException {
    // Statements here that might generate an uncaught java.io.IOException
}
public void myfunc(int arg) throws MyException1, MyException2 {
    ...
}
```

Note that the exception class specified in a `throws` clause may be a superclass of the exception type that is actually thrown. Thus if a method throws exceptions `a`, `b`, and `c`, all of which are subclasses of `d`, the `throws` clause may specify all of `a`, `b`, and `c`, or it may simply specify `d`.

We said above that the `throws` clause must be used to declare any "normal exceptions." This oxymoronic phrase refers to any subclass of `Throwable` that is not a subclass of `Error` or a subclass of `RuntimeException`. Java does not require these types of exceptions to be declared because practically any method can conceivably generate them, and it would quickly become tedious to properly declare them all. For example, every method running on a buggy Java interpreter can throw an `InternalError` exception (a subclass of `Error`) and it doesn't make sense to have to declare this in a `throws` clause for every method. Similarly, as far as the Java compiler is concerned, any method that accesses an array can generate an `ArrayIndexOutOfBoundsException` exception (a subclass of `RuntimeException`).

The standard exceptions that you often have to declare are `java.io.IOException` and a number of its more specific subclasses. `java.lang.InterruptedException` and several other less commonly used exceptions must also be declared. How do you know when you have to declare a `throws` clause? One way is to pay close attention to the documentation for the methods you call--if any "normal exceptions" can be thrown, either catch them or declare them. Another way to know what exceptions you've got to declare is to declare none and wait for the compilation errors--the compiler will tell you what to put in your `throws` clause!

Defining and Generating Exceptions

You can signal your own exceptions with the `throw` statement. The `throw` keyword must be followed by an object that is Throwable or a subclass. Often, exception objects are allocated in the same statement that they are thrown in:

```
throw new MyException("my exceptional condition occurred.");
```

When an exception is thrown, normal program execution stops and the interpreter looks for a catch clause that can handle the exception. Execution propagates up through enclosing statements and through invoking functions until such a handler is found. Any finally blocks that are passed during this propagation are executed.

Using exceptions is a good way to signal and handle errors in your own code. By grouping all your error handling and recover code together within the try/catch/finally structure, you will end up with cleaner code that is easier to understand. Sometimes, when you are throwing an exception, you can use one of the exception classes already defined by Java API. Often, though, you will want to define and throw your own exception types.

Example 2.3 shows how you can define your own exception types, throw them, and handle them. It also helps clarify how exceptions propagate. It is a long example, but worth studying in some detail. You'll know you understand exception handling if you can answer the following: What happens when this program is invoked with no argument; with a string argument; and with integer arguments 0, 1, 2, and 99?

Example 2.3: Defining, Throwing, and Handling Exceptions

```
// Here we define some exception types of our own.
// Exception classes generally have constructors but no data or
// other methods.  All these do is call their superclass constructors.
class MyException extends Exception {
  public MyException() { super(); }
  public MyException(String s) { super(s); }
}
class MyOtherException extends Exception {
  public MyOtherException() { super(); }
  public MyOtherException(String s) { super(s); }
}
class MySubException extends MyException {
  public MySubException() { super(); }
  public MySubException(String s) { super(s); }
}
public class throwtest {
  // This is the main() method.  Note that it uses two
  // catch clauses to handle two standard Java exceptions.
  public static void main(String argv[]) {
    int i;

    // First, convert our argument to an integer.
    // Make sure we have an argument and that it is convertible.
    try {  i = Integer.parseInt(argv[0]);  }
    catch (ArrayIndexOutOfBoundsException e) { // argv is empty
      System.out.println("Must specify an argument");
      return;
    }
    catch (NumberFormatException e) { // argv[0] isn't an integer
      System.out.println("Must specify an integer argument");
      return;
    }

    // Now, pass that integer to method a().
    a(i);
  }

  // This method invokes b(), which is declared to throw
  // one type of exception.  We handle that one exception.
  public static void a(int i) {
    try {
      b(i);
    }
    catch (MyException e) {                                      // Point 1
      // Here we handle MyException and its subclass MySubException.
      if (e instanceof MySubException)
        System.out.print("MySubException: ");
      else
        System.out.print("MyException: ");
      System.out.println(e.getMessage());
      System.out.println("Handled at point 1");
    }
  }

  // This method invokes c(), and handles one of the two exception
  // types that that method can throw.  The other exception type is
  // not handled, and is propagated up and declared in this method's
  // throws clause.  This method also has a finally clause to finish
  // up the work of its try clause.  Note that the finally clause is
  // executed after a local catch clause, but before a containing
  // catch clause or one in an invoking procedure.
  public static void b(int i) throws MyException {
    int result;
    try {
      System.out.print("i = " + i);
      result = c(i);
      System.out.print(" c(i) = " + result);
    }
    catch (MyOtherException e) {                                 // Point 2
```

```
      // Handle MyOtherException exceptions:
      System.out.println("MyOtherException: " + e.getMessage());
      System.out.println("Handled at point 2");
    }
    finally {
      // Terminate the output we printed above with a newline.
      System.out.print("\n");
    }
  }

  // This method computes a value or throws an exception.
  // The throws clause only lists two exceptions, because
  // one of the exceptions thrown is a subclass of another.
  public static int c(int i) throws MyException, MyOtherException {
    switch (i) {
    case 0:      // processing resumes at point 1 above
      throw new MyException("input too low");
    case 1:      // processing resumes at point 1 above
      throw new MySubException("input still too low");
    case 99:     // processing resumes at point 2 above
      throw new MyOtherException("input too high");
    default:
      return i*i;
    }
  }
}
```

Miscellaneous Differences

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.14 Miscellaneous Differences

A number of miscellaneous differences between Java and C are described in the sections that follow. Miscellaneous differences that were mentioned elsewhere, such as the lack of the `goto` statement and the `sizeof` operator, are not repeated here.

Local Variable Declarations

A feature that Java has borrowed from C++ is the ability to declare and initialize local variables anywhere in a method body or other block of code. Declarations and their initializers no longer have to be the first statements in any block--you can declare them where it is convenient and fits well with the structure of your code.

Don't let this freedom make you sloppy, however! For someone reading your program, it is nice to have variable declarations grouped together in one place. As a rule of thumb, put your declarations at the top of the block, unless you have some good organizational reason for putting them elsewhere.

Forward References

For compiler efficiency, C requires that variables and functions must be defined, or at least declared, before they can be used or called. That is, forward references are not allowed in C. Java does not make this restriction, and by lifting it, it also does away with the whole concept of a variable or function declaration that is separate from the definition.

Java allows very flexible forward references. A method may refer to a variable or another method of its class, regardless of where in the current class the variable or method is defined. Similarly, it may refer to any class, regardless of where in the current file (or outside of the file) that class is defined. The only place that forward references are not allowed is in variable initialization. A variable initializer (for local variables, class variables, or instance variables) may not refer to other variables that have not yet been declared and initialized.

Method Overloading

A technique that Java borrows from C++ is called *method overloading*. Overloaded methods are methods that have the same name, but have different signatures. In other words, they take different types of arguments, a different number of arguments, or the same type of arguments in different positions in the argument list. You cannot overload a method by changing only its return type. Two methods with the same name may have different return types, but only if the method arguments also differ. Similarly, two overloaded methods may throw different exceptions, but only if their arguments differ as well.

Method overloading is commonly used in Java to define a number of related functions with the same name, but different arguments. Overloaded methods usually perform the same basic operation, but allow the programmer to specify arguments in different ways depending on what is convenient in a given situation. Method overloading is discussed in more detail in the next chapter.

The void Keyword

The `void` keyword is used in Java, as in C, to indicate that a function returns no value. (As we will see in the next section, constructor methods are an exception to this rule.)

Java differs from C (and is similar to C++) in that methods that take no arguments are declared with empty parentheses, not with the `void` keyword. Java does not have any `void *` type, nor does it use a `(void)` cast in order to ignore the result returned by a call to a non-`void` method.

Modifiers

Java defines a number of modifier keywords that may be applied to variable and/or method declarations to provide additional information or place restrictions on the variable or method:

`final`

> The `final` keyword is a modifier that may be applied to classes, methods, and variables. It has a similar, but not identical, meaning in each case. A `final` class may never be subclassed. A `final` method may never be overridden. A `final` variable may never have its value set. In Java 1.1, this modifier may also be applied to local variables and method parameters. This modifier is discussed in more detail in the next chapter.

`native`

> `native` is a modifier that may be applied to method declarations. It indicates that the method is implemented elsewhere in C, or in some other platform-dependent fashion. A `native` method should have a semicolon in place of its body.

synchronized

> We saw the synchronized keyword in a previous section where it was a statement that marked a critical section of code. The same keyword can also be used as a modifier for class or instance methods. It indicates that the method modifies the internal state of the class or the internal state of an instance of the class in a way that is not thread-safe. Before running a synchronized class method, Java obtains a lock on the class, to ensure that no other threads can modif the class concurrently. Before running a synchronized instance method, Java obtains a lock on the instance that invoked the method, ensuring that no other thread can modify the object at the same time.

transient

> The transient keyword is a modifier that may be applied to instance fields in a class. This modifier is legal but unused in Java 1.0. In Java 1.1, it indicates a field that is not part of an object's persistent state and thus does not need to be serialized with the object.

volatile

> The volatile keyword is a modifier that may be applied to fields. It specifies that the field is used by synchronized threads and that the compiler should not attempt to perform optimizations with it. For example, it should read the variable's value from memory every time and not attempt to save a copy of it on the stack.

No Structures or Unions

Java does not support C struct or union types. Note, however, that a class is essentially the same thing as a struct, but with more features. And you can simulate the important features of a union by subclassing.

No Enumerated Types

Java does not support the C enum keyword for defining types that consist of one of a specified number of named values. This is somewhat surprising for a strongly-typed language like Java. Enumerated types can be partially simulated with the use of static final constant values.

No Method Types

C allows you to store the address of a function in a variable and to pass function addresses to other functions. You cannot do this in Java: methods are not data, and cannot be manipulated by Java programs. Note, however, that objects are data, and that objects can define methods. [9] So, when you need to pass a method to another method, you declare a class that defines the desired method and pass an instance of that class. See, for example, the `FilenameFilter` interface in the `java.io` package.

[9] An interesting way to think about objects in Java is as a kind of method that defines multiple entry points.

No Bitfields

Java does not support the C ability to define variables that occupy particular bits within `struct` and `union` types. This feature of C is usually only used to interface directly to hardware devices, which is never necessary with Java's platform-independent programming model.

No typedef

Java does not support the C `typedef` keyword to define aliases for type names. Java has a much simpler type naming scheme than C does, however, and so there is no need for something like `typedef`.

No Variable-Length Argument Lists

Java does not allow you to define methods that take a variable number of arguments, as C does. This is because Java is a strongly typed language and there is no way to do appropriate type checking for a method with variable arguments. Method overloading allows you to simulate C "varargs" functions for simple cases, but there is no general replacement for this C feature.

3. Classes and Objects in Java

Contents:

Java is an *object-oriented* language. "Object-oriented" is a term that has become so commonly used as to have practically no concrete meaning. This chapter explains just what "object-oriented" means for Java. It covers:

- Classes and objects in Java
- Creating objects
- Garbage collection to free up unused objects
- The difference between class (or static) variables and instance variables, and the difference between class (or static) methods and instance methods
- Extending a class to create a subclass
- Overriding class methods and dynamic method lookup
- Abstract classes

- Interface types and their implementation by classes

If you are a C++ programmer, or have other object-oriented programming experience, many of the concepts in this list should be familiar to you. If you do not have object-oriented experience, don't fear: This chapter assumes no knowledge of object-oriented concepts.

We saw in the last chapter that close analogies can be drawn between Java and C. Unfortunately for C++ programmers, the same is not true for Java and C++. Java uses object-oriented programming concepts that are familiar to C++ programmers, and it even borrows from C++ syntax in a number of places, but the analogies between Java and C++ are not nearly as strong as those between Java and C. [1] C++ programmers may have an easier time with this chapter than C programmers will, but they should still read it carefully and try not to form preconceptions about Java based on their knowledge of C++.

[1] As we'll see, Java supports garbage collection and dynamic method lookup. This actually makes it a closer relative, beneath its layer of C-like syntax, to languages like Smalltalk than to C++.

3.1 Introduction to Classes and Objects

A *class* is a collection of data and methods that operate on that data. [2] The data and methods, taken together, usually serve to define the contents and capabilities of some kind of *object*.

[2] A *method* is the object-oriented term for a procedure or a function. You'll see it used a lot in this book. Treat it as a synonym for "procedure."

For example, a circle can be described by the x, y position of its center and by its radius. There are a number of things we can do with circles: compute their circumference, compute their area, check whether points are inside them, and so on. Each circle is different (i.e., has a different center or radius), but as a *class*, circles have certain intrinsic properties that we can capture in a definition. Example 3.1 shows how we could partially define the class of circles in Java. Notice that the class definition contains data and methods (procedures) within the same pair of curly brackets. [3]

[3] C++ programmers should note that methods go inside the class definition in Java, not outside with the `::` operator as they usually do in C++.

Example 3.1: The Class of Circles, Partially Captured in Java Code

```
public class Circle {
    public double x, y;   // The coordinates of the center
    public double r;      // The radius
    // Methods that return the circumference and area of the circle
    public double circumference() { return 2 * 3.14159 * r; }
    public double area() { return 3.14159 * r*r; }
}
```

Objects Are Instances of a Class

Now that we've defined (at least partially) the class `Circle`, we want to do something with it. We can't do anything with the class of circles itself--we need a particular circle to work with. We need an *instance* of the class, a single circle object.

By defining the `Circle` class in Java, we have created a new data type. We can declare variables of that type:

```
Circle c;
```

But this variable `c` is simply a name that *refers to* a circle object; it is not an object itself. In Java, all objects must be created dynamically. This is almost always done with the `new` keyword:

```
Circle c;
c = new Circle();
```

Now we have created an instance of our `Circle` class--a circle object--and have assigned it to the variable `c`, which is of type `Circle`.

Accessing Object Data

Now that we've created an object, we can use its data fields. The syntax should be familiar to C programmers:

```
Circle c = new Circle();
c.x = 2.0;  // Initialize our circle to have center (2, 2) and radius 1.0.
c.y = 2.0;
c.r = 1.0;
```

Using Object Methods

This is where things get interesting! To access the methods of an object, we use the same syntax as accessing the data of an object:

```
Circle c = new Circle();
double a;
c.r = 2.5;
a = c.area();
```

Take a look at that last line. We did not say:

```
a = area(c);
```

We said:

```
a = c.area();
```

This is why it is called "object-oriented" programming; the object is the focus here, not the function call. This is probably the single most important feature of the object-oriented paradigm.

Note that we don't have to pass an argument to `c.area()`. The object we are operating on, `c`, is implicit in the syntax. Take a look at Example 3.1 again: you'll notice the same thing in the definition of the `area()` method--it doesn't take an argument. It is implicit in the language that a method operates on an instance of the class within which it is defined. Thus our `area()` method can use the `r` field of the class freely--it is understood that it is referring to the radius of whatever `Circle` instance invokes the method.

How It Works

What's going on here? How can a method that takes no arguments know what data to operate on? In fact, the `area()` method does have an argument! `area()` is implemented with an implicit argument that is not shown in the method declaration. The implicit argument is named `this`, and refers to "this object"--the `Circle` object through which the method is invoked. `this` is often called the "this pointer." [4]

[4] "this pointer" is C++ terminology. Since Java does not support pointers, I prefer the term "this reference."

The implicit `this` argument is not shown in method signatures because it is usually not needed--whenever a Java method accesses the fields in its class, it is implied that it is accessing fields in the object referred to by the `this` argument. The same is true, as we'll see, when a method in a class invokes other methods in the class--it is implicit that the methods are being invoked for the `this` object.

We can use the `this` keyword explicitly when we want to make explicit that a method is accessing its own variables and/or methods. For example, we could rewrite the `area()` method like this:

```
public double area() { return 3.14159 * this.r * this.r; }
```

In a method this simple, it is not necessary to be explicit. In more complicated cases, however, you may find that it increases the clarity of your code to use an explicit `this` where it is not strictly required.

An instance where the `this` keyword *is* required is when a method argument or a local variable in a method has the same name as one of the fields of the class. In this case, you must use `this` to access the field. If you used the field name alone, you would end up accessing the argument or local variable with the same name. We'll see examples of this in the next section.

Miscellaneous Differences BOOK INDEX Object Creation

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

3.2 Object Creation

Take another look at how we've been creating our circle object:

```
Circle c = new Circle();
```

What are those parentheses doing there? They make it look like we're calling a function! In fact, that is exactly what we're doing. Every class in Java has at least one *constructor* method, which has the same name as the class. The purpose of a constructor is to perform any necessary initialization for the new object. Since we didn't define one for our `Circle` class, Java gave us a default constructor that takes no arguments and performs no special initialization.

The way it works is this: The `new` keyword creates a new dynamic instance of the class--i.e., it allocates the new object. The constructor method is then called, passing the new object implicitly (a `this` reference, as we saw above), and passing the arguments specified between parentheses explicitly.

Defining a Constructor

There is some obvious initialization we could do for our circle objects, so let's define a constructor. Example 3.2 shows a constructor that lets us specify the initial values for the center and radius of our new `Circle` object. The example also shows a use of the `this` keyword, as described in the previous section.

Example 3.2: A Constructor for the Circle Class

```
public class Circle {
    public double x, y, r;  // The center and the radius of the circle
    // The constructor method.
    public Circle(double x, double y, double r)
    {
        this.x = x;
        this.y = y;
        this.r = r;
    }
    public double circumference() { return 2 * 3.14159 * r; }
    public double area() { return 3.14159 * r*r; }
}
```

With the old, default constructor, we had to write code like this:

```
Circle c = new Circle();
c.x = 1.414;
c.y = -1.0;
c.r = .25;
```

With this new constructor the initialization becomes part of the object creation step:

```
Circle c = new Circle(1.414, -1.0, .25);
```

There are two important notes about naming and declaring constructors:

- The constructor name is always the same as the class name.
- The return type is implicitly an instance of the class. No return type is specified in constructor declarations, nor is the `void` keyword used. The `this` object is implicitly returned; a constructor should not use a `return` statement to return a value.

Multiple Constructors

Sometimes you'll want to be able to initialize an object in a number of different ways, depending on what is most convenient in a particular circumstance. For example, we might want to be able to initialize the radius of a circle without initializing the center, or we might want to initialize a circle to have the same center and radius as another circle, or we might want to initialize all the fields to default values. Doing this is no problem: A class can have any number of constructor methods. Example 3.3 shows how.

Example 3.3: Multiple Circle Constructors

```
public class Circle {
    public double x, y, r;
    public Circle(double x, double y, double r) {
        this.x = x; this.y = y; this.r = r;
    }
    public Circle(double r) { x = 0.0; y = 0.0; this.r = r; }
    public Circle(Circle c) { x = c.x; y = c.y; r = c.r; }
    public Circle() { x = 0.0; y = 0.0; r = 1.0; }
    public double circumference() { return 2 * 3.14159 * r; }
    public double area() { return 3.14159 * r*r; }
}
```

Method Overloading

The surprising thing in this example (not so surprising if you're a C++ programmer) is that all the constructor methods have the same name! So how can the compiler tell them apart? The way that you and I tell them apart is that the four methods take different arguments and are useful in different circumstances. The compiler tells them apart in the same way. In Java, a method is distinguished by its name, and by the number, type, and position of its arguments. This is not limited to constructor methods--any two methods are not the same unless they have the same name, and the same number of arguments of the same type passed at the same position in the argument list. When you call a method and there is more than one method with the same name, the compiler automatically picks the one that matches the data types of the arguments you are passing.

Defining methods with the same name and different argument types is called *method overloading*. It can be a convenient technique, as long as you only give methods the same name when they perform similar functions on slightly different forms of input data. Overloaded methods may have different return types, but only if they have different arguments. Don't confuse method overloading with *method overriding*, which we'll discuss later.

this Again

There is a specialized use of the `this` keyword that arises when a class has multiple constructors--it can be used from a constructor to invoke one of the other constructors of the same class. So we could rewrite the additional constructors from Example 3.3 in terms of the first one like this:

```
public Circle(double x, double y, double r) {
    this.x = x; this.y = y; this.r = r;
}
public Circle(double r) { this(0.0, 0.0, r); }
public Circle(Circle c) { this(c.x, c.y, c.r); }
public Circle() { this(0.0, 0.0, 1.0); }
```

Here, the `this()` call refers to whatever constructor of the class takes the specified type of arguments. This would be a more impressive example, of course, if the first constructor that we were invoking did a more significant amount of initialization, as it might, for example, if we were writing a more complicated class.

There is a very important restriction on this `this` syntax: it may only appear as the first statement in a constructor. It may, of course, be followed by any additional initialization that a particular version of the constructor needs to do. The reason for this restriction involves the automatic invocation of superclass constructor methods, which we'll explore later in this chapter.

Introduction to Classes and Objects | BOOK INDEX | Class Variables

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

3.3 Class Variables

In our `Circle` class definition, we declared three "instance" variables: `x`, `y`, and `r`. Each instance of the class--each circle--has its own copy of these three variables. These variables are like the fields of a `struct` in C--each instance of the `struct` has a copy of the fields. Sometimes, though, we want a variable of which there is only one copy--something like a global variable in C.

The problem is that Java doesn't allow global variables. (Actually, those in the know consider this is feature!) Every variable in Java must be declared inside a class. So Java uses the `static` keyword to indicate that a particular variable is a *class variable* rather than an *instance variable*. That is, that there is only one copy of the variable, associated with the class, rather than many copies of the variable associated with each instance of the class. The one copy of the variable exists regardless of the number of instances of the class that are created--it exists and can be used even if the class is never actually instantiated.

This kind of variable, declared with the `static` keyword, is often called a *static variable*. I prefer (and recommend) the name "class variable" because it is easily distinguished from its opposite, "instance variable." We'll use both terms in this book.

An Example

As an example (a somewhat contrived one), suppose that while developing the `Circle` class we wanted to do some testing on it and determine how much it gets used. One way to do this would be to count the number of `Circle` objects that are instantiated. To do this we obviously need a variable associated with the class, rather than with any particular instance. Example 3.4 shows how we can do it--we declare a `static` variable and increment it each time we create a `Circle`.

Example 3.4: Static Variable Example

```
public class Circle {
    static int num_circles = 0; // class variable: how many circles created
    public double x, y, r;      // instance vars: the center and the radius
    public Circle(double x, double y, double r) {
        this.x = x; this.y = y; this.r = r;
        num_circles++;
    }
    public Circle(double r) { this(0.0, 0.0, r); }
    public Circle(Circle c) { this(c.x, c.y, c.r); }
    public Circle() { this(0.0, 0.0, 1.0); }
    public double circumference() { return 2 * 3.14159 * r; }
    public double area() { return 3.14159 * r*r; }
}
```

Accessing Class Variables

Now that we are keeping track of the number of `Circle` objects created, how can we access this information? Because `static` variables are associated with the class rather than with an instance, we access them through the class rather than through the instance. Thus, we might write: [5]

> [5] Recall that `System.out.println()` prints a line of text, and that the string concatenation operator, `+`, converts non-string types to strings as necessary.

```
System.out.println("Number of circles created: " + Circle.num_circles);
```

Notice that in our definition of the constructor method in Example 3.4, we just used `num_circles` instead of `Circle.num_circles`. We're allowed to do this within the class definition of `Circle` itself. Anywhere else, though, we must use the class name as well.

Global Variables?

Earlier we said that Java does not support global variables. In a sense, though, `Circle.num_circles` behaves just like one. What is different from a global variable in C is that there is no possibility of name conflicts. If we use some other class with a class variable named `num_circles`, there won't be a "collision" between these two "global" variables, because they must both be referred to by their class names. Since each class variable must be part of a class and must be referred to with its class name, each has a unique name. Furthermore, each class has a unique name because, as we saw in Chapter 2, *How Java Differs from C*, it is part of a package with a unique name.

Constants: Another Class Variable Example

Let's try a less forced example of why you might want to use a class variable with the `Circle` class. When computing the area and circumference of circles, we use the value pi. Since we use the value frequently, we don't want to keep typing out 3.14159, so we'll define it as a class variable that has a convenient name:

```
public class Circle {
    public static final double PI = 3.14159265358979323846;
    public double x, y, r;
    // ... etc....
}
```

Besides the static keyword that we've already seen, we use the final keyword, which means that this variable can never have its value changed. This prevents you from doing something stupid like:

```
Circle.PI = 4;
```

which would tend to give you some pretty square-looking circles.

The Java compiler is smart about variables declared both static and final--it knows that they have constant values. So when you write code like this:

```
double circumference = 2 * Circle.PI * radius;
```

the compiler precomputes the value 2 * Circle.PI , instead of leaving it for the interpreter.

Java does not have a preprocessor with a C-style #define directive. static final variables are Java's substitute for C's #define'd constants. Note that the C convention of capitalizing constants has been carried over into Java.

PREVIOUS Object Creation | HOME BOOK INDEX | NEXT Class Methods

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

3.4 Class Methods

Let's define a new method in our `Circle` class. This one tests whether a specified point falls within the defined circle:

```
public class Circle {
    double x, y, r;
    // is point (a,b) inside this circle?
    public boolean isInside(double a, double b)
    {
        double dx = a - x;
        double dy = b - y;
        double distance = Math.sqrt(dx*dx + dy*dy);
        if (distance < r) return true;
        else return false;
    }
        .
        .  // Constructor and other methods omitted.
        .
}
```

What's this `Math.sqrt()` thing? It looks like a method call and, given its name and its context, we can guess that it is computing a square root. But the method calls we've discussed are done through an object. `Math` isn't the name of an object that we've declared, and there aren't any global objects in Java, so this must be a kind of method call that we haven't seen before.

static Methods

What's going on here is that `Math` is the name of a class. `sqrt()` is the name of a *class method* (or static method) defined in `Math`. It differs from the *instance methods*, such as `area()` in `Circle`, that we've seen so far.

Class methods are like class variables in a number of ways:

- Class methods are declared with the `static` keyword.

- Class methods are often referred to as "static methods."

- Class methods are invoked through the class rather than through an instance. (Although within the class they may be invoked by method name alone.)

- Class methods are the closest Java comes to "global" methods. Because they must be referred to by the class name, there is no danger of name conflicts.

No this

Class methods differ from instance methods in one important way: they are not passed an implicit `this` reference. Thus, these `this`-less methods are not associated with any instance of the class and may not refer to any instance variables or invoke instance methods.

Since class methods are not passed a `this` reference, and are not invoked through an object, they are the closest thing that Java offers to the "normal" C procedures that you may be accustomed to, and may therefore seem familiar and comforting. If you're sick and tired of this object-oriented business, it is perfectly possible to write complete Java programs using only class methods, although this does defeat an important purpose of using the language!

But don't think that class methods are somehow cheating--there are perfectly good reasons to declare a method `static`. And indeed, there are classes like `Math` that declare all their methods (and variables) `static`. Since `Math` is a collection of functions that operate on floating-point numbers, which are a primitive type, there are no objects involved, and no need for instance methods. `System` is another class that defines only class methods--it provides a varied collection of system functions for which there is no appropriate object framework.

A Class Method for Circles

Example 3.5 shows two (overloaded) definitions of a method for our `Circle` class. One is an instance method and one is a class method.

Example 3.5: A Class Method and an Instance Method

```
public class Circle {
    public double x, y, r;
    // An instance method.  Returns the bigger of two circles.
    public Circle bigger(Circle c) {
        if (c.r > r) return c; else return this;
    }
    // A class method.  Returns the bigger of two circles.
    public static Circle bigger(Circle a, Circle b) {
        if (a.r > b.r) return a; else return b;
    }
```

```
        .
        .  // Other methods omitted here.
        .
}
```

You would invoke the instance method like this:

```
Circle a = new Circle(2.0);
Circle b = new Circle(3.0);
Circle c = a.bigger(b);         // or, b.bigger(a);
```

And you would invoke the class method like this:

```
Circle a = new Circle(2.0);
Circle b = new Circle(3.0);
Circle c = Circle.bigger(a,b);
```

Neither of these is the "correct" way to implement this method. One or the other will seem more natural, depending on circumstances.

A Mystery Explained

Now that we understand class variables, instance variables, class methods, and instance methods, we are in a position to explore that mysterious method call we saw in our very first Java "Hello World" example:

```
System.out.println("Hello world!");
```

One hypothesis is that `println()` is a class method in a class named `out`, which is in a package named `System`. Syntactically, this is perfectly reasonable (except perhaps that class names always seem to be capitalized by convention, and `out` isn't capitalized). But if you look at the API documentation, you'll find that `System` is not a package name; it is the name of a class (which is in the `java.lang` package, by the way). Can you figure it out?

Here's the story: `System` is a class. It has a class variable named `out`. `out` refers to an object of type `PrintStream`. The object `System.out` has an instance method named `println()`. Mystery solved!

Static Initializers

Both class and instance variables can have initializers attached to their declarations. For example:

```
static int num_circles = 0;
float r = 1.0;
```

Class variables are initialized when the class is first loaded. Instance variables are initialized when an object is created.

Sometimes we need more complex initialization than is possible with these simple variable initializers. For instance variables, there are constructor methods, which are run when a new instance of the class is created. Java also allows you to write an initialization method for class variables. Such a method is called a *static initializer*.

The syntax of static initializers gets kind of bizarre. Consider that a static initializer is invoked automatically by the system when the class is loaded. Thus there are no meaningful arguments that can be passed to it (unlike the arguments we can pass to a constructor method when creating a new instance). There is also no value to return. So a static initializer has no arguments and no return value. Furthermore, it is not really necessary to give it a name, since the system calls the method automatically for us. What part of a method declaration is left? Just the `static` keyword and the curly brackets!

Example 3.6 shows a class declaration with a static initializer. Notice that the class contains a regular static variable initializer of the kind we've seen before, and also a static initializer--an arbitrary block of code between `{` and `}`.

Example 3.6: A Static Initializer

```
// We can draw the outline of a circle using trigonometric functions.
// Trigonometry is slow though, so we pre-compute a bunch of values.
public class Circle {
    // Here are our static lookup tables, and their own simple initializers.
    static private double sines[] = new double[1000];
    static private double cosines[] = new double[1000];
    // Here's a static initializer "method" that fills them in.
    // Notice the lack of any method declaration!
    static {
        double x, delta_x;
        int i;
        delta_x = (Circle.PI/2)/(1000-1);
        for(i = 0, x = 0.0; i < 1000; i++, x += delta_x) {
            sines[i] = Math.sin(x);
            cosines[i] = Math.cos(x);
        }
    }
        .
        .  // The rest of the class omitted.
        .
}
```

The syntax gets even a little stranger than this. Java allows any number of static initializer blocks of code to appear within a class definition. What the compiler actually does is to internally produce a single class initialization routine that combines all the static variable initializers and all of the static initializer blocks of code, in the order that they appear in the class declaration. This single initialization procedure is run automatically, one time only, when the class is first loaded.

One common use of static initializers is for classes that implement `native` methods--i.e., methods written in C. The static initializer for such a class should call `System.load()` or `System.loadLibrary()` to read in the native library that implements these native methods.

Instance Initializers

In Java 1.1, a class definition may also include *instance initializers*. These look like static initializers, but without the `static` keyword. An instance initializer is like a constructor: it runs when an instance of the class is created. We'll see more about instance initializers in Chapter 5, *Inner Classes and Other New Language Features*, *Inner Classes and Other New Language Features*.

5. Inner Classes and Other New Language Features

Contents:

The largest enhancement to the Java language in Java 1.1 is something called "inner classes." With this addition to the language, classes can be defined as members of other classes, just as fields and methods can be defined within classes. Classes can also be defined within a block of Java code, just as local variables can be defined within a block of code.

From one point of view, the addition of inner classes regularizes the syntax of Java. From another point of view, though, inner classes create quite a few special cases, and a confusing array of new rules. In practice, however, if you avoid the obscure and pathological cases, inner classes prove to be an elegant and extremely useful addition to the language. Their use is particularly common in conjunction with the new event model defined by the AWT in Java 1.1.

5.1 An Overview of Inner Classes

Java 1.0 allowed classes and interfaces to be defined in exactly one context: at the "top level," as members of packages. Java 1.1 adds one new type of top-level classes and interfaces, and adds three new types of "inner classes," as outlined below. Later sections of this chapter describe each of these new types of classes and interfaces in more detail and present examples of their use.

Nested top-level classes and interfaces

A *nested top-level* class or interface is defined as a static member of an enclosing top-level class or interface. The definition of a nested top-level class uses the `static` modifier, just as the definition of a static method or static field does. Nested interfaces are implicitly static (though they may be declared `static` to make this explicit) and so are always top-level. A nested top-level class or interface behaves just like a "normal" class or interface that is a member of a package. The difference is that the name of a nested top-level class or interface includes the name of the class in which it is defined. Thus, a `LinkedList` class could define a nested top-level interface `Linkable`. This interface would be referred to as `LinkedList.Linkable`. Nested top-level classes and interfaces are typically used as a convenient way to group related classes.

Member classes

A *member class* is also defined as a member of an enclosing class, but unlike a nested top-level class, it is not defined with the `static` modifier. This means that it is an inner class, rather than a top-level class. Nested interfaces are always implicitly `static`, so they are always top-level; there is no such thing as a "member interface," or any kind of "inner interface." In many ways, a member class is analogous to the other members--the instance fields and methods--of a class. Member classes are of interest because the code within a member class can implicitly refer to any of the fields and methods, including `private` fields and methods, of its enclosing class. [1] Every instance of a member class is associated with an enclosing instance of the class that defines it. Because of the requirement for this enclosing instance, several new pieces of syntax have been introduced into the Java language.

[1] Unfortunately, in Java 1.1 and 1.1.1 there are compiler bugs that prevent access to the `private` fields and methods of enclosing classes from working correctly. It is not yet clear when these bugs will be fixed. So while access to `private` members of enclosing classes is part of the inner class specification, it is a feature that is currently best avoided. If a field or method must be visible to nested classes, you should give it package visibility rather than `private` visibility.

Local classes

A *local class* is an inner class defined within a block of Java code; it is visible only within that block. Interfaces can not be defined locally. Because a local class is defined within a block of code, it is analogous, in some ways, to a local variable. Local classes are not member classes, but can still use the fields and methods of enclosing classes. More important, however, the code within a local class definition can use any `final` local variables or parameters that are accessible in the scope of the block that defines the class. Local classes are useful primarily as "adapter classes" and are commonly used with the new event-handling model required by the Java 1.1 AWT and by JavaBeans. For example, a block of Java 1.1 code that creates a `java.awt.Button` object could use a local class to define a simple implementation of the `java.awt.event.ActionListener` interface. Then it could instantiate this simple implementation and pass the resulting object to the button's `addActionListener()` method, thereby connecting the button to the "callback" code that is executed when the button is pressed.

Anonymous classes

An *anonymous class* is an extension to the local class concept described above. Instead of declaring a local class with one Java statement, and then instantiating and using it in another statement, an anonymous class combines the two steps in a single Java expression. An anonymous class, as you might guess, does not have a name. And because it is instantiated in the same expression that defines it, it can only be instantiated once. Except for these differences, anonymous classes are quite similar to local classes in behavior and use. Interfaces cannot be defined anonymously, of course. When writing a simple adapter class, the choice between a named local class and an unnamed anonymous class typically comes down to a matter of style and code clarity, rather than any difference in functionality.

Table 5.1 summarizes the types of classes and interfaces that can be defined in Java 1.1; the remaining sections of the chapter document each type in more detail.

Table 5.1: Inner Class Summary

Class Type		**Description**
Top-level classes and interfaces	Package member class or interface	An ordinary class or interface that is a direct member of a package. The basic Java class understood by the VM. All nested and inner classes are converted to this type.
	Nested top-level class or interface	A conveniently nested top-level class or interface. Must be declared `static` within another top-level class or interface. (Nested interfaces are implicitly `static`.) May use the `static` members of its containing type.

Inner classes	Member class	A class defined as a member (non-`static`) of another. Each instance has an enclosing instance, and can use its members. New syntax for `this`, `new`, and `super`. Cannot have `static` members. Cannot have same name as a containing class.
	Local class	A class defined in a block of code. Can use members of enclosing classes and `final` local variables and parameters. New `this` syntax. Same restrictions as member classes.
	Anonymous class	Unnamed class defined within an expression. Has features of a local class. Allows a one-shot class to be defined exactly where needed. Same restrictions as local class, plus has no name or constructor. Only one instance of the class is created.

4.12 New JDK Utilities

JDK 1.1 includes a number of new tools. In the discussion of applets above, we've already seen *jar* for creating JAR archives and *javakey* for adding digital signatures to JAR archives. In fact, *javakey* can do much more than that--it is a very flexible tool for managing a database of entities, generating keys and certificates, and generating digital signatures.

serialver is a new tool used in conjunction with object serialization. When an object is deserialized, it is important to verify that the version of the class file for that object matches the version that was used to serialize it. This is done by computing a unique identifier for the class and encoding it in a private variable of the class. When an incompatible change is made to the class, a new unique identifier is computed, and the new value is stored in the private variable. It is the *serialver* tool that is used to compute this unique identifier.

native2ascii is a tool for programmers who program in a locale that uses a non-ASCII file encoding. The *javac* compiler can only compile files encoded in ASCII, with all Unicode characters converted to the `\u`*xxxx* format. What *native2ascii* does is to convert its input file to Unicode, and then output that Unicode version as an ASCII file that uses the `\u` escape for all non-ASCII Unicode characters. After you process a locally-encoded file with *native2ascii*, *javac* can compile it.

In addition to the tools described here, JDK 1.1 also includes two new programs, *rmic* and *rmiregistry*, that are used in conjunction with Remote Method Invocation. They will be documented in *Java Enterprise in a Nutshell*.

4.11 Applet Changes

There are several new features in Java 1.1 that affect applets. The first is the introduction of JAR files. "JAR" stands for Java ARchive, and a JAR file is just that: an archive of files used by a Java applet. An applet often requires multiple class files, as well as images, sounds, and other resources, to be loaded over the network. Prior to Java 1.1, each of these files was loaded through a separate HTTP request, which is fairly inefficient. With Java 1.1, all (or many) of the files an applet needs can be combined into a single JAR file, which an applet viewer or Web browser can download with a single HTTP request. Chapter 6, *Applets*, demonstrates the use of JAR files.

JAR files are stored in the ZIP file format. A JAR archive can be created with the *jar* tool shipped with the JDK. Once you have created a JAR file, you refer to it in a `<APPLET>` tag with the `ARCHIVE` attribute. This `ARCHIVE` attribute may actually be set to a comma-separated list of archive files to be downloaded. Note that specifying an `ARCHIVE` attribute simply tells the applet viewer or browser the name of a JAR file or files to load; it does not tell the browser the name of the applet that is to be run. Thus, you still must specify the `CODE` attribute (or the new `OBJECT` attribute, as we'll see below). For example, you might use an `<APPLET>` tag like the following to tell the browser to download the *animation.jar* file and start the applet contained in the file *Animator.class*:

```
<APPLET CODE="Animator.class" ARCHIVE="animation.jar" WIDTH=500 HEIGHT=200>
</APPLET>
```

There is another advantage to the use of JAR files. Every JAR file contains a "manifest" file, which you either specify explicitly when you create the archive, or which is created for you by the *jar* tool. The manifest is stored in a file named `META-INF/MANIFEST.MF` and contains meta-information about the files in the archive. By default, the *jar* tool creates a manifest file that contains MD5 and SHA message digests for each file in the archive. This information can be used by the applet viewer or Web browser to verify that the files in the archive have not been corrupted since the JAR file was created.

The main reason to include message digests in the manifest file, however, is so that a JAR file can have digital signatures added to it. An archive can be signed with the *javakey* tool. What a digital signature allows you to do is verify that the files in a JAR file have not been modified since the digital signature was added to the archive. If you trust the person or entity who signed the file, then you ought to trust the applet contained in the JAR file. (The *javakey* tool allows you to specify whether or not you trust any given entity.) Chapter 6, *Applets* also describes how you might use digital signatures and *javakey*.

In JDK 1.1, the *appletviewer* tool understands digitally signed JAR files. When it loads an applet that has been signed by a trusted entity, it runs that applet without subjecting it to the usual security restrictions--the applet can read and write files, and do anything that a standalone Java application can do. Common Web browsers are likely to follow suit and give special privileges to trusted applets. One refinement we may see in the future is the ability to specify varying levels of trust, and to assign different sets of privileges to applets at those varying trust levels.

Besides the introduction of JAR files and trusted applets, Java 1.1 also supports "serialized applets." In an `<APPLET>` tag, you can specify the `OBJECT` attribute instead of the `CODE` attribute. If you do this, the value of the `OBJECT` attribute should be the name of a file that contains a serialized representation of the applet to be run. Graphical application-builder tools may prefer to output applets as pre-initialized object trees, rather than generating custom Java code to perform the initializations. See Chapter 9, *Object Serialization* for more information on serialized applets.

4.10 Enterprise APIs: JDBC, RMI, and Security

Java 1.1 provides a number of important new features that are loosely grouped under the name "Enterprise APIs." These include JDBC (Java DataBase Connectivity), RMI (Remote Method Invocation), and Java Security. With release 1.1, Java has grown too big for all of it to be documented, even in quick-reference format, in a single volume. Therefore, the JDBC, RMI, and Security packages will be documented, along with other, forthcoming Enterprise APIs, in a separate volume, *Java Enterprise in a Nutshell*. Note, however, that while this volume does not cover the Java Security API, it *does* cover applet security, signed applets, and the *javakey* program that is used to create digital signatures, generate key pairs, and manage a database of entities and their keys.

4.9 Java Beans

JavaBeans is a "software component model" for Java that has generated quite a lot of interest from many quarters. The JavaBeans API specification defines "beans" as follows: "A Java Bean is a reusable software component that can be manipulated visually in a builder tool." The `java.beans` package defines classes and interfaces designed to work with beans at three distinct levels, described below.

Much of the JavaBeans API is intended for use only by those few people who are writing interface builder tools that manipulate beans. The main thing that a builder tool needs to be able to do with beans is "introspect" on them--i.e., to determine what properties are exposed by a bean, what methods it exports, and what events it can generate. This is information that a builder tool must be able to display to the programmer who is using the tool. The JavaBeans API defines a set of naming conventions for the methods that a bean defines. If a bean follows these conventions, a builder tool can use the new Reflection API to determine what properties, methods, and events the bean supports. The `Introspector` class uses reflection to obtain information about a bean and presents it to the builder tool in the form of a `BeanInfo` object, which itself contains various `FeatureDescriptor` objects describing the properties, methods, and events of the bean.

At the second level, the JavaBeans API contains classes and interfaces intended for use by programmers who are creating beans for others to use. Chapter 10, *Java Beans* describes how to use the classes in `java.beans` in this manner. One of the surprising features of the JavaBeans API is that there is no `Bean` class that all beans must extend. A bean can be of any class; however, as we've seen, beans should follow certain naming conventions. The `java.beans` classes that a bean creator uses are generally auxiliary classes, used not by the bean, but by the builder tool that manipulates the bean. These auxiliary classes are shipped with a bean, and provide additional information or methods that a builder tool may use with the bean. These classes are not included in finished software built with the bean.

For example, one of the auxiliary classes a bean may define is a custom `BeanInfo` class to provide information to the builder tool that is not available through the Reflection API. This information might include a human-readable description of the bean's properties, methods, and events, for example. Or, if a bean does not follow the standard naming conventions, this custom `BeanInfo` class must also provide more basic information about the bean's properties, methods, and events.

Besides a `BeanInfo` class, complex beans may also provide a `Customizer` class and one or more `PropertyEditor` classes. A `Customizer` class is a kind of configuration tool or "wizard" for a bean. It is instantiated by the builder tool in order to guide the user through bean customization. A `PropertyEditor` class is used to allow the user to edit the value of bean properties of a particular class. Builder tools have built-in property editors for common types such as strings, colors, and fonts, but a bean that has properties of some unusual or custom type may want to provide a `PropertyEditor` subclass to allow the user to easily specify values for those properties.

The third level at which the JavaBeans API can be used is by programmers who are assembling an application using beans. Some programmers may do this through a builder tool, while others may do it "by hand", the old-fashioned way. Programmers using beans do not typically have to use the `java.beans` package. At this level, it is more a matter of reading the documentation for the particular beans being used and following those instructions. Nevertheless, a programmer using beans does need to be familiar with the event model used by beans, which is the same as the Java 1.1 event model for AWT. Also, programmers using beans "by hand" should be familiar with the naming conventions for bean properties, methods, and events, in order to more easily understand how a given bean can be used. In Java 1.1, all AWT components are beans and follow these naming conventions.

4.8 Reflection

Reflection in Java 1.1 refers to the ability of Java classes to reflect upon themselves, or to "look inside themselves." The `java.lang.Class` class has been greatly enhanced in Java 1.1. It now includes methods that return the fields, methods, and constructors defined by a class. These items are returned as objects of type `Field`, `Method`, and `Constructor`, respectively. These new classes are part of the new `java.lang.reflect` package, and they each provide methods to obtain complete information about the field, method, or constructor they represent. For example, the `Method` object has methods to query the name, the parameter types, and the return type of the method it represents. Chapter 12, *Reflection* provides some examples of using the Reflection API.

Besides allowing a program to inspect the members of a class, the `java.lang.reflect` package also allows a program to manipulate these fields and methods. The `Field` class defines methods that get and set the value of the represented field for any given object of the appropriate type. Similarly, the `Method` object defines an `invoke()` method that allows the represented method to be invoked, and the `Constructor` class defines a `newInstance()` method that creates a new object and invokes the represented constructor on it. `java.lang.reflect` also defines an `Array` class. It does not represent a specific array, but defines static methods that read and write array elements and dynamically create new arrays.

With the addition of reflection, the `Class` class has been expanded to represent not just Java classes, but any Java type, including primitive types and array types. There is a special `Class` object that represents each of the eight Java primitive types, and another special `Class` object that represents the `void` type. These special `Class` objects are available as constants in the wrapper objects for the primitive types. `Integer.TYPE` is a `Class` object that represents the `int` type, for example, and `Void.TYPE` is a `Class` object that represents the `void` type.

Finally, new Java language syntax makes it easier to obtain a `Class` object that represents a Java class. If you follow the name of a class, interface, or other type with `.class`, Java evaluates that expression and returns the corresponding `Class` object. So, for example, the following two expressions are equivalent:

```
String.class
Class.forName("java.lang.String")
```

Note that this syntax also works with primitive type names: you can write `short.class`, for example, which returns the same value as `Short.TYPE`.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

4.7 Object Serialization

Object serialization is one of the major new features of Java 1.1. It refers to the ability to write the complete state of an object (including any objects it refers to) to an output stream, and then recreate that object at some later time by reading its serialized state from an input stream. You can serialize an object simply by passing it to the `writeObject()` method of an `ObjectOutputStream`. Similarly, you can create an object from a serialized object stream by calling the `readObject()` method of an `ObjectInputStream`. Both of these new object stream types are part of the `java.io` package.

Typically, object serialization is as simple as calling `writeObject()` and `readObject()`. There are a few additional twists, however, that are worth mentioning here. First, only objects that subclass the `Serializable` (or `Externalizable`) interface can be serialized. The `Serializable` interface does not define any methods, but merely acts as a marker that indicates whether serialization is allowed on a given object. Second, fields of a class declared `transient` are not serialized as part of an object's state. The `transient` modifier was legal in Java 1.0, but had no defined behavior. Third, some objects may need to implement custom serialization or de-serialization behavior. They can do this by implementing special `readObject()` and `writeObject()` methods. Chapter 9, *Object Serialization* describes all of these aspects of object serialization in more detail.

Despite the fact that only a few classes and interfaces are part of the Object Serialization API, serialization is a very important technology and is used in several places in Java 1.1. It is used as the basis for transferring objects via cut-and-paste. It is used to transfer objects between a client and a server for remote method invocation. It is used by the JavaBeans API--beans are often provided as pre-initialized, serialized objects, rather than merely as class files. Java 1.1 also adds the capability for applets to be loaded into an applet viewer or browser as serialized objects. One common use we are likely to see for object serialization is as a way to save user preferences and other application states--a serialized object is an instant file format that works for any application. Another use that should be popular with GUI builder tools is saving the complete `Component` hierarchy of an application's GUI as a serialized object, and then later loading in that object in order to automatically recreate the GUI.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

4.6 Internationalization

Internationalization [1] is the process of enabling a program to run internationally. That is, an internationalized program has the flexibility to run correctly in any country. Once a program has been internationalized, enabling it to run in a particular country and/or language is merely a matter of "localizing" it for that country and language, or *locale*.

You might think that the main task of localization is the matter of translating a program's user-visible text into a local language. While this is an important task, it is not by any means the only one. Other concerns include displaying dates and times in the customary format for the locale, displaying number and currency values in the customary format for the locale, and sorting strings in the customary order for the locale.

Underlying all these localization issues is the even more fundamental issue of character encodings. Almost every useful program must perform input and output of text, and before we can even think about textual I/O, we must be able to work with the local character encoding standard. This hurdle to internationalization lurks slightly below the surface, and is not very "programmer-visible." Nevertheless, it is one of the most important and difficult issues in internationalization.

As described in Chapter 11, *Internationalization*, Java 1.1 provides facilities that address all of these internationalization issues. If you write programs that correctly make use of these facilities, the task of localizing your program for a new country really does boil down to the relatively simple matter of hiring a translator to convert your program's messages. With the expansion of the global economy, and particularly of the global Internet, writing internationalized programs is going to become more and more important, and you should begin to take advantage of Java's internationalization capabilities right away.

There are several distinct pieces to the problem of internationalization, and Java's solution to this problem also comes in distinct pieces. The first issue in internationalization is the matter of knowing

[1] This word is sometimes abbreviated I18N, because there are 18 letters between the first I and the last N.

what locale a program is running in. A locale is typically defined as a political, geographical, or cultural region that has a distinct language or distinct conventions for things such as date and time formats. The notion of a locale is encapsulated in Java 1.1 by the `Locale` class, which is part of the `java.util` package. Every Java program has a default locale, which is inherited from the operating system (where it may be set by the user). A program can simply rely on this default, or it can change the default. Additionally, all Java methods that rely on the default locale also have variants that allow you to explicitly specify a locale. Typically, though, using the default locale is exactly what you want to do.

Once a program knows what locale it is running in, the most fundamental internationalization issue, as noted above, is the ability to read and write localized text. Since Java uses the Unicode encoding for its characters and strings, any character of any commonly-used modern written language is representable in a Java program, which puts Java at a huge advantage over older languages such as C and C++. Thus, working with localized text is merely a matter of converting from the local character encoding to Unicode when reading text, such as a file or input from the user, and converting from Unicode to the local encoding when writing text. Java's solution to this problem is in the `java.io` package, in the form of a new suite of character-based input and output streams (known as "readers" and "writers") that complement the existing byte-based input and output streams.

The `FileReader` class, for example, is a character-based input stream used to read characters (which are not the same as bytes in all languages) from a file. The `FileReader` class assumes that the specified file is encoded using the default character encoding for the default locale, so it converts characters from the local encoding to Unicode characters as it reads them. In most cases, this assumption is a good one, so all you need to do to internationalize the character set handling of your program is to switch from a `FileInputStream` to a `FileReader` object, and make similar switches for text output as well. On the other hand, if you need to read a file that is encoded using some character set other than the default character set of the default locale, you can use a `FileInputStream` to read the bytes of the file, and then use an `InputStreamReader` to convert the stream of bytes to a stream of characters. When you create an `InputStreamReader`, you specify the name of the encoding in use, and it performs the appropriate conversion automatically.

As you can see, internationalizing the character set of your programs is a simple matter of switching from byte I/O streams to character I/O streams. Internationalizing other aspects of your program requires a little more effort. The classes in the `java.text` package are designed to allow you to internationalize your handling of numbers, dates, times, string comparisons, and so on. `NumberFormat` is used to convert numbers, monetary amounts, and percentages to an appropriate textual format for a locale. Similarly, the `DateFormat` class, along with the `Calendar` and `TimeZone` classes from the `java.util` package, are used to display dates and times in a locale-specific way. The `Collator` class is used to compare strings according to the alphabetization rules of a given locale, and the `BreakIterator` class is used to locate word, line, and sentence boundaries.

The final major problem of internationalization is making your program flexible enough to display messages (or any type of user-visible text, such as the labels on GUI buttons) to the user in an appropriate language for the current locale. Typically, this means that the program cannot use hard-coded messages and must instead read in a set of messages at run-time, based on the locale setting. Java provides an easy way to do this. You define your messages as key/value pairs in a `ResourceBundle` subclass. Then, you create a subclass of `ResourceBundle` for each language or locale your application supports, naming each class following a convention that includes the locale name. At run-time, you can use the `ResourceBundle.getBundle()` method to load the appropriate `ResourceBundle` class for the current locale. The `ResourceBundle` contains the messages your application uses, each associated with a key, that serves as the message name. Using this technique, your application can look up a locale-dependent message translation based on a locale-independent message name. Note that this technique is useful for things other than textual messages. It can be used to internationalize icons, or any other locale-dependent object used by your application.

There is one final twist to this problem of internationalizing messages. Often, we want to output messages such as, "Error at line 5 of file hello.java.", where parts of the message are static, and parts are dynamically generated at run-time (such as the line number and filename above). This is further complicated by the fact that when we translate such messages the values we substitute in at run-time may appear in a different order. For example, in some different English speaking locale, we might want to display the line above as: "hello.java: error at line 5". The `MessageFormat` class of the `java.text` package allows you to substitute dynamic values into static messages in a very flexible way and helps tremendously with this situation, particularly when used in conjunction with resource bundles.

4.5 Other AWT Improvements

In addition to the major change in the AWT event model, there have been quite a few other improvements to the AWT. These improvements are summarized in the sections below.

Printing

Printing in Java 1.1 is implemented through the new `PrintJob` class and `PrintGraphics` interface. The `PrintJob` class represents a print request. When a `PrintJob` object is created, the user is prompted with a platform-dependent print dialog, which allows her to specify options such as which printer to use.

The `getGraphics()` method of a `PrintJob` object returns a `Graphics` object that can be used for printing. This object is an instance of a subclass of `Graphics` that knows how to print in a platform-dependent way. The object also implements the `PrintGraphics` interface. To print a component, you simply pass this `Graphics` object to the component's `print()` method. If the component does not define this method, the default implementation simply invokes the `paint()` method, which usually does the right thing. When you want to print a component and all of its subcomponents, you can simply pass the `Graphics` object to the `printAll()` method of the component.

Printing multiple pages is more complex, of course. The application is responsible for pagination of the output, and in order to draw the output on the page the application may also need to query the `PrintJob` object to determine the page size (in pixels) and page resolution (in pixels per inch).

For security reasons, applets are not allowed to initiate print jobs; if they were, you could expect to see applets on the Net that automatically printed hardcopy advertisements to your printer! Note, however, that this does not mean that applets cannot print themselves when the browser or applet viewer initiates the print request object and invokes the `printAll()` method of the applet.

Chapter 8, *New AWT Features* contains an example that uses the printing capabilities of Java 1.1.

Cut-and-Paste

Data transfer via the cut-and-paste metaphor is supported in Java 1.1 by the classes and interfaces in the `java.awt.datatransfer` package. One half of this package provides generic data-transfer functionality, and the other half provides the classes and interfaces needed for clipboard-based cut-and-paste. In future versions of the JDK, we can expect to see support for the drag-and-drop data transfer metaphor added to this package.

For the purposes of data transfer, the `DataFlavor` class represents the notion of a data type or data format. A `DataFlavor` consists of a human-readable name for the flavor and one of two possible machine-readable format definitions. The first of the machine-readable descriptions is a `String` that specifies a MIME type for the transferred data. The second is a `Class` object that represents a Java class. When a `DataFlavor` is specified with a `Class` object, it is an instance of this class that is passed when data transfer actually occurs.

Any value that can be transferred through the Java 1.1 data transfer mechanism must be represented by a class that implements the `Transferable` interface. This interface defines methods to query the data flavors that the class supports, and it defines a method that the data transfer mechanism calls to convert the transferable value into the appropriate form for a given `DataFlavor`.

While the `DataFlavor` class and the `Transferable` interface define the fundamental data transfer mechanism, they, by themselves, are not enough to initiate or perform data transfer. For this purpose, `java.awt.datatransfer` also defines the `Clipboard` class and the `ClipboardOwner` interface. Together, they support a cut-and-paste metaphor for data transfer. Because strings are often transferred between applications, `java.awt.datatransfer` provides the `StringSelection` class. This class implements both the `Transferable` and the `ClipboardOwner` interfaces and makes it very easy to transfer textual data through cut-and-paste.

Inter-application data transfer is performed through the system clipboard. It is also possible to perform intra-application transfers through a private clipboard that an application creates for itself. Note that untrusted applets are not allowed to access the system clipboard--there could be sensitive information contained on it that untrusted code should not have access to. This means that applets cannot participate in inter-application cut-and-paste. Chapter 8, *New AWT Features* provides an example that demonstrates intra-application cut-and-paste data transfer.

Popup Menus and Menu Shortcuts

Java 1.1 adds support for popup menus to the AWT. The `PopupMenu` class is a subclass of `Menu`; menu items are added to it just as they are added to regular pulldown menus. A popup menu can be attached to an arbitrary AWT component, using the new `add()` method of the `Component` class. And, finally, a popup menu can be "popped up" by calling its `show()` method. (The menu pops itself down automatically.)

An application typically displays a popup menu when the user clicks a certain mouse button over the component that the menu is attached to. However, different platforms traditionally use different mouse buttons to display popup menus. You can use the new `isPopupTrigger()` method of `MouseEvent` to determine whether a given mouse click has the appropriate modifiers set to trigger the popup menu for the current platform.

Java 1.1 also adds support for menu shortcut keys. The new `MenuShortcut` class represents a menu shortcut key. An instance of this class may optionally be specified whenever you create a `MenuItem` object. Again, different platforms use different modifier keys to invoke menu shortcuts, so when you create a `MenuShortcut` object, you specify only the key in question (plus, optionally, the **Shift** key). The system translates this into a platform-dependent shortcut using **Ctrl**, **Alt**, or some other modifier key.

The example in Chapter 8, *New AWT Features* demonstrates both a popup menu and menu shortcuts.

Keyboard Focus Traversal

The ability to operate a GUI without using the mouse is an important feature of any windowing toolkit. The addition of menu shortcuts in Java 1.1 is an important step in this direction. Java 1.1 also adds rudimentary facilities for keyboard focus traversal (i.e., moving keyboard focus among the individual components in a window) using the **Tab** and **Shift-Tab** keys.

Under the new focus traversal scheme, components within a container are traversed in the order in which they were added to the container. (Note, however, that it is possible to override this order by specifying an explicit position within the container's component list for a new component as it is added to the container with the `add()` method.) Beyond adding components to their container in the order desired for traversal, nothing else is required of the programmer in order to make keyboard focus traversal work.

If you are creating a custom component that can accept keyboard focus, you should override the `isFocusTraversable()` method to return `true`. The component should call the `requestFocus()` method it inherits from `Component` when the user clicks on it or otherwise activates it. Finally, when a component receives focus, (i.e., when its `processFocusEvent()` method is invoked), it should provide some sort of visual indication, such as a highlighted border, that it has the focus.

Miscellaneous Improvements

The `SystemColor` class represents a color used by the desktop system. On some platforms, these colors may be dynamically updated while the system is running. The `SystemColor` class also implements quite a few constants that represent system colors for various GUI components. Thus, if you want your GUIs to match the desktop color scheme, you might create them using colors such as `SystemColor.menu` (the background color for menus) and `SystemColor.menuText` (foreground color for menus), for example.

The treatment of fonts has been changed and improved somewhat in Java 1.1. The use of the font names "TimesRoman," "Helvetica," and "Courier" is now discouraged. Instead, you should use "serif," "sansserif," and "monospaced"--these names convey the essential style of the font face, without specifying the exact font to be used. The font names "Dialog" and "DialogInput" are still supported in Java 1.1. An important reason for switching to generic font names is that Java can now display any Unicode character for which there is an appropriate font installed on the host system. The names "serif" and "sansserif" have meaning even when applied to non-Latin character sets, such as Japanese Kanji characters; the names "timesroman" and "helvetica" clearly do not. Another result of this fuller Unicode support is that the use of the "ZapfDingbats" font is also discouraged. Instead, regardless of what font you are using, you can simply encode these graphical symbols using Unicode characters between `\u2700` and `\u27ff`. (See Chapter 11, *Internationalization* for an example.) This improved support for Unicode makes it much easier to write internationalized programs in Java.

In Java 1.0, mouse cursors could only be specified for a `Frame`. In Java 1.1, every component can have a its own cursor, represented by the new `Cursor` object. There are new methods of `Component` for setting and querying the cursor. This change does not add any new predefined cursor images, nor does it add the ability to create custom cursors; it merely allows you to specify a cursor for any arbitrary component, and to do so in a more logical fashion.

The `ScrollPane` class is new in Java 1.1. It is a `Container` that makes it very easy to scroll a large component or GUI within a smaller visible area. Doing this in Java 1.0 required a custom container, and suffered from some serious performance problems. Chapter 8, *New AWT Features* shows the use of a `ScrollPane` object.

Another new feature is the ability to create "lightweight components." These are components and containers that do not have a native window of their own. In Java 1.0, custom components and containers had to be subclassed from `Canvas` or `Panel`. In Java 1.1, however, you can subclass `Component` and `Container` directly. Doing so creates a simpler component or container, without the overhead of a native window. It also allows you to create partially transparent components that appear non-rectangular.

Java 1.1 also includes several miscellaneous changes to clipping and image manipulation:

- The `Graphics` class defines a method to set an arbitrary clipping rectangle, even to one that is larger than the current clipping region. There is also a new method to query the current clipping region.

- `Graphics` also defines two new `drawImage()` methods that are more flexible than the existing drawImage() methods. These new methods allow arbitrary image cropping, scaling, and flipping.

- There are two new classes, ReplicateScaleFilter and AreaAveragingScaleFilter, that can be used to scale an image as it is loaded, and a new convenience method, Image.getScaledInstance(), to obtain a new Image object that contains a scaled version of some other Image.

- New methods have been added to the MemoryImageSource class that allow images generated from memory to be dynamically and efficiently updated, allowing a kind of image animation.

- New methods have been added to the PixelGrabber class to make it more efficient and flexible to use.

4.4 Deprecated Features

Although you can use the old AWT event model in Java 1.1, it has been officially "deprecated," and its use in new software is discouraged. When you compile code that uses the 1.0 event model, you'll be made aware of this by the "deprecation warning" that the *javac* compiler issues. This warning notifies you that your code relies on methods or classes in the Java API that have been superseded by newer, preferred alternatives. If you compile using the `-deprecation` flag, *javac* provides a detailed warning about each use of a deprecated feature. You can simply ignore these warnings, but when time permits, the better approach is to update your code so that it no longer relies on deprecated features of the Java API. While it is not strictly true to say that deprecated features are "unsupported," they will almost certainly receive far less support in practice than the features that replace them.

The reason that the compiler is able to issue deprecation warnings at all is the addition of a new `@deprecated` tag to the documentation-comment syntax of Java 1.1. As you may be aware, comments that begin with the `/**` character sequence are treated specially in Java, and are used by the *javadoc* tool to automatically generate online documentation for packages, classes, methods, and fields. Prior to Java 1.1, the compiler ignored the contents of documentation comments. In Java 1.1, however, it scans these comments for the `@deprecated` tag. If it is found, the compiler marks the class, interface, constructor, method, or field following the comment as deprecated, and issues a warning when the deprecated feature is used.

The old AWT event-handling model is not the only Java 1.0 feature that has been deprecated in Java 1.1; merely the one you are most likely to encounter first. A number of common AWT component methods have been renamed, to follow a more regular naming scheme that fits the JavaBeans naming conventions. These methods can be invoked by the old name or the new, but if you use the old name, you'll be rewarded with a deprecation warning. Fortunately, in simple cases like this, it is trivial to write a script or program to mechanically convert from the old name to the new. Other areas of the Java API have been deprecated as well. You'll notice that a few of the input and output stream classes in the `java.io` package have been deprecated and superseded by "Reader" and "Writer" stream classes, for example.

4.3 The New AWT Event Model

The Java 1.1 change that will probably affect Java programmers the most is the new event processing model adopted for the AWT windowing and graphical user interface (GUI) toolkit. If you created applets or GUIs with Java 1.0, you know that it was necessary to subclass GUI components in order to handle events. This model worked okay for simple programs, but proved increasingly awkward as programs became more complex. Furthermore, with the development of the JavaBeans API, the AWT package needed an event model that would allow AWT GUI components to serve as beans. For these reasons, Java 1.1 defines a new model for dispatching and handling events.

As explained in Chapter 7, *Events*, the new event handling model is essentially a "callback" model. When you create a GUI component, you tell it what method or methods it should invoke when a particular event occurs on it (e.g., when the user clicks on a button or selects an item from a list). This model is very easy to use in C and C++ because those languages allow you to manipulate method pointers--to specify a callback, all you need to do is pass a pointer to the appropriate function. In Java, however, methods are not data and cannot be manipulated in this way. Only objects can be passed like this in Java, so to define a Java callback, you must define a class that implements some particular interface. Then, you can pass an instance of that class to a GUI component as a way of specifying the callback. When the desired event occurs, the GUI component invokes the appropriate method of the object you have specified.

As you might imagine, this new event handling model can lead to the creation of many small helper classes. (Sometimes these helper classes are known as "adaptor classes" because they serve as the interface between the body of an application and the GUI for that application. They are the "adaptors" that allow the GUI to be "plugged in" to the application.) This proliferation of small classes could become quite a burden, were it not for the introduction of inner classes, which, as noted above, allows this kind of special-purpose class to be nested and defined exactly where it is needed within your program.

Despite the major AWT event-handling changes, Java 1.1 does retain backwards compatibility with the event-handling model of Java 1.0. It is an all-or-nothing type of backwards compatibility, however--the two models are so different from each other that it is not really possible to mix them within the same application.

Inner Classes | BOOK INDEX | Deprecated Features

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

4.2 Inner Classes

While the bulk of the changes in Java 1.1 are additions to the core Java API, there has also been a major addition to the language itself. The language has been extended to allow class definitions to be nested within other classes, and even to be defined locally, within blocks of code. Altogether, there are four new types of classes that can be defined in Java 1.1; these four new types are sometimes loosely referred to as "inner classes."

Chapter 5, *Inner Classes and Other New Language Features* explains in detail how to define and use each of the four new types of classes. As we'll see, inner classes are useful primarily for defining simple "helper" or "adaptor" classes that serve a very specific function at a particular place in a program, and are not intended to be general-purpose "top-level" classes. By using inner classes nested within other classes, you can place the definition of these special-purpose helper classes closer to where they are actually used in your programs. This makes your code clearer, and also prevents you from cluttering up the package namespace with small special purpose classes that are not of interest to programmers using your package. We'll also see that inner classes are particularly useful in conjunction with the new AWT event model in Java 1.1.

One important feature of inner classes is that no changes to the Java Virtual Machine are required to support them. When a Java 1.1 compiler encounters an inner class, it transforms the Java 1.1 source code in a way that converts the nested class to a regular top-level class. Once that transformation has been performed, the code can be compiled just as it would have been in Java 1.0.

4. What's New in Java 1.1

Contents:

Java 1.1 is a *huge* new release. The number of packages in the API has increased from 8 in Java 1.0 to 23 in Java 1.1, and the number of classes has more than doubled from 211 to 503. On top of these changes to the core Java class libraries, there have been some important changes to the language itself. Also, the JDK--the Java Development Kit from Sun--includes a number of new tools in version 1.1.

The new features of Java 1.1 include:

Inner classes

> Changes to the Java language itself to allow classes to be nested within each other, and within blocks of code.

Java Beans

> A framework for defining reusable modular software components.

Internationalization

A variety of new features that make it possible to write programs that run around the globe.

New event model

A new model for handling events in graphical user interfaces that should make it easier to create those interfaces.

Other new AWT features

The Java 1.1 AWT includes support for printing, cut-and-paste, popup menus, menu shortcuts, and focus traversal. It has improved support for colors, fonts, cursors, scrolling, image manipulation, and clipping.

Applets

JAR files allow all of an applet's files to be grouped into a single archive. Digital signatures allow trusted applets to run with fewer security restrictions. The HTML `<APPLET>` tag has new features.

Object serialization

Objects can now be easily "serialized" and sent over the network or written to disk for persistent storage.

Reflection

Java programs can now "reflect" upon themselves or upon an arbitrary class to determine the methods and fields defined by the class, the arguments passed to a method, and so on. The Reflection API also allows the invocation of methods specified by name.

Security

Java 1.1 includes a new package that supports digital signatures, message digests, key management, and access control lists.

Java Database Connectivity (JDBC)

A new package that allows Java programs to send SQL queries to database servers. It includes a "bridge" that allows it to inter-operate with existing ODBC database servers.

Remote Method Invocation (RMI)

> An interface that supports distributed Java applications in which a program running on one computer can invoke methods of Java objects that exist on a different computer.

These and other new features are summarized in the sections below. Many of them are also described in more detail elsewhere in this book.

4.1 Java 1.1 Package-by-Package

The packages and classes of the Java class library are interlinked and interdependent. Many of the major new features of Java 1.1 rely on classes from multiple packages in the Java API. Before we examine those new features in detail, therefore, we need to understand the big picture of Java 1.1. The paragraphs below discuss each of the 23 packages that constitute the core API for Java 1.1; they introduce the new packages and explain the changes to existing packages.

`java.applet`

> Despite the introduction of JAR files, digitally signed applets, and new attributes of the `<APPLET>` tag, the `java.applet` package has not changed in any significant way.

`java.awt`

> The `java.awt` package contains new classes and interfaces to support printing, popup menus, and menu shortcuts, and to improve support for layout management, cursors, scrolling, colors, and clipping. Several classes provide support for the new AWT event model, but most event support is contained in one of several new sub-packages of `java.awt`.

`java.awt.datatransfer`

> The classes and interfaces in this package define a generic framework for inter-application (and intra-application) data transfer. This package also includes classes to support a clipboard-based cut-and-paste data transfer model. In the future, this package may be extended to include support for data transfer through a drag-and-drop metaphor. One of the two underlying data transfer mechanisms supported by this package relies on the Object Serialization API of the `java.io` package.

`java.awt.event`

> This package defines the classes and interfaces of the new AWT event handling model. The

classes and interfaces of this package fall into three categories:

- Event classes--the classes that actually represent events.
- Event "listeners"--interfaces that define methods that must be implemented by objects interested in being notified when an event of a particular type occurs.
- Event "adaptors"--trivial no-op implementations of the event listener interfaces that are suitable for easy subclassing.

All the events and event listeners defined in this package extend the `EventObject` class or the `EventListener` interface defined in `java.util`.

`java.awt.image`

This package has two new image filter classes that implement improved image scaling. Changes have also been made to the `MemoryImageSource` and `PixelGrabber` classes.

`java.awt.peer`

The changes to this package for the most part simply reflect changes to `java.awt`. There are new interfaces that represent a platform-dependent popup menu and scrolling area, for example.

`java.beans`

This package constitutes the much-touted JavaBeans API for creating and using embeddable, reusable software components. The classes and interfaces in this package can be used at three different levels:

- To create application builder tools that programmers (or even non-programmers) can use to compose applications out of individual Java beans.
- To develop Java beans for use in such application builders.
- To develop applications (without using a builder tool) that use Java beans.

Most of the classes and interfaces of the package are for use by application builders or by developers of advanced beans. Programmers using beans or writing simple beans do not need to be familiar with most of the package.

Application builders that manipulate beans rely on the Reflection API defined in java.lang.reflect, and many beans take advantage of the Object Serialization API defined in the java.io package. The JavaBeans API uses the same event model that the Java 1.1 AWT does, and event-related classes and interfaces in this package are extensions of a class and an interface defined in java.util.

java.io

The java.io package has become by far the largest of the core Java packages. This is because Java 1.1 adds:

- A complete suite of new "character stream" classes to complement most of the existing "byte stream" input and output classes. These new "reader" and "writer" streams offer improved efficiency and support internationalization for textual input and output.
- New classes and interfaces to support object serialization.
- A number of new IOException types.

java.lang

This package has several new Exception and Error types, as well as new Byte, Short, and Void classes. With the addition of these new classes, all primitive Java data types (including the void type) have corresponding object types. This is important for the java.lang.reflect package, which defines the new Reflection API. In addition, the Class class has been greatly enhanced for use with the Reflection API. Class and ClassLoader have methods to locate "resources" associated with a class, such as images, audio files, Properties files, and so on. Resources are important for internationalization in Java 1.1.

java.lang.reflect

This new package enables a Java program to examine the structure of Java classes and to "reflect upon" its own structure. java.lang.reflect contains classes that represent the fields, methods, and constructors of a class, and enable a program to obtain complete information about any object, array, method, constructor, or field. The java.beans package relies heavily upon this package.

java.math

This new package contains only two classes, which support arithmetic on arbitrary-size integers and arbitrary-precision floating-point numbers. The BigInteger class also defines methods for modular arithmetic, primality testing, and other features required for cryptography.

`java.net`

The changes to the `java.net` package are quite low-level. They include the addition of multicast sockets, Unix-style socket options, and new exception types that provide finer granularity when handling networking exceptions.

`java.rmi`

This package defines the fundamental classes and interfaces used for Remote Method Invocation. Most of the classes in this package are exception types. Subpackages of `java.rmi` provide additional, more specialized functionality. When objects must be passed as arguments to remote methods, RMI relies on the object serialization functionality provided in the `java.io` package.

`java.rmi.dgc`

This small package defines the classes and interfaces required for distributed garbage collection (DGC).

`java.rmi.registry`

This is another small package that defines the classes and interfaces required for a Java client to look up a remote object by name or for a Java server to advertise the service it provides.

`java.rmi.server`

This package is the largest of the RMI packages and is at the heart of Remote Method Invocation. It defines the classes and interface that allow a Java program to create an object that can be used remotely by other Java programs.

`java.security`

This package contains the classes and interfaces that represent the fundamental abstractions of cryptographic security: public and private keys, certificates, message digests, and digital signatures. This package does not provide implementations of these abstractions; by design, the Java Security API is implementation independent. Java 1.1 does include a default implementation, but vendor-specific implementations may also be used in conjunction with this package. The default security implementation relies on the `BigInteger` class defined in the `java.math` package.

`java.security.acl`

This package defines high-level interfaces, and some exceptions, for manipulating access control lists.

`java.security.interfaces`

This package defines a few interfaces that are required for the Java Security API's implementation-independent design.

`java.sql`

This package is the Java Database Connectivity (JDBC) API. The classes and interfaces it contains allow Java programs to send SQL queries to databases and retrieve the results of those queries.

`java.text`

The classes and interfaces in this package are used for internationalization. The package includes classes for formatting dates, times, numbers, and textual messages in a manner appropriate for the default locale, or for any specified locale. It also includes classes for collating strings according to the rules of a given locale and iterating through the characters, words, and sentences of a string in a locale-specific manner.

`java.util`

As its name indicates, the `java.util` package contains miscellaneous utility classes. In Java 1.1, new classes have been added to this package to support the AWT and Java Beans event model, to define "locales" and "resource bundles" used for internationalization, and to manipulate dates, times, and time zones.

`java.util.zip`

This package implements classes for computing checksums on streams of data, and for compressing and archiving (and uncompressing and unarchiving) streams of data, using ZLIB compression library and ZIP and GZIP file formats.

Summary | BOOK INDEX | Inner Classes

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.2 Nested Top-Level Classes and Interfaces

As explained above, a nested top-level class or interface is just like a regular package-member class or interface, except that, for convenience, it has been nested within another class or interface. Note that nested top-level classes and interfaces must be declared `static`. They can only be nested within other top-level classes and interfaces (i.e., they cannot be declared within inner classes), but they can be nested to any depth.

Example 5.1 shows how you might define a nested top-level "helper" interface. Note the use of the `static` keyword in the declaration of the interface. The example also shows how this interface is used both within the class that contains it and by external classes. Note the use of its hierarchical name in the external class.

Example 5.1: Defining and Using a Nested Top-Level Interface

```
public class LinkedList {
  // This nested top-level helper interface is defined as a static member.
  public interface Linkable {
    public Linkable getNext();
    public void setNext(Linkable node);
  }
  // The head of the list is a Linkable object.
  Linkable head;
  // Method bodies omitted.
  public void insert(Linkable node) { ... }
  public remove(Linkable node) { ... }
}
// This class defines a type of node that we'd like to use in
// a linked list.  Note the nested interface name in the implements clause.
class LinkableInteger implements LinkedList.Linkable
{
  // Here's the node's data and constructor.
  int i;
  public LinkableInteger(int i) { this.i = i; }
  // Here are the data and methods required to implement the interface.
  LinkedList.Linkable next;
  public LinkedList.Linkable getNext() { return next; }
  public void setNext(LinkedList.Linkable node) { next = node; }
}
```

The `import` statement can be used to import nested top-level classes and interfaces from the class that defines them, just as it can be used to import package member top-level classes and interfaces from the package that defines them. Example 5.2 shows a new definition of the `LinkableInteger` class from Example 5.1 that uses an `import` statement to allow it to refer to the `Linkable` interface by its simple, unqualified name (i.e., the name of the enclosing class is no longer needed).

Example 5.2: Importing a Static Member Class

```
import LinkedList.*;     // Or use import LinkedList.Linkable;
// Since we use an import statement, we can just type
// "Linkable" instead of "LinkedList.Linkable".
class LinkableInteger2 implements Linkable
{
  int i;
  public LinkableInteger2(int i) { this.i = i; }
  Linkable next;
  public Linkable getNext() { return next; }
  public void setNext(Linkable node) { next = node; }
}
```

Nested Top-Level Classes and .class Files

When you compile the *LinkedList.java* file shown in Example 5.1, you'll find that two class files are generated. The first is named *LinkedList.class*, as expected. The second, however, is named *LinkedList$Linkable.class*. The `$` in this name is automatically inserted by the Java 1.1 compiler.

The Java Virtual Machine knows nothing about nested top-level classes and interfaces or the various types of inner classes. Therefore, the Java compiler must convert these new types into standard, non-nested class files that the Java interpreter can understand. This is done through source-code transformations that insert `$` characters into nested class names. These source-code transformations may also insert hidden fields, methods, and constructor arguments into the affected classes. Unless you are writing a Java 1.1 compiler, however, you do not need to know the details of these source-code transformations, and you will typically not even notice them, except in the names of class files. [2]

[2] See the *Java Language Specification* if you want complete details on the source-code transformations performed by the Java 1.1 compiler to support inner classes.

PREVIOUS | HOME | NEXT
An Overview of Inner Classes | BOOK INDEX | Member Classes

5.3 Member Classes

While nested top-level classes are nested within a containing class, we've seen that they are still top-level classes, and that the nesting is purely a matter of organizational convenience. The same is not true of member classes, however. These classes are also nested, but they are not declared `static`, and in this case, the nesting is significant. The main features of member classes are:

- Every instance of a member class is internally associated with an instance of the class that defines or contains the member class.
- The methods of a member class can implicitly refer to the fields defined within the member class, as well as those defined by any enclosing class, including `private` fields of the enclosing class.

Like nested top-level classes, member classes are commonly used for helper classes required by the enclosing class. You use a member class instead of a nested top-level class when the member class requires access to the instance fields of the enclosing class, or when every instance of the helper class must refer to an instance of the enclosing class. When you use a member class, this reference from member class to enclosing class is implemented automatically for you.

Let's return to the `LinkedList` example that we saw above. Suppose we want to add the ability to loop through the elements in the linked list using the `java.util.Enumeration` interface. To do this, we define a separate class that implements this interface, and then add a method to the `LinkedList` class that returns an instance of the separate `Enumeration` class. Example 5.3 shows a typical Java 1.0-style implementation. [3]

[3] For simplicity, this example implements a very simple `Enumeration` class that is not thread-safe and that may return incorrect results if items are added to or removed from the list while an `Enumeration` object is in use.

Example 5.3: A LinkedList Enumerator, as a Separate Top-Level Class

```
import java.util.*;
public class LinkedList {
  // Our nested top-level interface.  Body omitted here...
  public interface Linkable { ... }
  // The head of the list.
  Linkable head;
  // Method bodies omitted here.
  public void addToHead(Linkable node) { ... }
  public Linkable removeHead() { ...  }
  // This method returns an Enumeration object for this LinkedList.
  public Enumeration enumerate() {
    return new LinkedListEnumerator(this);
  }
}
// This class defines the Enumeration type we use to list the elements in
// a LinkedList.  Note that each LinkedListEnumerator object is associated
// with a particular LinkedList object which is passed to the constructor.
class LinkedListEnumerator implements Enumeration {
  private LinkedList container;
  private LinkedList.Linkable current;
  public LinkedListEnumerator(LinkedList l) {
    container = l;
    current = container.head;
  }
  public boolean hasMoreElements() { return (current != null); }
  public Object nextElement() {
    if (current == null) throw new NoSuchElementException("LinkedList");
    Object value = current;
    current = current.getNext();
    return value;
  }
}
```

The point to notice about the `LinkedListEnumerator` class in Example 5.3 is that we must explicitly pass a `LinkedList` object to its constructor.

The problem with Example 5.3 is that `LinkedListEnumerator` is defined as a separate top-level class, when it really would be more elegant to define it as part of the `LinkedList` class itself. In Java 1.1, this is easily done using a member class, as shown in Example 5.4.

Example 5.4: A LinkedList Enumerator, as a Member Class

```
import java.util.*;
public class LinkedList
{
  // Our nested top-level interface.  Body omitted here...
  public interface Linkable { ... }
  // The head of the list.
  // This field could be private except for inner class-related compiler bugs.
  /* private */ Linkable head;
  // Method bodies omitted here.
  public void addToHead(Linkable node) { ... }
  public Linkable removeHead() { ...  }
  // This method returns an Enumeration object for this LinkedList.
  // Note: no LinkedList object is explicitly passed to the constructor.
  public Enumeration enumerate() { return new Enumerator(); }
  // And here is the implementation of the Enumeration interface,
  // defined as a private member class.
  private class Enumerator implements Enumeration {
    Linkable current;
    // Note: the constructor implicitly refers to 'head' in containing class.
    public Enumerator() { current = head; }
    public boolean hasMoreElements() {  return (current != null); }
    public Object nextElement() {
      if (current == null) throw new NoSuchElementException("LinkedList");
      Object value = current;
      current = current.getNext();
      return value;
    }
  }
}
```

In this version of the example, notice how the `Enumerator` class is nested within the `LinkedList` class. There is a real elegance to defining the helper class so close to where it is used by the containing class. [4] Of course, if you compiled this example you'd find that the `Enumerator` member class is compiled to a file named *LinkedList$Enumerator.class*--while one class is nested within the other in source code form, the same is not true of their compiled byte-code forms.

> [4] John Rose, the author of Sun's inner class specification, points out that the advantages of inner classes are not only their elegance, but also their "conciseness, expressiveness, and modularity." He says, "Even prosy-minded programmers who don't care a fig for prissy elegance...will appreciate the fact that they can define their adapter classes right next to the code that needs them, and that they won't have to manually wire the adapter to the main object...and that they won't have to pollute the name space of the package..."

Notice that no instance of the containing `LinkedList` class is passed to the `Enumerator()` constructor of the member class. A member class can refer to the members of its enclosing class implicitly; no explicit reference is necessary. Also note that the `Enumerator` class makes use of the `head` field of the enclosing class, even though `head` is declared `private`. Because the member class is defined within the enclosing class, it is "inside" the class as far as the definition of `private` fields and methods is concerned. In general, member classes, as well as local and anonymous classes can use the `private` fields and methods (and classes!) of their containing class. Similarly, a containing class can use the `private` fields, methods, and classes of the classes it contains. And any two classes that are enclosed by the same third class can access each other's `private` members. [5]

> [5] As noted earlier, however, bugs in *javac* in current versions of JDK 1.1 prevent this kind of access to `private` members. Until these bugs are fixed, you should use use package visibility instead of `private` visibility.

How Member Classes Work

The `Enumerator` member class of `LinkedList` can refer to the `head` field of `LinkedList` because every instance of a member class implicitly refers to an instance of the class that contains it--this is one of the fundamental features of member classes. It works because the compiler automatically inserts a `private` field in the member class to hold the required reference to the containing object. The compiler also automatically inserts a hidden argument to all constructors of a member class and passes the containing object as the value of this argument. [6] Once the compiler automatically adds this `private` field and constructor argument to the code in Example 5.4, you can see that we end up with code very much like what we saw in Example 5.3!

> [6] If you're curious about this, use *javap -p* to disassemble the class file of a member class. It shows you both the inserted `private` field and the extra constructor argument.

Because the Java Virtual Machine has no notion of inner classes, the Java 1.1 compiler also must take special action to allow member classes (and local and anonymous classes) to use the `private` fields and methods in their enclosing classes (and vice versa). When a `private` field or method is used in a way that is allowed in Java 1.1, but is not allowed by the Java interpreter, the compiler automatically inserts a special accessor method to allow the access.

New Syntax for Member Classes

The most important feature of a member class is that it can implicitly refer to fields in its containing object. We saw this in the following constructor from Example 5.4:

```
public Enumerator() { current = head; }
```

In this example, `head` is a field of the `LinkedList` class, and we assign it to the `current` field of the `Enumerator` class. What if we want to make these references explicit? We could try code like this:

```
public Enumerator() { this.current = this.head; }
```

This code does not compile, however. `this.current` is fine; it is an explicit reference to the `current` field in the newly created `Enumerator` object. It is the `this.head` expression that causes the problem--it refers to a field named `head` in the `Enumerator` object. There is no such field, so the compiler generates an error. To prevent this problem, Java 1.1 defines new syntax for explicitly referring to the containing instance of the current instance of a member class. If we wanted to be explicit in our constructor, we'd use the new syntax like this:

```
public Enumerator() { this.current = LinkedList.this.head; }
```

Similarly, we can use `LinkedList.this` to refer to the containing `LinkedList` object itself. In general, the syntax is *`classname`*`.this`, where *`classname`* is the name of a containing class. Note that member classes can themselves contain member classes, nested to any depth, and no member class can have the same name as any containing class. Thus, the use of the class name prepended to `this` is a perfectly general way to refer to any containing instance, as the following nested class example demonstrates:

```
public class A {
  public String name = "a";
  public class B {
    public String name = "b";
    public class C {
      public String name = "c";
      public void print_names() {
        System.out.println(name);        // "c": name field of class C
        System.out.println(this.name);   // "c": name field of class C
        System.out.println(C.this.name); // "c": name field of class C
        System.out.println(B.this.name); // "b": name field of class B
        System.out.println(A.this.name); // "a": name field of class A
      }
    }
  }
}
```

Another new piece of Java 1.1 syntax has to do with the way member classes are created. As we've seen, member classes work the way they do because the compiler automatically adds an argument to each member class constructor. This argument passes a reference to the containing instance to the newly created member instance. Now look again at our definition of the `enumerate()` method in Example 5.4:

```
public Enumeration enumerate() { return new Enumerator(); }
```

Nowhere in this `new` expression do we specify what the containing instance of the new `Enumerator` instance should be. In this case, the `this` object is used as the containing instance, which is what you would expect to happen. It is also what you want to occur in most cases. Nevertheless, Java 1.1 supports a new syntax that lets you explicitly specify the containing instance when creating an instance of a member class. We can make our method more explicit by using the following code:

```
public Enumeration enumerate() { return this.new Enumerator(); }
```

The syntax is *`containing_instance`* `.new`, where *`containing_instance`* is an expression that evaluates to an instance of the class that defines the desired member class.

Let's look at another example of this syntax. Recall that we declared the `Enumerator` member class to be `private` in Example 5.4. We did this for reasons of modularity and encapsulation. Suppose, however, that we had given `Enumerator` package visibility. In that case, it would be accessible outside of the `LinkedList` class, and we could instantiate our own copy of it. In order to create an instance of the member class `LinkedList.Enumerator`, however, we must specify the instance of `LinkedList` that contains it (and is implicitly passed to its constructor). Our code might look like the following:

```
// First create a linked list, and add elements to it (omitted).
LinkedList list = new LinkedList();
// Create an enumerator for the linked list.  Note the syntax of the
// 'new' expression.
Enumerator e = list.new Enumerator();
```

As a more complex example, consider the following lines of code used to create an instance of class `C` nested within an instance of class B nested within an instance of class A:

```
A a = new A();         // Create an instance of A.
A.B b = a.new B();     // Create an instance of B within the instance of A.
A.B.C c = b.new C();   // Create an instance of C within the instance of B.
c.print_names();       // Invoke a method of the instance of c.
```

Note that in the new expressions we name the class to be created relative to the instance that will contain it. That is, we say b.new C(), not b.new A.B.C() .

There is one final piece of new Java 1.1 syntax related to member class instantiation and initialization. Before we consider it, however, let me point out that you should rarely, if ever, need to use this syntax. It represents one of the pathological cases that snuck into the language along with all the elegant features of inner classes.

The new syntax for the new operator described above allows us to specify the containing instance that is passed to the constructor of a member class. There is one circumstance in which a constructor is invoked without the use of the new operator--when it is invoked with the super keyword from a subclass constructor. As strange as it may seem, it *is* possible for a top-level class to extend a member class. This means that the subclass does not have a containing instance, but that its superclass does. When the subclass constructor invokes the superclass constructor, it must specify the containing instance. It does this by prepending the containing instance and a period to the super keyword. If we had not declared our Enumerator class to be a private member of LinkedList, then we could subclass it. Although it is not clear why we would want to do so, we could write code like the following:

```
// A top-level class that extends a member class
class SpecialEnumerator extends LinkedList.Enumerator {
  // The constructor must take the LinkedList argument explicitly,
  // and then must pass it implicitly to the superclass constructor
  // using the new 'super' syntax.
  public SpecialEnumerator(LinkedList l) { l.super(); }
  // Here we override one or the other of the LinkedList.Enumerator
  // methods to have some kind of special behavior.
     . . .
}
```

Scope Versus Inheritance

Having noted that a top-level class can extend a member class, it is important to point out that with the introduction of member classes there are two entirely separate hierarchies that must be considered for any class. The first is the class hierarchy, from superclass to subclass, that defines the fields that a member class inherits. The second is the containment hierarchy, from containing class to contained class, that defines the fields that are in the scope of (and are therefore accessible to) the member class.

The two hierarchies are entirely distinct from each other, and it is important that you do not confuse them. This should not be a problem if you refrain from creating name conflicts where a field or method in a superclass has the same name as a field or method in a containing class. If such a name conflict does arise, however, the inherited field or method hides (i.e., takes precedence over) the field or method of the same name in the containing class or classes. This behavior is logical because when a class inherits a field or method, that field or method effectively becomes part of that class. Therefore, inherited fields and methods are in the scope of the class that inherits them, and take precedence over fields and methods by the same name in enclosing scopes.

Because this can be quite confusing, Java does not leave it to chance that you get it right! Whenever there is a name conflict between an inherited field or method and a field or method in a containing class, Java 1.1 requires that you *explicitly* specify which one you mean. For example, if a member class `B` inherits a field named `x` and is contained within a class `A` that also defines a field named `x`, you must use `this.x` to specify the inherited field, or `A.this.x` to specify the field in the containing class. An attempt to use the field `x` without an explicit specification of the desired instance causes a compilation error.

A good way to prevent confusion between the class hierarchy and the containment hierarchy is to avoid deep containment hierarchies. If a class is nested more than two levels deep, it is probably going to cause more confusion than it is worth. Furthermore, if a class has a deep class hierarchy (i.e., if it has many superclass ancestors), consider defining it as a top-level class rather than as a member class.

Restrictions on Member Classes

There are two important restrictions on member classes. First, they cannot have the same name as any containing class or package. This is an important rule, and one that is not shared by fields and methods.

Second, member classes, like all inner classes, cannot contain any static members (fields, methods, or classes). The justification for this restriction is that `static` fields, methods, and classes are "top level" constructs, and it is therefore reasonable that they only be defined at the "top level"--i.e., within top-level classes. Defining a static, top-level member within a non-top-level member class would simply promote confusion and bad programming style. It is clearer (and therefore required) to define all static members within a top-level class. (Which may be a nested top-level class, of course.)

Member Classes and Visibility Modifiers

A member class, like any member of a class, may be assigned one of three visibility levels: `public`, [7] `protected`, or `private`. If none of these visibility modifiers is specified, the default "package" visibility is used. However, as mentioned earlier, there have been no changes to the Java Virtual Machine to support member classes, and member classes are compiled to class files just like top-level classes are. As far as the Java interpreter is concerned, therefore, member classes, like top-level classes, can only have public or package visibility. Thus, a member class declared `protected` is actually treated as a public class, and a member class declared `private` actually has package visibility. While this is unfortunate, and is something you should be aware of, it does not constitute a major security flaw.

> [7] Because member classes are nested, and because of their nature as "helper" classes, it is unusual to ever declare a member class `public`.

Note that this does not mean that you should never declare a member class as `protected` or `private`. Although the interpreter cannot enforce these visibility attributes, the desired attributes are noted in the class file. This means that any conforming Java 1.1 compiler can enforce the visibility attributes and prevent the member classes from being accessed in unintended ways.

Local Classes

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.4 Local Classes

A local class is a class declared locally within a block of Java code. Typically, a local class is defined within a method, but local classes can also be defined within static initializers and instance initializers of a class. (Instance initializers are a new feature of Java 1.1 that we'll see later in this chapter.)

Because Java code can only appear within class definitions, all local classes are nested within a containing class. For this reason, local classes share many of the features of member classes. It is usually more appropriate, however, to think of them as an entirely separate kind of inner class. A local class has approximately the same relationship to a member class as a local variable has to an instance variable of a class. Local classes have the following interesting features:

- They are only visible and usable within the block of code in which they are defined.
- They can use any `final` local variables or method parameters that are visible from the scope in which they are defined. [8]

> [8] As we'll see shortly, one of the other language changes in Java 1.1 is that local variables and method parameters can be declared `final`.

The first defining characteristic of a local class is obviously that it is local. Like a local variable, the name of a local class is only valid within the block of code in which it was defined (and within any blocks nested with that block, of course). In many cases, this is not a problem. If a helper class is used only within a single method of a containing class, there is no reason that that helper cannot be coded as a local class rather than a member class. Example 5.5 shows how we can modify the `enumerate()` method of the `LinkedList` class we saw in previous examples so that it defines the `Enumerator` class as a local class, rather than as a member class. By doing this, we move the definition of the helper class even closer to the location where it is used and hopefully improve the clarity of the code even further.

Example 5.5: Defining and Using a Local Class

```
import java.util.*;
public class LinkedList
{
  // Our nested top-level interface.  Body omitted here...
  public interface Linkable { ... }
  // The head of the list
  /* private */ Linkable head;
  // Method bodies omitted here.
  public void addToHead(Linkable node) { ... }
  public Linkable removeHead() { ...  }
  // This method creates and returns an Enumeration object for this
  // LinkedList.
  public Enumeration enumerate()
  {
    // Here's the definition of Enumerator as a local class.
    class Enumerator implements Enumeration {
      Linkable current;
      public Enumerator() { this.current = LinkedList.this.head; }
      public boolean hasMoreElements() {  return (current != null); }
      public Object nextElement() {
        if (current == null) throw new NoSuchElementException("LinkedList");
        Object value = current;
        current = current.getNext();
        return value;
      }
    }
    // Create and return an instance of the Enumerator class defined here.
    return new Enumerator();
  }
}
```

How Local Classes Work

A local class is able to refer to fields and methods in its containing class for exactly the same reason that a member class can--it is passed a hidden reference to the containing class in its constructor, and it saves that reference away in a `private` field added by the compiler. Also like member classes, local classes can use `private` fields and methods of their containing class, because the compiler inserts any required accessor methods. [9]

> [9] As previously noted, bugs in the compiler prevent this from working correctly in the current versions of the JDK.

What makes local classes different from member classes is that they have the ability to refer to local variables from the scope that defines them. The crucial restriction on this ability, however, is that local classes can only reference local variables and parameters that are declared `final`. The reason for this is apparent from the implementation. A local class can use local variables because the compiler automatically gives the class a `private` instance field to hold a copy of each local variable the class refers to. The compiler also adds hidden arguments to each of the local class constructors to initialize these automatically created `private` fields to the appropriate values. So, in fact, a local class does not actually access local variables, but merely its own private copies of them. The only way this can work correctly is if the local variables are declared `final`, so that they are guaranteed not to change. With this guarantee, the local class can be assured that its internal copies of the variables are "in sync" with the real local variables.

New Syntax for Local Classes

In Java 1.0, only fields, methods, and classes may be declared `final`. The addition of local classes to Java 1.1 has required a liberalization in the use of the `final` modifier. It can now be applied to local variables, arguments to methods, and even to the exception parameter of a `catch` statement (Local classes can refer to `catch` parameters, just as they can refer to method parameters, as long as they are in scope and are declared `final`.) The meaning of the `final` modifier remains the same in these new uses: once the local variable or argument has been assigned a value, that value may not be changed.

Instances of local classes, like instances of member classes, have an enclosing instance that is implicitly passed to all constructors of the local class. Local classes can use the same new `this` syntax that member classes do to explicitly refer to members of enclosing classes. Local classes cannot use the new `new` and `super` syntax used by member classes, however.

Restrictions on Local Classes

Like member classes, and for the same reasons, local classes cannot contain fields, methods, or classes that are declared `static`. `static` members must be declared at the top level. Since nested interfaces are implicitly `static`, local classes may not contain nested interface definitions.

Another restriction on local classes is that they cannot be declared `public`, `protected`, `private`, or `static`. These modifiers are all used for members of classes, and are not allowed with local variable declarations; for the same reason they are not allowed with local class declarations.

And finally, a local class, like a member class, cannot have the same name as any of its enclosing classes.

Typical Uses of Local Classes

One common application of local classes is to implement "event listeners" for use with the new event model implemented by AWT and JavaBeans in Java 1.1. An event listener is a class that implements a specific "listener" interface. This listener is registered with an AWT component, such as a `Button`, or with some other "event source." When the `Button` (or other source) is clicked (or activated in some way), it responds to this event by invoking a method of the event listener. Since Java does not support method pointers, implementing a pre-defined interface is Java's way of defining a "callback" that is notified when some event occurs. The classes used to implement these interfaces are often called *adapter classes*. Working with adapter classes can become quite cumbersome when they all must be defined as top-level classes. But the introduction of local classes makes them much easier to use. Example 5.6 shows a local class used as an adapter class for handling GUI events. [10] This example also shows how a local class can make use of a method parameter that is declared `final`.

> [10] As we'll see in the next section, this adapter class could be written more succinctly as an anonymous class.

Example 5.6: Using a Local Class as an Adapter

```
import java.awt.*;
import java.awt.event.*;
// This class implements the functionality of some application.
public class Application {
  // These are some constants used as the command argument to doCommand().
  static final int save = 1;
  static final int load = 2;
  static final int quit = 3;
  // This method dispatches all the commands to the application.
  // Body omitted.
  void doCommand(int command) { }
  // Other methods of the application omitted...
}
// This class defines a GUI for the application.
class GUI extends Frame {
  Application app;  // holds a reference to the Application instance
  // Constructor and other methods omitted here...

  // This is a convenience method used to create menu items with
  // a specified label, keyboard shortcut, and command to be executed.
  // We declare the "command" argument final so the local
  // ActionListener class can refer to it.
  MenuItem createMenuItem(String label, char shortcut, final int command)
  {
    // First we create a MenuItem object.
    MenuItem item = new MenuItem(label, new MenuShortcut(shortcut));
    // Then we define a local class to serve as our ActionListener.
    class MenuItemListener implements ActionListener {
      // Note that this method uses the app field of the enclosing class
      // and the (final) command argument from its containing scope.
      public void actionPerformed(ActionEvent e) {
        app.doCommand(command);
      }
    }
    // Next, we create an instance of our local class that will be
    // the particular action listener for this MenuItem.
    ActionListener listener = new MenuItemListener();
    // Then we register the ActionListener for our new MenuItem.
    item.addActionListener(listener);
    // And return the item, ready to be inserted into a menu.
    return item;
  }
}
```

`createMenuItem()` is the method of interest in Example 5.6. It creates a `MenuItem` object with the specified label and keyboard shortcut, and then uses a local class to create an `ActionListener` object for the menu item.

The `ActionListener` is responsible for translating the selection of the `MenuItem` into an invocation of the application's `doCommand()` method. Note that the `command` method parameter is declared `final` so it can be used by the local class. Also note that the local class uses the `app` field of the class that contains it. Because this is an instance variable instead of a local variable, it does not need to be declared `final`.

A local class can use fields defined within the local class itself or inherited by the local class, `final` local variables and `final` parameters in the scope of the local class definition, and fields defined by or inherited by the containing class. Example 5.7 is a program that demonstrates these various fields and variables that are accessible to a local class. If you can make sense of the code, you have a good understanding of local classes.

Example 5.7: Fields and Variables Accessible to a Local Class

```
class A { protected char a = 'a'; }
class B { protected char b = 'b'; }
public class C extends A
{
  private char c = 'c';         // Private fields visible to local class.
  public static char d = 'd';
  public void createLocalObject(final char e)
  {
    final char f = 'f';
    int i = 0;                  // i not final; not usable by local class.
    class Local extends B
    {
      char g = 'g';
      public void printVars()
      {
        // All of these fields and variables are accessible to this class.
        System.out.println(g);  // (this.g) g is a field of this class.
        System.out.println(f);  // f is a final local variable.
        System.out.println(e);  // e is a final local argument.
        System.out.println(d);  // (C.this.d) d -- field of containing class.
        System.out.println(c);  // (C.this.c) c -- field of containing class.
        System.out.println(b);  // b is inherited by this class.
        System.out.println(a);  // a is inherited by the containing class.
      }
    }
    Local l = this.new Local(); // Create an instance of the local class
    l.printVars();              // and call its printVars() method.
  }

  public static void main(String[] args)
  {
    // Create an instance of the containing class, and invoke the
    // method that defines and creates the local class.
    C c = new C();
    c.createLocalObject('e');   // pass a value for final parameter e.
  }
}
```

Anonymous Classes

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.5 Anonymous Classes

An anonymous class is essentially a local class without a name. Instead of defining a local class and then instantiating it, you can often use an anonymous class to combine these two steps. Anonymous classes are very commonly used as adapter classes, like the one we saw in Example 5.6. As we'll see, anonymous classes (and their corresponding anonymous objects) are created through another extension to the syntax of the `new` operator. Thus, an anonymous class is defined by a Java expression, not a Java statement. This means that an anonymous class definition can be included within a larger Java expression such as an assignment or method call.

Example 5.8 shows the use of an anonymous class to implement the `java.io.FilenameFilter` interface. The implementation in this example is used to list only the files whose names end with *.java* from a specified directory.

Example 5.8: Implementing an Interface with an Anonymous Class

```
import java.io.*;
// A simple program to list all Java source code files in a directory
// specified as a command-line argument.
public class Lister
{
  public static void main(String[] args)
  {
    File f = new File(args[0]);  // f represents the specified directory.
    // List the files in the directory, using the specified filter object.
    // The anonymous class is defined as part of a method call expression.
    String[] list = f.list(new FilenameFilter() {
      public boolean accept(File f, String s) {
        return s.endsWith(".java");
      }
    });
    for(int i = 0; i < list.length; i++)  // output the list
      System.out.println(list[i]);
  }
}
```

As you can see in Example 5.8, the syntax for defining an anonymous class and creating an instance of that class is a regular `new` expression, followed by a class body definition in curly braces. If the name following the `new` keyword is the name of a class, the anonymous class is a subclass of the named class. If the name following `new` specifies an interface, as in our example, the anonymous class is an implementation of the interface. In this case, the anonymous class is always a subclass of `Object`--there is no way to specify an `extends` clause (or an `implements` clause). In addition, since this syntax creates an anonymous class, there is obviously no way to specify a name for the newly defined class.

Because an anonymous class has no name, it is not possible to define constructors for it within the class body. This is one of the basic restrictions on anonymous classes. Any arguments you specify between the parentheses following the superclass name in an anonymous class definition are implicitly passed to the superclass constructor. Anonymous classes are commonly used to subclass simple classes that do not take any constructor arguments, so the parentheses in the anonymous class definition syntax are often empty, as we saw in Example 5.8. When you use an anonymous class to implement an interface, the constructor argument list is always empty, of course, since the superclass constructor, `Object()`, expects no arguments.

One of the most elegant things about anonymous classes is that they allow you to define a one-shot class exactly where it is needed. Other important features are the succinctness of the syntax and the fact that no clutter is created by an unnecessary name.

Since anonymous classes have no names, you may wonder what the class files that represent them are named. If you compile the example shown in Example 5.8 you'll find that it produces two class files, *Lister.class* and *Lister$1.class*. Anonymous classes are given numbers to produce unique class file names based on the name of the containing class.

Anonymous Class Indentation and Formatting

The common indentation and formatting conventions we are familiar with for languages like Java and C begin to break down somewhat once we start placing class definitions within arbitrary expressions. Based on their experience with inner classes, the engineers at JavaSoft recommend the following formatting rules, which are followed in Example 5.8:

- The opening curly brace should not be on a line by itself; instead, it should follow the close parenthesis of the `new` operator. Similarly, the `new` operator should, when possible, appear on the same line as the assignment or other expression of which it is a part.

- The body of the anonymous class should be indented relative to the beginning of the line that contains the `new` keyword.

- The closing curly brace of an anonymous class should not be on a line by itself either; it should be followed by whatever tokens are required by the rest of the expression. Often this is a semicolon or a close parenthesis followed by a semicolon. This extra punctuation serves as a flag to the reader that this is not just an ordinary block of code, and makes it easier to make sense of anonymous classes in a code listing.

Anonymous Classes versus Local Classes

As we've discussed, an anonymous class behaves just like a local class, and is distinguished from a local class merely in the syntax used to define and instantiate it. In your own code, when you have to choose between using an anonymous class or using a local class, the decision often comes down to stylistic matters. You should use whichever syntax makes your code clearer. In general, you should consider using an anonymous class instead of a local class if:

- The class has a very short body.
- Only one instance of the class is needed.
- The class is used right after it is defined.
- The name of the class does not make your code any easier to understand.

When considering the use of an anonymous class, there are two important restrictions to bear in mind:

- An anonymous class has no name, and the syntax for defining one combines definition with instantiation. Thus, using an anonymous class instead of a local class is not appropriate if you need to create more than a single instance of the class each time the containing block is executed.
- It is not possible to define constructors for anonymous classes. If your class requires a constructor, you must use a local class instead. However, as we'll see, the Java syntax has been extended to allow "instance initializers" to be defined for a class; an instance initializer can often substitute for a constructor.

Consider Example 5.9, which shows the `Enumeration` class we've used throughout this chapter implemented as an anonymous class within the `enumerate()` method of the `LinkedList` class. Compare it with Example 5.5, which shows the same class implemented as a local class. In this case, because of the size of the class in question, using local class syntax probably results in code that is a little clearer. Still, if you are a fan of anonymous classes, you might choose to code the example in this way.

Example 5.9: An Enumeration Implemented with an Anonymous Class

```
import java.util.*;
public class LinkedList
{
  // Our nested top-level interface.  Body omitted here...
  public interface Linkable { ... }
  // The head of the list.
  /* private */ Linkable head;
  // Method bodies omitted here.
  public void addToHead(Linkable node) { ... }
  public Linkable removeHead() { ...  }
  // This method creates and returns an Enumeration object for this
  // LinkedList.
  public Enumeration enumerate()
  {
    // Instantiate and return this implementation.
    return new Enumeration() {
      Linkable current = head; // This used to be in the constructor, but
                               // anonymous classes don't have constructors.
      public boolean hasMoreElements() {  return (current != null); }
      public Object nextElement() {
        if (current == null) throw new NoSuchElementException("LinkedList");
        Object value = current;
        current = current.getNext();
        return value;
      }
    };  // Note the required semicolon.  It terminates the return statement.
  }
}
```

As another example, consider Example 5.10, which shows the `createMenuItem()` method of Example 5.6 rewritten to use an anonymous class instead of a local class. In this case, using an anonymous class is probably the right thing to do.

Example 5.10: Using an Anonymous Class as an Adapter

```
MenuItem createMenuItem(String label, char shortcut, final int command)
{
  // First we create a MenuItem object.
  MenuItem item = new MenuItem(label, new MenuShortcut(shortcut));
  // Then we register an anonymous ActionListener for our new MenuItem.
  item.addActionListener(new ActionListener() {
    public void actionPerformed(ActionEvent e) { app.doCommand(command); }
  });
  // And return the item, ready to be inserted into a menu.
  return item;
}
```

New Java Syntax for Anonymous Classes

We've already seen examples of the syntax for defining and instantiating an anonymous class. More formally, we can write it as the following:

```
new class-name ( [ argument-list ] ) { class-body }
```

or

```
new interface-name () { class-body }
```

There is one additional new piece of syntax to support anonymous classes. As noted, anonymous classes cannot define constructors, since they do not have names. Therefore Java 1.1 adds a feature known as an *instance initializer*, which is similar to the static initializer of Java 1.0. Example 5.11 illustrates this new syntax.

Example 5.11: Java 1.1 Instance Initializers

```
public class InitializerDemo
{
  // This is an instance variable.
  public int[] array1;
  // This is an instance initializer.  It is an arbitrary block of code.
  // It runs for every new instance, after the superclass constructor
  // and before the class constructor, if any.  It can serve the same
  // function as a constructor with no arguments.
  {
    array1 = new int[10];
    for(int i = 0; i < 10; i++) array1[i] = i;
  }
  // The line below contains another instance initializer.  The instance
  // initializers for an object are run in the order in which they appear
  // in the class definition.
  int[] array2 = new int[10]; { for(int i=0; i<10; i++) array2[i] = i*2; }
  static int[] static_array = new int[10];
  // By contrast, the block below is a static initializer.  Note the static
  // keyword.  It runs only once, when the class is first loaded.
  static {
    for(int i = 0; i < 10; i++) static_array[i] = i;
  }
}
```

An instance initializer is simply a block of code inside curly braces that is embedded in a class definition, where a field or method definition normally appears. [11] A class (any class--not just anonymous classes) can have any number of instance initializers. The instance initializers and any variable initializers that appear in field definitions for the class are executed in the order they appear in the Java source code. These initializers are automatically run after the superclass constructor has returned but before the constructor, if any, of the current class runs.

[11] Notice that Java 1.1 now allows blocks of code to be inserted in class definitions, and local class definitions to be inserted in blocks of code.

Because an instance initializer can serve the same function as a no-argument constructor method, these initializers are particularly useful for anonymous classes. They can also be useful in non-anonymous classes. Instance initializers allow you to initialize an object's fields near the definition of those fields, rather than deferring that initialization to a constructor defined further away in the class. Used in this way, they can sometimes improve code readability.

Restrictions on Anonymous Classes

Because anonymous classes are just a type of local class, they share the same restrictions: an anonymous class cannot define any `static` fields, methods, or classes. Since nested interfaces are implicitly `static`, they cannot be defined within anonymous classes. Similarly, interfaces cannot be defined anonymously.

Anonymous classes, like local classes, cannot be `public`, `private`, `protected`, or `static`. In fact, the syntax for defining anonymous classes does not allow any modifiers to be specified.

5.6 Other New Features of Java 1.1

While the addition of inner classes is by far the most important and far-reaching change to the Java language in Java 1.1, there have been several other changes to the language as well. They are:

- `final` local variables, method parameters and `catch` statement parameters
- Instance initializers
- "Blank finals"--`final` variable and field declarations without initializer expressions
- Anonymous arrays
- Class literals

As you can see, the first two items in this list are language changes that are related to, though not exclusively used by, the inner class changes. We covered `final` local variables and parameters in our discussion of local classes above. And we covered instance initializers in the discussion of anonymous classes. The following subsections discuss the remaining three changes.

Blank Finals

We've already seen that local variables, method parameters, and exception parameters of `catch` statements may be declared `final`. A related change is that `final` fields do not require initializers. In Java 1.0, any `final` field had to be initialized as part of the field declaration. In Java 1.1, this restriction has been relaxed. A field or local variable can be declared `final` without specifying an intial value as part of the declaration. These "blank finals," as they are called, must have a value assigned to them before they are ever used, of course. And, once a value has been assigned to a blank final, that value can never be changed. This allows you, for example, to use an instance initializer or a constructor to compute a value for a `final` field.

Blank finals are particularly useful in defining immutable data types. They allow a class to have immutable fields that are initialized based on run-time arguments to a constructor. Once assigned, these fields cannot be accidentally or maliciously changed.

Anonymous Arrays

In Java 1.0, you can create and initialize an array with code like the following:

```
int[] a = {1, 2, 3, 4, 5};
```

Unfortunately, this syntax is only allowed in initializer expressions that follow the declaration of a field or variable of array type. That is, you *cannot* write code like this:

```
int[] a;
a = {1, 2, 3, 4, 5};            // Error
int total = sum({1,2,3,4,5});  // Error
```

You cannot write code like that in Java 1.1 either, but you can write code using a similar array initializer syntax. When you use the `new` operator to create an array, you may omit the dimension that specifies the number of array elements to create and instead follow the empty square bracket pair (`[]`) with a list of initial values in curly braces. Such an expression creates an array large enough to hold all of the elements specified between the braces, and initializes the array to contain those elements. The elements in braces must all be of the type specified after the `new` keyword, of course.

Code that uses anonymous arrays looks like this:

```
int[] a;
a = new int[] {1, 2, 3, 4, 5};
int total = sum(new int[] {1, 2, 3, 4, 5});
System.out.println(new char[] {'h', 'e', 'l', 'l', 'o'});
```

As you can see, this new syntax allows you to create and initialize arrays without using a variable initializer, or without even assigning the array to a variable at all. That is why arrays created and initialized this way are called *anonymous arrays*.

Class Literals

Another major change in Java 1.1 is the introduction of the Reflection API in the `java.lang.reflect` package. As part of this new package, the `java.lang.Class` class has been broadened to represent not just Java classes, but all Java data types. In other words, there are now special

`Class` objects that represent each of the Java primitive types.

You can access these special `Class` objects through the `TYPE` field of each of the primitive wrapper classes. For example, the static variable `Boolean.TYPE` holds the `Class` object that represents the `boolean` data type. And the `Float.TYPE` static variable holds the `Class` object that represents the `float` data type. A new class `Void` has been added, and `Void.TYPE` represents the type `void`.

The changes described in the paragraph above are all changes to the Java class libraries, rather than changes to the Java language itself. The language change is a related one, however. In Java 1.1, you can obtain the `Class` object for any class or primitive type by following the class name or type name by a period and the `class` keyword. For example, `String.class` evaluates to the `Class` object that represents the `java.lang.String` class. Similarly, `int.class` evaluates to the special class object `Integer.TYPE` that represents the `int` data type.

In Java 1.0, it is much more cumbersome (and less efficient) to obtain a `Class` object--you have to use the static `Class.forName()` method, so you end up with expressions like:

```
Class c = Class.forName("java.util.Vector");
```

Where in Java 1.1 you can simply write:

```
Class c = java.util.Vector.class;
```

Remember that `class` is a keyword in Java, so this syntax does not simply constitute a reference to a static variable pre-defined in each class.

This new syntax is meant to simplify use of the new reflection facilities in Java 1.1. It is also necessary because using `Class.forName()` with inner classes requires knowledge of the way the compiler transforms the names of inner classes (i.e., where it replaces "`.`" with "`$`"). While compiler writers need to know about these transformation rules, Java programmers should not. Thus the new `.class` syntax provides a way to obtain a `Class` object that works with inner classes, as well as with top-level classes and interfaces.

6. Applets

Contents:

This chapter demonstrates the techniques of applet writing. It proceeds from a trivial "Hello World" applet to more sophisticated applets. Along the way, it explains how to:

- Draw graphics in your applet.
- Handle and respond to simple user input.
- Read and use values of applet parameters, allowing customization of an applet.
- Load and display images and load and play sounds.
- Package an applet and related files into a JAR file.
- Attach a digital signature to an applet.

Study the examples carefully. They are the important part of this chapter! You may find it useful to refer to the quick reference in Chapter 17, *The java.applet Package* while reading these examples.

Note that this chapter merely introduces the framework for writing applets. Applets, like other Java programs, use features from throughout the Java API. See Chapter 7, *Events*, in particular, for details on event processing in Java applets and applications.

6.1 Introduction to Applets

An applet, as the name implies, is a kind of mini-application, designed to be run by a Web browser, or in the context of some other "applet viewer." Applets differ from regular applications in a number of ways. One of the most important is that there are a number of security restrictions on what applets are allowed to do. An applet often consists of untrusted code, so it cannot be allowed access to the local file system, for example. The details of applet security and the restrictions placed on applets are discussed at the end of this chapter.

From a programmer's standpoint, one of the biggest differences between applets and applications is that applets do not have a `main()` method, or other single entry point from which the program starts running. Instead, to write an applet, you subclass the `Applet` class and override a number of standard methods. At appropriate times, under well-defined circumstances, the Web browser or applet viewer invokes the methods you have defined. The applet is not in control of the thread of execution; it simply responds when the browser or viewer tells it to. For this reason, the methods you write must take the necessary action and return promptly--they are not allowed to enter time-consuming (or infinite) loops. In order to perform a time-consuming or repetitive task, such as animation, an applet must create its own thread, over which it does have complete control.

The task of writing an applet, then, comes down to defining the appropriate methods. A number of these methods are defined by the `Applet` class:

`init()`

> Called when the applet is first loaded into the browser or viewer. It is typically used to perform applet initialization, in preference to a constructor method. (The Web browser doesn't pass any arguments to an applet's constructor method, so defining one isn't too useful.)

`destroy()`

> Called when the applet is about to be unloaded from the browser or viewer. It should free any resources, other than memory, that the applet has allocated.

`start()`

> Called when the applet becomes visible and should start doing whatever it is that it does. Often

used with animation and with threads.

`stop()`

Called when the applet becomes temporarily invisible, for example, when the user has scrolled it off the screen. Tells the applet to stop performing an animation or other task.

`getAppletInfo()`

Called to get information about the applet. Should return a string suitable for display in a dialog box.

`getParameterInfo()`

Called to obtain information about the parameters the applet responds to. Should return strings describing those parameters.

In addition to these `Applet` methods, there are a number of other methods, inherited from superclasses of `Applet`, that the browser invokes at appropriate times, and that an applet should override. The most obvious of these methods is `paint()`, which the browser or viewer invokes to ask the applet to draw itself on the screen. In Java 1.1, a related method is `print()`, which an applet should override if it wants to display itself on paper differently than it does on the screen. There are quite a few other methods that applets should override to respond to events. For example, if an applet wants to respond to mouse clicks, it should override `mouseDown()`. (As we'll see in Chapter 7, *Events*, however, there are other, preferred, ways to receive mouse events in Java 1.1.)

The `Applet` class also defines some methods that are commonly used by applets:

`getImage()`

Loads an image file from the network and returns an `Image` object.

`getAudioClip()`

Loads a sound clip from the network and returns an `AudioClip` object.

`getParameter()`

Looks up and returns the value of a named parameter, specified in the HTML file that refers to the applet with the `<PARAM>` tag.

`getCodeBase()`

Returns the base URL from which the applet class file was loaded.

`getDocumentBase()`

Returns the base URL of the HTML file that refers to the applet.

`showStatus()`

Displays a message in the status line of the browser or applet viewer.

`getAppletContext()`

Returns the `AppletContext` object for the applet. `AppletContext` defines the useful `showDocument()` method that asks the browser to load and display a new Web page.

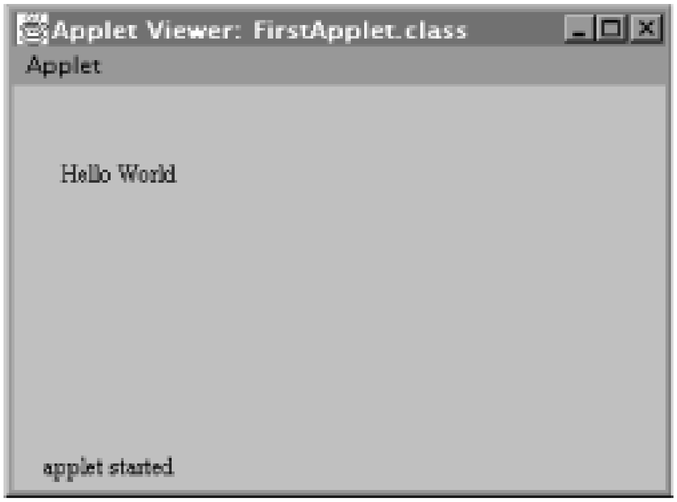
JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

6.2 A First Applet

Figure 6.1 shows what is probably the simplest possible applet you can write in Java. Example 6.1 lists its code. This example introduces the `paint()` method, which is invoked by the applet viewer (or Web browser) when the applet needs to be drawn. This method should perform graphical output--such as drawing text or lines or displaying images--for your applet. The argument to `paint()` is a `Graphics` object that you use to do the drawing.

Figure 6.1: A simple applet



Hello World

applet started

Example 6.1: The Simplest Applet

```
import java.applet.*;   // Don't forget this import statement!
import java.awt.*;          // Or this one for the graphics!
public class FirstApplet extends Applet {
  // This method displays the applet.
  // The Graphics class is how you do all drawing in Java.
  public void paint(Graphics g) {
    g.drawString("Hello World", 25, 50);
  }
}
```

To display an applet, you need an HTML file that references it. Here is an HTML fragment that can be used with our first applet:

```
<APPLET code="FirstApplet.class" width=150 height=100>
</APPLET>
```

With an HTML file that references the applet, you can now view the applet with an applet viewer or Web browser. Note that the `width` and `height` attributes of this HTML tag are required. See Chapter 15, *Java-Related HTML Tags* for more details on the HTML `<APPLET>` tag. For most applet examples in this book, we show only the Java code and not the corresponding HTML file that goes with it. Typically, that HTML file contains a tag as simple as the one shown here.

6.3 Drawing Graphics

Example 6.2 shows a fancier version of our simple applet. As you can see from Figure 6.2 , we've made the graphical display more interesting. This applet also does all of its drawing in the `paint()` method. It demonstrates the use of `Font` and `Color` objects.

This example also introduces the `init()` method, which is used, typically in place of a constructor, to perform any one-time initialization that is necessary when the applet is first created. The `paint()` method may be invoked many times in the life of an applet, so this example uses `init()` to create the `Font` object that `paint()` uses.

Figure 6.2: A fancier applet

[Graphic: Figure 6-2]

Example 6.2: An Applet with Fancier Graphics

```
import java.applet.*;
import java.awt.*;
public class SecondApplet extends Applet {
  static final String message = "Hello World";
  private Font font;
  // One-time initialization for the applet
  // Note: no constructor defined.
  public void init() {
    font = new Font("Helvetica", Font.BOLD, 48);
  }
  // Draw the applet whenever necessary.  Do some fancy graphics.
  public void paint(Graphics g) {
    // The pink oval
    g.setColor(Color.pink);
    g.fillOval(10, 10, 330, 100);
    // The red outline. Java doesn't support wide lines, so we
    // try to simulate a 4-pixel wide line by drawing four ovals.
    g.setColor(Color.red);
    g.drawOval(10, 10, 330, 100);
    g.drawOval(9, 9, 332, 102);
    g.drawOval(8, 8, 334, 104);
    g.drawOval(7, 7, 336, 106);
    // The text
    g.setColor(Color.black);
    g.setFont(font);
    g.drawString(message, 40, 75);
  }
}
```

Java Fundamental Classes Reference

By Mark Grand and Jonathan Knudsen; 1-56592-241-7, 1152 pages
1st Edition May 1997

Table of Contents

Part I: Using the Fundamental Classes

This part of the book, Chapters 2 through 10, provides a brief guide to many of the features of the fundamental classes in Java. These tutorial-style chapters are meant to help you learn about some of the basic functionality of the Java API. They provide short examples where appropriate that illustrate the use of various features.

Part II: Reference

This part of the book is a complete reference to all of the fundamental classes in the core Java API. The material is organized alphabetically by package, and within each package, alphabetically by class. The reference page for a class tells you everything you need to know about using that class. It provides a detailed description of the class as a whole, followed by a complete description of every variable, constructor, and method defined by the class.

Part III: Appendixes

This part provides information about the Unicode 2.0 standard and the UTF-8 encoding used by Java.

15. Java-Related HTML Tags

Contents:

This chapter explains what you need to know about HTML to work with Java applets.

15.1 The <APPLET> Tag

A Java applet is included in a Web page with the `<APPLET>` tag, which has the following syntax. Items in brackets (`[]`) are optional.

```
<APPLET
    CODE = applet-filename
    WIDTH = pixel-width
    HEIGHT = pixel-height
    [OBJECT = serialized-applet-filename]
    [ARCHIVE = jar-file-list]
    [CODEBASE = applet-url]
    [ALT = alternate-text]
    [NAME = applet-name]
    [ALIGN = alignment]
    [VSPACE = vertical-pixel-space]
    [HSPACE = horizontal-pixel-space]
>
[<PARAM NAME = parameter VALUE = value>]
[<PARAM NAME = parameter VALUE = value>]
    ...
[alternate-text]
```

```
</APPLET>
```

`APPLET`

The `<APPLET>` tag specifies an applet to be run within a Web document. A Web browser that does not support Java and does not understand the `<APPLET>` tag ignores this tag and any related `<PARAM>` tags, and simply displays any *`alternate-text`* that appears between `<APPLET>` and `</APPLET>`. A browser that does support Java runs the specified applet, and does *not* display the *`alternate-text`*.

`CODE`

This required attribute specifies the file that contains the compiled Java code for the applet. It must be relative to the `CODEBASE` if that attribute is specified, or relative to the current document's URL. It must not be an absolute URL. In Java 1.1, this attribute can be replaced with an `OBJECT` attribute.

`WIDTH`

This attribute specifies the initial width, in pixels, that the applet needs in the browser's window. It is required.

`HEIGHT`

This attribute specifies the initial height, in pixels, that the applet needs in the browser's window. It is required.

`OBJECT`

As of Java 1.1, this attribute specifies the name of a file that contains a serialized applet that is to be created by deserialization. An applet specified in this way does not have its `init()` method invoked, but does have its `start()` method invoked. Thus, before an applet is saved through serialization, it should be initialized, but should not be started, or, if started, it should be stopped. An applet must have either the `CODE` or `OBJECT` attribute specified, but not both.

`ARCHIVE`

As of Java 1.1, this attribute specifies a comma-separate list of JAR (Java Archive) files that are "preloaded" by the Web browser or applet viewer. These archive files may contain Java class files, images, sounds, properties, or any other resources required by the applet. The Web browser or applet viewer searches for required files in the archives before attempting to load them over the network.

`CODEBASE`

This optional attribute specifies the base URL (absolute or relative) of the applet to be displayed. This should be a directory, not the applet file itself. If this attribute is unspecified, then the URL of the current document is used.

`ALT`

This optional attribute specifies text that should be displayed by browsers that understand the `<APPLET>` tag but do not support Java.

`NAME`

This optional attribute gives a name to the applet instance. Applets that are running at the same time can look each other up by name and communicate with each other.

`ALIGN`

This optional attribute specifies the applet's alignment on the page. It behaves just like the `ALIGN` attribute of the `<IMG>` tag. Its allowed values are: `left`, `right`, `top`, `texttop`, `middle`, `absmiddle`, `baseline`, `bottom`, and `absbottom`.

`VSPACE`

This optional attribute specifies the margin, in pixels, that the browser should put above and below the applet. It behaves just like the `VSPACE` attribute of the `<IMG>` tag.

`HSPACE`

This optional attribute specifies the margin, in pixels, that the browser should put on either side of the applet. It behaves just like the `HSPACE` attribute of the `<IMG>` tag.

PREVIOUS
Working with System Properties
HOME
BOOK INDEX
NEXT
The <PARAM> Tag

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

14.2 Working with System Properties

The system property list is not a static. Other properties can be added to it (and read from it) to allow easy customization of application behavior.

Specifying Individual Properties

You can specify individual properties to be inserted into the system properties list with the `-D` option to the Java interpreter. For example, you might invoke a program like this:

```
% java -Dgames.tetris.level=9 -Dgames.tetris.sound=off games.tetris
```

Note the format of each property specification: the property name, which is often a hierarchical one, followed by an equals sign, followed by the property value. A property value may include spaces, but any `-D` option specifying a property value containing spaces would have to be quoted when passed to *java*, of course.

If you write a platform-specific script file to invoke your Java application, you can use this `-D` option to translate native environment variable settings into Java system properties. On a Unix system, for example, such a script might look like this:

```
#!/bin/sh
exec java -Dgames.tetris.level=$TETRIS_LEVEL \
          -Dgames.tetris.sound=$TETRIS_SOUND \
          games.tetris
```

Using Property Files

Properties in Java are represented by the `java.util.Properties` object, which is essentially a hash table that can be read from and written to a file. A program need not limit itself to the use of system properties. It can also read in its own files of properties to support user preferences and user customization.

For example, when the *appletviewer* program starts up, it reads the properties from the *lib/appletviewer.properties* file in the JDK distribution. This file contains the various messages that `appletviewer` displays to the user and provides the flexibility to translate those messages into other languages. The following lines are an excerpt from *appletviewer.properties*:

```
#
# Applet status messages
#
appletloader.nocode=APPLET tag missing CODE parameter.
appletloader.notfound=load: class %0 not found.
appletloader.nocreate=load: %0 can't be instantiated.
```

Note that comments in a properties file start with #, and that the property specification format is the same as with the `-D` option. Also note that these property values do contain spaces. Some of them also contain the `%` substitution character and are intended for use with the `java.text.MessageFormat` class.

When reading in a file of properties, it can be convenient to merge those properties with the standard system properties, so that the program need only look in one place to find both loaded properties and standard properties (and properties specifed wiht the `-D` option). Every `Properties` object can have a "parent" properties object; if a property is not found in the `Properties` object, it is searched for in the parent. Thus, it is possible to merge in properties with code like this:

```
// Create a new Properties object with system props as its parent.
Properties props = new Properties(System.getProperties());
// Load a file of properties into it.  We may get an exception here...
props.load(new BufferedInputStream(new FileInputStream(propsfilename)));
// Set these new combined properties as the system properties.
System.setProperties(props);
```

Specifying Font Properties

As noted above, a program can read the string value of a system property with the `System.getProperty()` method. There are also some convenience methods that read a property value and convert that value into some other type of object. One of these convenience methods is `Font.getFont()`. This method reads the value of a named property and attempts to parse it into a font specification. The font specification syntax it uses is:

```
name[-style][-size]
```

The*`style`* should be `italic`, `bold` or `bolditalic`. If omitted, a plain font is used. The `size` should be an integer that specifies the font size in points. If omitted, 12-point is used. If the *`style`* is specified, the *`size`* must also be specified. For example, you might specify font properties like the following:

```
games.tetris.titlefont=sanserif-bolditalic-48
games.tetris.mainfont=serif-14
games.tetris.scorefont=monospaced
```

Specifying Color Properties

`Color.getColor()` is another convenience routine that reads a system property and converts it into a `Color` object. To specify a color property, you specify the color as an integer value, typically as a hexadecimal value in the format `0x`*RRGGBB*. For example:

```
# A green foreground
games.tetris.foreground=0x00FF00
# A light gray background
games.tetris.background=0xD0D0D0
```

15.3 An Example HTML File

Example 15.1 shows an applet embedded in an HTML file. This file is a lightly edited version of one of the demos that ships with the JDK. Notice the use of the <PARAM> tags to supply arguments to the applet.

Example 15.1: Example HTML Page Containing an Applet

```
<HTML>
<HEAD>
<TITLE>The Animator Applet (1.1) - example 1</TITLE>
</HEAD>
<BODY>
<H1>The Animator Applet (1.1) - example 1</H1>
<APPLET CODE=Animator.class WIDTH=460 HEIGHT=160>
<PARAM NAME=imagesource VALUE="images/Beans">
<PARAM NAME=backgroundcolor VALUE="0xc0c0c0">
<PARAM NAME=endimage VALUE=10>
<PARAM NAME=soundsource VALUE="audio">
<PARAM NAME=soundtrack VALUE=spacemusic.au>
<PARAM NAME=sounds VALUE="1.au|2.au|3.au|4.au|5.au|6.au|7.au|8.au|9.au|0.au">
<PARAM NAME=pause VALUE=200>
</APPLET>
</BODY>
</HTML>
```

28.24 java.net.URLEncoder (JDK 1.0)

This class defines a single static method which is used to convert a string to its URL-encoded form. That is, spaces are converted to "+", and non-alphanumeric characters other than underscore are output as two hexadecimal digits following a percent sign. Note that this technique only works for 8-bit characters. This method is used to "canonicalize" a URL specification so that it uses only characters from an extremely portable subset of ASCII which can be correctly handled by computers around the world.

```
public class URLEncoder extends Object {
    // No Constructor
    // Class Methods
            public static String encode(String s);
}
```

13.3 Operators

Operators lists the operators of the Java language, along with their precedence, operand types, and associativity.

Table 13.3: Java Operators

Prec.	Operator	Operand Type(s)	Assoc.	Operation Performed
1	++	arithmetic	R	pre-or-post increment (unary)
	--	arithmetic	R	pre-or-post decrement (unary)
	+, -	arithmetic	R	unary plus, unary minus
	~	integral	R	bitwise complement (unary)
	!	boolean	R	logical complement (unary)
	(*type*)	any	R	cast
2	*, /, %	arithmetic	L	multiplication, division, remainder
3	+, -	arithmetic	L	addition, subtraction
	+	string	L	string concatenation
4	<<	integral	L	left shift
	>>	integral	L	right shift with sign extension
	>>>	integral	L	right shift with zero extension
5	<, <=	arithmetic	L	less than, less than or equal
	>, >=	arithmetic	L	greater than, greater than or equal
	instanceof	object, type	L	type comparison
6	==	primitive	L	equal (have identical values)
	!=	primitive	L	not equal (have different values)

	==	object	L	equal (refer to same object)
	!=	object	L	not equal (refer to different objects)
7	&	integral	L	bitwise AND
	&	boolean	L	boolean AND
8	^	integral	L	bitwise XOR
	^	boolean	L	boolean XOR
9	|	integral	L	bitwise OR
	|	boolean	L	boolean OR
10	&&	boolean	L	conditional AND
11	||	boolean	L	conditional OR
12	?:	boolean, any, any	R	conditional (ternary) operator
13	=	variable, any	R	assignment
	*=, /=, %=, +=, -=, <<=, >>=, >>>=, &=, ^=, |=	variable, any	R	assignment with operation

Operator precedence controls the order in which operations are performed. Consider the following example:

```
w = x + y * z;
```

The multiplication operator `*` has a higher precedence than the addition operator `+`, so the multiplication is performed before the addition. Furthermore, the assignment operator `=` has the lowest precedence of any operator, so the assignment is done after all the operations on the right-hand side are performed. Operators with the same precedence (like addition and subtraction) are performed in order according to their associativity (usually left-to-right). Operator precedence can be overridden with the explicit use of parentheses. For example:

```
w = (x + y) * z;
```

The associativity of an operator specifies the order that operations of the same precedence are performed in. In Table 13.3 a value of L specifies left-to-right associativity, and a value of R specifies right-to-left associativity. Left-to-right associativity means that operations are performed left-to-right. For example:

```
w = x + y + z;
```

is the same as:

```
w = ((x + y) + z);
```

because the addition operator has left-to-right associativity. On the other hand, the following expressions:

```
x = ~-~y;
q = a?b:c?d:e?f:g;
```

are equivalent to:

```
x = ~(-(~y));
q = a?b:(c?d:(e?f:g));
```

because the unary operators and the ternary conditional `?:` operator have right-to-left associativity.

Java operators are basically identical to C operators, except for these differences:

- The `+` operator applied to `String` values concatenates them. If only one operand of `+` is a `String`, the other one is converted to a string. The conversion is done automatically for primitive types and by calling the `toString` method of non-primitive types.

- Java does not have the comma operator like C does. It does, however, simulate this operator in the limited context of the `for` loop initialization and increment expressions.

- Since all Java integral types are signed, the `>>` operator always does a signed right shift, filling in high bits with the sign bit of the operand. The new `>>>` operator performs an unsigned right shift, filling in high bits of the shifted value with zero bits.

- The & and `|` operators perform bitwise AND and OR operations on integral operands, and perform logical AND and OR operators on `boolean` operands. && and `||` also perform logical AND and OR on `boolean` operands, but do not evaluate the right-hand operand, if the result of the operation is fully determined by the left-hand operand.

- The `instanceof` operator returns `true` if the object on the left-hand side is an instance of the class or implements the interface on the right-hand side. Otherwise it returns `false`. If the left-hand side is `null`, it returns `false`.

13.6 Java Documentation Comment Syntax

The Java language supports special "doc comments," which begin with `/**` and end with `*/`. These comments are not actually treated specially by the compiler, but can be extracted and automatically turned into HTML documentation by the *javadoc* program.

Because the lines of a doc comment are embedded within a Java comment, any leading spaces and asterisks (`*`) are stripped from each comment line before processing. A doc comment may contain HTML markup tags, such as <PRE> and <TT> for code usage examples, but should not contain HTML structural tags such as <H2> or <HR>. Doc comments should immediately precede the declaration of the class, field, or method that they are associated with. The first sentence of a doc comment should be a summary sentence, suitable for display on its own. The following sentences may document the feature in more detail.

Following the initial summary sentence and any additional documentation, a doc comment may use special tags, which all begin with the `@` character and allow *javadoc* to provide additional formatting for the documentation. The available tags are listed below. When you use a special *javadoc* tag, it must be the first thing on its line within the doc comment. The text that follows a tag may span more than one line, and continues until the next *javadoc* tag is encountered or until the comment ends. If you use more than one tag of the same type, they should be on subsequent lines. For example, a class with multiple authors, or a method with multiple arguments would use multiple `@author` or `@param` tags.

`@see` *classname*

> This tag adds a "See Also:" entry to the documentation that contains a hyperlink to the specified class. It may be used before classes, methods, or fields.

`@see` *full-classname*

> This tag adds a "See Also:" entry to the documentation that contains a hyperlink to the specified class. It may be used before classes, methods, or fields.

`@see` *full-classname#method-name*

This tag adds a "See Also:" entry to the documentation that contains a hyperlink to the specified method of the specified class. It may be used before classes, methods, or fields.

`@version` *text*

This tag adds a "Version:" entry containing the specified text to the documentation. May only be used before a class definition. *javadoc* ignores this tag unless the `-version` command-line argument is specified.

`@author` *text*

This tag adds an "Author:" entry containing the specified text to the documentation. May only be used before a class definition. *javadoc* ignores this tag unless the `-author` command-line argument is specified.

`@param` *parameter-name description*

This tag adds the specified parameter and its specified description to the "Parameters:" section of the current method. If the description is longer than one line, it may be continued on the next. May only be used before a method definition.

`@return` *description*

Adds a "Returns:" section containing the specified description to the documentation. May only be used before a method definition.

`@exception` *full-classname description*

Adds a "Throws:" entry to the documentation. The entry contains the specified class name of the exception and the description specified, which should explain the significance of the exception. May only be used before a method definition.

`@deprecated` *explanation*

As of Java 1.1, this tag specifies that the following class, method, or field has been deprecated. *javac* notes this information in the class file it produces and issues a warning when a program uses the deprecated feature. *javadoc* adds a "Deprecated" entry to the documentation that includes the specified explanation.

`@since` *version*

> As of Java 1.1, this undocumented tag is used to specify when the class, method, or field that follows it was added to the API. It should be followed by a version number or other version specification. The JDK 1.1 version of *javadoc* appears to ignore this tag.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1. Yet Another Language?

Contents:

The greatest challenges and most exciting opportunities for software developers today lie in harnessing the power of networks. Applications created today, whatever their intended scope or audience, will almost certainly be run on machines linked by a global network of computing resources. The increasing importance of networks is placing new demands on existing tools, and fueling the demand for a rapidly growing list of completely new kinds of applications.

We want software that works--consistently, anywhere, on any platform--and that plays well with other applications. We want dynamic applications that take advantage of a connected world, capable of accessing disparate and distributed information sources. We want truly distributed software that can be extended and upgraded seamlessly. We want intelligent applications--like autonomous agents that can roam the Net for us, ferreting out information and serving as electronic emissaries. We know, at least to some extent, what we want. So why don't we have it?

The problem has been that the tools for building these applications have fallen short. The requirements of speed and portability have been, for the most part, mutually exclusive, and security has largely been ignored or misunderstood. There are truly portable languages, but they are mostly bulky, interpreted, and slow. These languages are popular as much for their high level functionality as for their portability. And there are fast languages, but they usually provide speed by binding themselves to particular platforms, so they can meet the portability issue only half way. There are even a few recent safe languages, but they are primarily offshoots of the portable languages and suffer from the same problems.

1.1 Enter Java

The Java programming language, developed at Sun Microsystems under the guidance of Net luminaries James Gosling and Bill Joy, is designed to be a machine-independent programming language that is both safe enough to traverse networks and powerful enough to replace native executable code. Java addresses the issues raised here and may help us start building the kinds of applications we want.

Right now, most of the enthusiasm for Java stems from its capabilities for building embedded applications for the World Wide Web; these applications are called *applets*. This book will teach you how to build applets. But there is more to Java than applets, and I'll also try to show you the "more." The book will also show you how to use the tools of Java to accomplish real programming tasks, such as building networked applications and creating functional user interfaces. By the end of the book, you will be able to use these tools to build powerful Java applets and standalone applications.

Java's Origins

The seeds of Java were planted in 1990 by Sun Microsystems patriarch and chief researcher, Bill Joy. Since Sun's inception in the early '80s, it has steadily pushed one idea: "The network is the computer." At the time though, Sun was competing in a relatively small workstation market, while Microsoft was beginning its domination of the more mainstream, Intel-based PC world. When Sun missed the boat on the PC revolution, Joy retreated to Aspen, Colorado, to work on advanced research. He was committed to accomplishing complex tasks with simple software, and founded the aptly named Sun Aspen Smallworks.

Of the original members of the small team of programmers assembled in Aspen, James Gosling is the one who will be remembered as the father of Java. Gosling first made a name for himself in the early '80s as the author of Gosling Emacs, the first version of the popular Emacs editor that was written in C and ran under UNIX. Gosling Emacs became popular, but was soon eclipsed by a free version, GNU Emacs, written by Emacs's original designer. By that time, Gosling had moved on to design Sun's NeWS window system, which briefly contended with the X Window System for control of the UNIX graphic user interface (GUI) desktop in 1987. While some people would argue that NeWS was superior to X, NeWS lost out because Sun kept it proprietary and didn't publish source code, while the primary developers of X formed the X Consortium and took the opposite approach.

Designing NeWS taught Gosling the power of integrating an expressive language with a network-aware windowing GUI. It also taught Sun that the Internet programming community will refuse to accept proprietary standards, no matter how good they may be. The seeds of Java's remarkably permissive licensing scheme were sown by NeWS's failure. Gosling brought what he had learned to Bill Joy's nascent Aspen project, and in 1992, work on the project led to the founding of the Sun subsidiary, FirstPerson, Inc. Its mission was to lead Sun into the world of consumer electronics.

The FirstPerson team worked on developing software for information appliances, such as cellular phones and personal digital assistants (PDA). The goal was to enable the transfer of information and real-time applications over cheap infrared and packet-based networks. Memory and bandwidth limitations dictated small and efficient code. The nature of the applications also demanded they be safe and robust. Gosling and his teammates began programming in C++, but they soon found themselves confounded by a language that was too complex, unwieldy, and insecure for the task. They decided to start from scratch, and Gosling began working on something he dubbed "C++ minus minus."

With the floundering of the Apple Newton, it became apparent that the PDA's ship had not yet come in, so Sun shifted FirstPerson's efforts to interactive TV (ITV). The programming language of choice for ITV set-top boxes was the near ancestor of Java, a language called Oak. Even with its elegance and ability to provide safe interactivity, Oak could not salvage the lost cause of ITV. Customers didn't want it, and Sun soon abandoned the concept.

At that time, Joy and Gosling got together to decide on a new strategy for their language. It was 1993, and the explosion of interest in the Internet, and the World Wide Web in particular, presented a new opportunity. Oak was small, robust, architecture independent, and object oriented. As it happens, these are also the requirements for a universal, network-savvy programming language. Sun quickly changed focus, and with a little retooling, Oak became Java.

Future Buzz?

I don't think it's overdoing it to say that Java has caught on like wildfire. Even before its first official release, while Java was still a nonproduct, nearly every major industry player jumped on the Java bandwagon. Java licensees include Microsoft, Intel, IBM, and virtually all major hardware and software vendors.

As we begin looking at the Java architecture, you'll see that much of what is exciting about Java comes from the self-contained, virtual machine environment in which Java applications run. Java has been carefully designed so that this supporting architecture can be implemented either in software, for existing computer platforms, or in customized hardware, for new kinds of devices. Sun and other industry giants have announced their intentions to produce cheap, fast Java chips, the first of which should be available by the time you read this. Hardware implementations of Java could power inexpensive network terminals, PDAs, and other information appliances, to take advantage of transportable Java applications.

Many people see Java as part of a trend toward cheap, Net-based, "operating system-less" appliances that will extend the Net into more and more consumer-related areas. Only time will tell what people will do with Java, but it's probably worth at least a passing thought that the applet you write today might well be running on someone's wristwatch tomorrow. If that seems too futuristic, remember that you can already get a "smart card" (essentially a credit card) that has a Java interpreter embedded in it. Such a card could do everything from financial transactions (paying a hotel bill) to unlocking a door (the door to your hotel room) to rerouting phone calls (so your hotel room receives your business calls). The card is already here; it won't be long before the rest of the software has been built. A Java wristwatch is certainly not far away.

2. A First Applet

Contents:

Before we turn our attention to the details of the language, let's take a crash course and jump right into some Java code. In this chapter, we'll build a contrived but friendly little applet that illustrates a number of techniques we use throughout the book. I'll take this opportunity to introduce general features of the Java language and of Java applets. However, many details won't be fleshed out here, but in subsequent chapters.

This chapter also serves as a brief introduction to the object-oriented and multithreaded features of Java. If these concepts are new to you, you can take comfort in the knowledge that encountering them for the first time in Java should be a straightforward and pleasant experience. If you have worked with another object-oriented or multithreaded programming environment, clear your mind; you will especially appreciate Java's simplicity and elegance.

I can't stress enough the importance of experimentation as you learn new concepts. If you follow along with the online examples, be sure to take some time and compile them locally. Play with them; change their behavior, break them, fix them, and, as Java developer Arthur van Hoff would say: "Have fun!"

2.1 Hello Web!

In the tradition of all good introductory programming texts, we begin with Java's equivalent of the archetypal "Hello World" application. In the spirit of our new world, we'll call it "Hello Web!"

I'll take four passes at this example, adding features and introducing new concepts along the way. Here's a minimalist version:

```
public class HelloWeb extends java.applet.Applet {
    public void paint( java.awt.Graphics gc ) {
        gc.drawString("Hello Web!", 125, 95 );
    }
}
```

Place this text in a file called *HelloWeb.java*. Now compile this source:

```
% javac HelloWeb.java
```

This produces the Java byte-code binary class file *HelloWeb.class*.

We need an HTML document that contains the appropriate `<applet>` tag to display our example. Place the following text in a file called *HelloWeb.html* in the same directory as the binary class file:

```
<html>
<head>
</head>
<body>
    <applet code=HelloWeb width=300 height=200></applet>
</body>
</html>
```

Finally, you can point your Java-enabled Web browser at this document with a URL such as:

```
http://yourServer/wherever/HelloWeb.html
```

or

```
file:/wherever/HelloWeb.html
```

You should see the proclamation shown in Figure 2.1. Now congratulate yourself: you have written your first applet! Take a moment to bask in the glow of your monitor.

Figure 2.1: Hello Web! applet

[Graphic: Figure 2-1]

`HelloWeb` may be a small program, but there is actually quite a bit going on behind the scenes. Those five lines represent the tip of an iceberg. What lies under the surface are layers of functionality provided by the Java language and its foundation class libraries. In this chapter, I'll cover a lot of ground quickly in an effort to show you the big picture. I'll try to offer enough detail for a complete understanding of what is happening in each example without exhaustive explanations until the appropriate chapters. This holds for both elements of the Java language and the object-oriented concepts that apply to them. Later chapters will provide more detailed cataloging of Java's syntax, components, and object-oriented features.

Classes

The previous example defines a *class* named `HelloWeb`. Classes are the fundamental building blocks of most object-oriented languages. A class in Java is akin to the C++ concept of a class. Specifically, it's a group of data items (à la a C struct), with associated functions that perform operations on this data. The data items in a class are called *fields* or *variables* ; the functions are called *methods*. A class might represent something concrete, like a button on a screen or the information in a spreadsheet, or it could be something more abstract, such as a sorting algorithm or possibly the sense of ennui in your MUD character. A hypothetical spreadsheet class might, for example, have variables that represent the values of its individual cells and methods that perform operations on those cells, such as "clear a row" or "compute values."

Our `HelloWeb` class is the container for our Java applet. It holds two general types of variables and methods: those we need for our specific applet's tasks and some special predesignated ones we provide to interact with the outside world. The Java run-time environment, in this case a Java-enabled Web browser, periodically calls methods in `HelloWeb` to pass us information and prod us to perform actions, as depicted in Figure 2.2. Our simple `HelloWeb` class defines a single method called `paint()`. The `paint()` method is called by Java when it's time for our application to draw itself on the screen.

Figure 2.2: Method invocation in the Java environment

[Graphic: Figure 2-2]

You will see that the `HelloWeb` class derives some of its structure from another class called `Applet`. This is why we refer to `HelloWeb` as an applet.

Class Instances and Objects

A class represents a particular thing; it contains methods and variables that assist in that representation. Many individual working copies of a given class can exist while an application is active. These individual incarnations are called *instances* of the class. Two instances of a given class may contain different states, but they always have the same methods.

As an example, consider a `Button` class. There is only one `Button` class, but many actual working instances of buttons can be in an application. Furthermore, two `Button` instances might contain different data, perhaps giving each a different appearance or specifying a different message for each to send when pushed. In this sense, a class can be considered a mold for making the object it represents: something like a cookie cutter stamping out working instances of itself in the memory of the computer. As you'll see later, there's a bit more to it than that--a class can in fact share information among its instances--but this explanation suffices for now.

The term *object* is very general and in some other contexts is used almost interchangeably with class. Objects are the abstract entities all object-oriented languages refer to in one form or another. I will use object as a generic term for an instance of a class. I might, therefore, refer to an instance of the `Button` class as a `Button`, a `Button` object, or, indiscriminately, as an object.

A Java-enabled Web browser creates an instance of our `HelloWeb` class when we first use our applet. If we had included the `HelloWeb` applet tag in our HTML document twice (causing it to appear twice on the screen), the browser would create and manage two separate HelloWeb objects (two separate instances of the `HelloWeb` class).

Variables

In Java, every class defines a new *type*. A variable can be of this type and then hold instances of that class. A variable could, for example, be of type `Button` and hold an instance of the `Button` class, or of type `SpreadSheetCell` and hold a `SpreadSheetCell` object, just as it could be any of the more familiar types such as `integer` or `float`. In this way, by having variables containing complex objects, a class may use other classes as tools within itself. Using classes in this way is called *composition*. Our examples in this chapter are somewhat unrealistic in that we are building only a single class of our own. However, we will be using many classes as tools within our applet.

You have seen only one variable so far in our simple `HelloWeb` example. It's found in the declaration of our lonely `paint()` method:

```
public void paint( java.awt.Graphics gc ) {...}
```

Just like functions in C (and many other languages), a method in Java declares a list of variables that hold its arguments, and it specifies the types of those arguments. Our `paint()` method takes one argument named (somewhat tersely) `gc`, which is of type `Graphics`. When the `paint()` method is invoked, a `Graphics` object is assigned to `gc`, which we use in the body of the method. I'll say more about `paint()` and the `Graphics` class in a moment.

But first, a few words about variables. I have loosely referred to variables as holding objects. In reality, variables that have complex types (class types) don't so much contain objects as point to them. Class-type variables are *references* to objects. A reference is a pointer to, or another name for, an object.

Simply declaring a variable doesn't imply that any storage is allocated for that variable or that an instance of its type even exists anywhere. When a reference-type variable is first declared, if it's not assigned to an instance of a class, it doesn't point to anything. It's assigned the default value of `null`, meaning "no value." If you try to use a variable with a `null` value as if it were pointing to a real object, a run-time error (NullPointerException) occurs.

This discussion begs the question as to where to get an instance of a class to assign to a variable in the first place. The answer, as you will see later, is through the use of the `new` operator. In our first two passes at this example, we are dealing only with objects handed to us prefabricated from somewhere outside of our class. We examine object creation later in the chapter.

Inheritance

Java classes are arranged in a parent-child hierarchy, in which the parent and child are known as the *superclass* and *subclass*, respectively. In Java, every class has exactly one superclass (a single parent), but possibly many subclasses. Of course, a class's superclass probably has its own superclass.

The declaration of our class in the previous example uses the keyword `extends` to specify that `HelloWeb` is a subclass of the `Applet` class:

```
public class HelloWeb extends java.applet.Applet {...}
```

A subclass may be allowed to inherit some or all of the variables and methods of its superclass. Through *inheritance*, the subclass can use those members as if it has declared them itself. A subclass can add variables and methods of its own, and it can also override the meaning of inherited variables and methods. When we use a subclass, overridden variables and methods are hidden (replaced) by the subclass's own versions of them. In this way, inheritance provides a powerful mechanism whereby a subclass can refine or extend its superclass.

For example, the hypothetical spreadsheet class might be subclassed to produce a new scientific spreadsheet class with extra mathematical functions and special built-in constants. In this case, the source code for the scientific spreadsheet might declare methods for the added mathematical functions and variables for the special constants, but the new class automatically has all the variables and methods that constitute the normal functionality of a spreadsheet; they are inherited from the parent spreadsheet class. This means the scientific spreadsheet maintains its identity as a spreadsheet, and we can use it anywhere the simpler spreadsheet is used.

Our `HelloWeb` class is a subclass of the `Applet` class and inherits many variables and methods not explicitly declared in our source code. These members function in the same way as the ones we add or override.

Applet

The `Applet` class provides the framework for building applets. It contains methods that support the basic functionality for a Java application that is displayed and controlled by a Java-enabled Web browser or other Java-enabled software.

We override methods in the `Applet` class in a subclass to implement the behavior of our particular applet. This may sound restrictive, as if we are limited to some predefined set of routines, but that is not the case at all. Keep in mind that the methods we are talking about are means of getting information from the outside world. A realistic application might involve hundreds or even thousands of classes, with legions of methods and variables and multiple threads of execution. The vast majority of these are related to the particulars of our job. The inherited methods of the `Applet` class, and of other special components, serve as a framework on which to hang code that handles certain types of events and performs special tasks.

The `paint()` method is an important method of the `Applet` class; we override it to implement the way in which our particular applet displays itself on the screen. We don't override any of the other inherited members of `Applet` because they provide basic functionality and reasonable defaults for this (trivial) example. As `HelloWeb` grows, we'll delve deeper into the inherited members and override additional methods. Inherited members will allow us to get information from the user and give us more control over what our applet does. We will also add some arbitrary, application-specific methods and variables for the needs of `HelloWeb`.

If you want to verify for yourself what functionality the `Applet` class is providing our example, you can try out the world's least interesting applet: the `Applet` base class itself. Just use the class name `java.applet.Applet` in your HTML code, instead of `HelloWeb`:

```
<applet code=java.applet.Applet width=300 height=200></applet>
```

You should get a blank area of screen. I told you it's not very interesting.

Relationships and Finger Pointing

We can correctly refer to `HelloWeb` as an `Applet` because subclassing can be thought of as creating an "is a" relationship, in which the subclass is a kind of its superclass. `HelloWeb` is therefore a kind of `Applet`. When we refer to a kind of object, we mean any instance of that object's class or any of its subclasses. Later, we will look more closely at the Java class hierarchy and see that `Applet` is itself a subclass of the `Panel` class, which is further derived from a class called `Container`, and so on, as shown in Figure 2.3.

Figure 2.3: Part of the Java class hierarchy

[Graphic: Figure 2-3]

In this sense, an `Applet` is a kind of `Panel`, which is, itself, a kind of `Container` and each of these can ultimately be considered to be a kind of `Component`. You'll see later that it's from these classes that `Applet` inherits its basic graphical user interface functionality and the ability to have other graphical components embedded within it.

`Component` is a subclass of `Object`, so all of these classes are a kind of `Object`. As you'll see later, the `Object` class is at the top of the Java class hierarchy; `Object` doesn't have a superclass. Every other class in the Java API inherits behavior from `Object`, which defines a few basic methods, as you'll see in Chapter 5, *Objects in Java*. The terminology here can become a bit muddled. I'll continue to use the word "object" (lowercase o) in a generic way to refer to an instance of any class; I'll use `Object` to refer specifically to that class.

Packages

In our previous example, the `Applet` class is referenced by its fully qualified name `java.applet.Applet`:

```
public class HelloWeb extends java.applet.Applet {...}
```

The prefix on the class name identifies it as belonging to the `java.applet` package. Packages provide a means for organizing Java classes. A *package* is a group of Java classes that are related by purpose or by application. Classes in the same package have special access privileges with respect to one another and may be designed to work together. Package names are hierarchical and are used somewhat like Internet domain and host names, to distinguish groups of classes by organization and application. Classes may be dynamically loaded over networks from arbitrary locations; within this context, packages provide a crude namespace of Java classes.[1]

> [1] There are many efforts under way to find a general solution to the problem of locating resources in a globally distributed computing environment. The Uniform Resource Identifier Working Group of the IETF has proposed Uniform Resource Names (URNs). A URN would be a more abstract and persistent identifier that would be resolved to a URL through the use of a name service. We can imagine a day when there will exist a global namespace of trillions of persistent objects forming the infrastructure for all computing resources. Java provides an important evolutionary step in this direction.

`java.applet` identifies a particular package that contains classes related to applets. `java.applet.Applet` identifies a specific class, the `Applet` class, within that package. The `java.` hierarchy is special. Any package that begins with `java.` is part of the core Java API and is available on any platform that supports Java. Figure 2.4 illustrates the core Java packages, showing a representative class or two from each package.

Figure 2.4: The core Java packages

[Graphic: Figure 2-4]

Some notable core packages include: `java.lang`, which contains fundamental classes needed by the Java language itself; `java.awt`, which contains classes of the Java Abstract Windowing Toolkit; and `java.net`, which contains the networking classes.

A few classes contain methods that are not written in Java, but are instead part of the native Java implementation on a particular platform. Approximately 22 such classes are in the `java` package hierarchy; these are the only classes that have to be ported to a new platform. They form the basis for all interaction with the operating system. All other classes are built on or around these and are completely platform independent.

The paint( ) Method

The source for our `HelloWeb` class defines just one method, `paint()`, which overrides the `paint()` method from the `Applet` class:

```
public void paint( java.awt.Graphics gc ) {
    gc.drawString("Hello Web!", 125, 95 );
}
```

The `paint()` method is called by Java when it's time for our applet to draw itself on the screen. It takes a single argument, a `Graphics` object, and doesn't return any type of value (`void`) to its caller.

Modifiers are keywords placed before classes, variables, and methods to alter their accessibility, behavior, or semantics. `paint()` is declared as `public`, which means it can be invoked (called) by methods in classes other than `HelloWeb`. In this case, it's the Java windowing environment that is calling our `paint()` method. A method or variable declared as `private` is inaccessible from outside of its class.

The `Graphics` object, an instance of the `Graphics` class, represents a particular graphical drawing area and is also called a graphics context. It contains methods the applet calls to draw in this area, and variables that represent characteristics such as clipping or drawing modes. The particular `Graphics` object we are passed in the `paint()` method corresponds to our applet's area of the screen.

The `Graphics` class provides methods for rendering primitive shapes, images, and text. In `HelloWeb`, we invoke the `drawString()` method of our `Graphics` object to scrawl our message at the specified coordinates. (For a description of the methods available in the `Graphics` class, see Chapter 13, *Drawing With the AWT*.)

As in C++, a method or variable of an object is accessed in a hierarchical way by appending its name with a "." (dot) to the object that holds it. We invoked the `drawString()` method of the `Graphics` object (referenced by our `gc` variable) in this way:

```
gc.drawString( "Hello Web!", 125, 95 );
```

You may need to get used to the idea that our application is drawn by a method that is called by an outside agent at arbitrary times. How can we do anything useful with this? How do we control what gets done and when? These answers will be forthcoming. For now, just think about how you would structure applications that draw themselves on command.

3. Tools of the Trade

Contents:

As I described at the end of Chapter 1, *Yet Another Language?*, by now you should have a number of options for Java development environments. The examples in this book were developed using the Solaris version of the Java Development Kit (JDK), so I'm going to describe those tools here. When I refer to the compiler or interpreter, I'll be referring to the command-line versions of these tools, so the book is decidedly biased toward those of you who are working in a UNIX or DOS-like environment with a shell and filesystem. However, the basic features I'll be describing for Sun's Java interpreter and compiler should be applicable to other Java environments as well.

In this chapter, I'll describe the tools you'll need to compile and run Java applications. I'll also cover the HTML `<applet>` tag and other information you'll need to know to incorporate Java applets in your Web pages.

3.1 The Java Interpreter

A Java interpreter is software that implements the Java virtual machine and runs Java applications. It can be a separate piece of software like the one that comes with the JDK, or part of a larger application like the Netscape Navigator Web browser. It's likely that the interpreter itself is written in a native, compiled language for your particular platform. Other tools, like Java compilers and development environments, can (and one could argue, should) be written in Java.

The Java interpreter performs all of the activities of the Java run-time system. It loads Java class files and interprets the compiled byte-code. It verifies compiled classes that are loaded from untrusted sources by applying the rules discussed in Chapter 1, *Yet Another Language?*. In an implementation that supports dynamic, or "just in time," compilation, the interpreter also serves as a specialized compiler that turns Java byte-code into native machine instructions.

Throughout the rest of this book, we'll be building both standalone Java programs and applets. Both are kinds of Java applications run by a Java interpreter. The difference is that a standalone Java application has all of its parts; it's a complete program that runs independently. An applet, as I described in Chapter 1, *Yet Another Language?*, is more like an embeddable program module; it relies on an applet viewer for support. Although Java applets are, of course, compiled Java code, the Java interpreter can't directly run them because they are used as part of a larger application. An applet-viewer application could be a Web browser like Sun's HotJava or Netscape Navigator, or a separate applet viewer application like the one that comes with Sun's Java Development Kit. All of Sun's tools, including HotJava, are written entirely in Java. Both HotJava and the applet viewer are standalone Java applications run directly by the Java interpreter; these programs implement the additional structure needed to run Java applets.

Sun's Java interpreter is called *java*. To start a standalone application with it, you specify an initial class to be loaded. You can also specify options to the interpreter, as well as any command-line arguments that are needed for the application:

```
% java [interpreter options] class name [program arguments]
```

The class should be specified as a fully qualified class name including the class package, if any. Note, however, that you don't include the *.class* file extension. Here are a few examples:

```
% java animals.birds.BigBird
% java test
```

java searches for the class in the current *class path*, which is a list of locations where packages of classes are stored. I'll discuss the class path in detail in the next section, but for now you should know that you can set the class path with the `-classpath` option.

There are a few other interpreter options you may find useful. The `-cs` or `-checksource` option tells *java* to check the modification times on the specified class file and its corresponding source file. If the class file is out of date, it's automatically recompiled from the source. The `-verify`, `-noverify`, and `-verifyremote` options control the byte-code verification process. By default, *java* runs the byte-code verifier only on classes loaded from an untrusted source; this is the `-verifyremote` option. If you specify `-verify`, the byte-code verifier is run on all classes; `-noverify` means that the verifier is never run.

Once the class is loaded, *java* follows a very C-like convention and looks to see if the class contains a method called `main()`. If it finds an appropriate `main()`method, the interpreter starts the application by executing that method. From there, the application can start additional threads, reference other classes, and create its user interface or other structures, as shown in Figure 3.1.

Figure 3.1: The Java interpreter starting a Java application

[Graphic: Figure 3-1]

In order to run, `main()` must have the right *method signature*. A method signature is a collection of information about the method, as in a C prototype or a forward function declaration in other languages. It includes the method's name, type, and visibility, as well as its arguments and return type. In this case, `main()` must be a `public`, `static` method that takes an array of `String` objects as its argument and does not return any value (`void`):

```
public static void main ( String [] myArgs )
```

Because `main()` is a `public` method, it can be accessed directly from any other class using the name of the class that contains it. We'll discuss the implications of visibility modifiers such as `public` in Chapter 5, *Objects in Java*.

The `main()` method's single argument, the array of `String` objects, holds the command-line arguments passed to *java*. As in C, the name that we give the parameter doesn't matter, only the type is important. Unlike C, the content of `myArgs` is a true array. There's no need for an argument count parameter, because `myArgs` knows how many arguments it contains and can happily provide that information:

```
int argc = myArgs.length;
```

Java also differs from C in another respect here: `myArgs[0]`is the first command-line argument, not the name of the application. If you're accustomed to parsing C command-line arguments, you'll need to be careful not to trip over this difference.

The Java virtual machine continues to run until the `main()`method of its initial class file has returned, and until any threads that it started are complete. Special threads designated as "daemon" threads are silently killed when the rest of the application has completed.

4. The Java Language

Contents:

In this chapter, we'll introduce the framework of the Java language and some of its fundamental tools. I'm not going to try to provide a full language reference here. Instead, I'll lay out the basic structures of Java with special attention to how it differs from other languages. For example, we'll take a close look at arrays in Java, because they are significantly different from those in some other languages. We won't, on the other hand, spend much time explaining basic language constructs like loops and control structures. We won't talk much about Java's object-oriented features here, as that's covered in Chapter 5, *Objects in Java*.

As always, we'll try to provide meaningful examples to illustrate how to use Java in everyday programming tasks.

4.1 Text Encoding

Java is a language for the Internet. Since the people of the Net speak and write in many different human languages, Java must be able to handle a number of languages as well. One of the ways in which Java supports international access is through Unicode character encoding. Unicode uses a 16-bit character encoding; it's a worldwide standard that supports the scripts (character sets) of most languages.[1]

[1] For more information about Unicode, see the following URL: http://www.unicode.org/. Ironically, one listed "obsolete and archaic" scripts not currently supported by the Unicode

standard is Javanese--a historical language of the people of the Island of Java.

Java source code can be written using the Unicode character encoding and stored either in its full form or with ASCII-encoded Unicode character values. This makes Java a friendly language for non-English speaking programmers, as these programmers can use their native alphabet for class, method, and variable names in Java code.

The Java `char` type and `String` objects also support Unicode. But if you're concerned about having to labor with two-byte characters, you can relax. The `String` API makes the character encoding transparent to you. Unicode is also ASCII-friendly; the first 256 characters are identical to the first 256 characters in the ISO8859-1 (Latin-1) encoding and if you stick with these values, there's really no distinction between the two.

Most platforms can't display all currently defined Unicode characters. As a result, Java programs can be written with special Unicode escape sequences. A Unicode character can be represented with the escape sequence:

```
\uxxxx
```

`xxxx` is a sequence of one to four hexadecimal digits. The escape sequence indicates an ASCII-encoded Unicode character. This is also the form Java uses to output a Unicode character in an environment that doesn't otherwise support them.

Java stores and manipulates characters and strings internally as Unicode values. Java also comes with classes to read and write Unicode-formatted character streams, as you'll see in Chapter 8, *Input/Output Facilities*.

5. Objects in Java

Contents:

In this chapter, we'll get to the heart of Java and explore the object-oriented aspects of the language. Object-oriented design is the art of decomposing an application into some number of objects--self-contained application components that work together. The goal is to break the problem down into a number of smaller problems that are simpler and easier to understand. Ideally, the components can be implemented directly as objects in the Java language. And if things are truly ideal, the components correspond to well-known objects that already exist, so they don't have to be created at all.

An object design methodology is a system or a set of rules created by someone to help you identify objects in your application domain and pick the real ones from the noise. In other words, such a methodology helps you factor your application into a good set of reusable objects. The problem is that though it wants to be a science, good object-oriented design is still pretty much an art form. While you can learn from the various off-the-shelf design methodologies, none of them will help you in all situations. The truth is that experience pays.

I won't try to push you into a particular methodology here; there are shelves full of books to do that.[1] Instead, I'll provide a few hints to get you started. Here are some general design guidelines, which should be taken with a liberal amount of salt and common sense:

> [1] Once you have some experience with basic object-oriented concepts, you might want to take a look at *Design Patterns: Elements of Reusable Object Oriented Software* by Gamma/Helm/Johnson/Vlissides (Addison-Wesley). This book catalogs useful object-oriented designs that have been refined over the years by experience. Many appear in the design of the Java APIs.

- Think of an object in terms of its interface, not its implementation. It's perfectly fine for an object's internals to be unfathomably complex, as long as its "public face" is easy to understand.

- Hide and abstract as much of your implementation as possible. Avoid public variables in your objects, with the possible exception of constants. Instead define "accessor" methods to set and return values (even if they are simple types). Later, when you need to, you'll be able to modify and extend the behavior of your objects without breaking other classes that rely on them.

- Specialize objects only when you have to. When you use an object in its existing form, as a piece of a new object, you are composing objects. When you change or refine the behavior of an object, you are using inheritance. You should try to reuse objects by composition rather than inheritance whenever possible because when you compose objects you are taking full advantage of existing tools. Inheritance involves breaking down the barrier of an object and should be done only when there's a real advantage. Ask yourself if you really need to inherit the whole public interface of an object (do you want to be a "kind" of that object), or if you can just delegate certain jobs to the object and use it by composition.

- Minimize relationships between objects and try to organize related objects in packages. To enhance your code's reusability, write it as if there *is* a tomorrow. Find what one object needs to know about another to get its job done and try to minimize the coupling between them.

5.1 Classes

Classes are the building blocks of a Java application. A *class* can contain methods, variables, initialization code, and, as we'll discuss later on, even other classes. It serves as a blueprint for making class *instances*, which are run-time objects that implement the class structure. You declare a class with the `class` keyword. Methods and variables of the class appear inside the braces of the class declaration:

```
class Pendulum {
    float mass;
    float length = 1.0;
    int cycles;

    float position ( float time ) {
        ...
    }
    ...
}
```

The above class, `Pendulum`, contains three variables: `mass`, `length`, and `cycles`. It also defines a method called `position()` that takes a `float` value as an argument and returns a `float` value. Variables and method declarations can appear in any order, but variable initializers can't use forward references to uninitialized variables.

Once we've defined the `Pendulum` class, we can create a `Pendulum` object (an instance of that class) as follows:

```
Pendulum p;
p = new Pendulum();
```

Recall that our declaration of the variable `p` does not create a `Pendulum` object; it simply creates a variable that refers to an object of type `Pendulum`. We still have to create the object dynamically, using the `new` keyword. Now that we've created a `Pendulum` object, we can access its variables and methods, as we've already seen many times:

```
p.mass = 5.0;
float pos = p.position( 1.0 );
```

Variables defined in a class are called *instance variables*. Every object has its own set of instance variables; the values of these variables in one object can differ from the values in another object, as shown in Figure 5.1. If you don't initialize an instance variable when you declare it, it's given a default value appropriate for its type.

Figure 5.1: Instances of the Pendulum class

[Graphic: Figure 5-1]

In Figure 5.1, we have a hypothetical `TextBook` application that uses two instances of `Pendulum` through the reference type variables `bigPendulum` and `smallPendulum`. Each of these `Pendulum` objects has its own copy of `mass`, `length`, and `cycles`.

As with variables, methods defined in a class are *instance methods*. An instance method is associated with an instance of the class, but each instance doesn't really have its own copy of the method. Instead, there's just one copy of the method, but it operates on the values of the instance variables of a particular object. As you'll see later when we talk about subclassing, there's more to learn about method selection.

Accessing Members

Inside of a class, we can access instance variables and call instance methods of the class directly by name. Here's an example that expands upon our `Pendulum`:

```
class Pendulum {
    ...
    void resetEverything() {
        cycles = 0;
        mass = 1.0;
        ...
        float startingPosition = position( 0.0 );
    }
    ...
}
```

Other classes generally access members of an object through a reference, using the C-style dot notation:

```
class TextBook {
    ...
    void showPendulum() {
        Pendulum bob = new Pendulum();
        ...
        int i = bob.cycles;
        bob.resetEverything();
        bob.mass = 1.01;
        ...
    }
    ...
}
```

Here we have created a second class, `TextBook`, that uses a `Pendulum` object. It creates an instance in `showPendulum()` and then invokes methods and accesses variables of the object through the reference `bob`.

Several factors affect whether class members can be accessed from outside the class. You can use the visibility modifiers, `public`, `private`, and `protected` to restrict access; classes can also be placed into packages that affect their scope. The `private` modifier, for example, designates a variable or method for use only by other members inside the class itself. In the previous example, we could change the declaration of our variable `cycles` to `private`:

```
class Pendulum {
    ...
    private int cycles;
    ...
```

Now we can't access `cycles` from `TextBook`:

```
class TextBook {
    ...
    void showPendulum() {
        ...
        int i = bob.cycles;         // Compile time error
```

If we need to access cycles, we might add a `getCycles()` method to the `Pendulum` class. We'll look at access modifiers and how they affect the scope of variables and methods in detail later.

Static Members

Instance variables and methods are associated with and accessed through a particular object. In contrast, members that are declared with the `static` modifier live in the class and are shared by all instances of the class. Variables declared with the `static` modifier are called *static variables* or *class variables* ; similarly, these kinds of methods are called *static methods* or *class methods*.

We can add a static variable to our `Pendulum` example:

```
class Pendulum {
    ...
    static float gravAccel = 9.80;
    ...
```

We have declared the new `float` variable `gravAccel` as `static`. That means if we change its value in any instance of a `Pendulum`, the value changes for all `Pendulum` objects, as shown in Figure 5.2.

Figure 5.2: A static variable

[Graphic: Figure 5-2]

Static members can be accessed like instance members. Inside our `Pendulum` class, we can refer to `gravAccel` by name, like an instance variable:

```
class Pendulum {
    ...
    float getWeight () {
        return mass * gravAccel;
    }
    ...
}
```

However, since static members exist in the class itself, independent of any instance, we can also access them directly through the class. We don't need a `Pendulum` object to set the variable `gravAccel`; instead we can use the class name as a reference:

```
Pendulum.gravAccel = 8.76;
```

This changes the value of `gravAccel` for any current or future instances. Why, you may be wondering, would we want to change the value of `gravAccel`? Well, perhaps we want to explore how pendulums would work on different planets. Static variables are also very useful for other kinds of data shared among classes at run-time. For instance you can create methods to register your objects so that they can communicate or you can count references to them.

We can use static variables to define constant values. In this case, we use the `static` modifier along with the `final` modifier. So, if we cared only about pendulums under the influence of the Earth's gravitational pull, we could change `Pendulum` as follows:

```
class Pendulum {
    ...
    static final float EARTH_G = 9.80;
    ...
```

We have followed a common convention and named our constant with capital letters; C programmers should recognize the capitalization convention, which resembles C `#define` statements. Now the value of `EARTH_G` is a constant; it can be accessed by any instance of `Pendulum` (or anywhere, for that matter), but its value can't be changed at run-time.

It's important to use the combination of static and final only for things that are really constant. That's because, unlike other kinds of variable references, the compiler is allowed to "inline" those values within classes that reference them. This is probably OK for things like PI, which aren't likely to change for a while, but may not be ideal for other kinds of identifiers, such as we'll discuss below.

Static members are useful as flags and identifiers, which can be accessed from anywhere. These are especially useful for values needed in the construction of an instance itself. In our example, we might declare a number of static values to represent various kinds of `Pendulum` objects:

```
class Pendulum {
    ...
    static int SIMPLE = 0, ONE_SPRING = 1, TWO_SPRING = 2;
    ...
```

We might then use these flags in a method that sets the type of a `Pendulum` or, more likely, in a special constructor, as we'll discuss shortly:

```
Pendulum pendy = new Pendulum();
pendy.setType( Pendulum.ONE_SPRING );
```

Remember, inside the `Pendulum` class, we can use static members directly by name as well:

```
class Pendulum {
    ...
    void resetEverything() {
        setType ( SIMPLE );
        ...
    }
    ...
}
```

7. Basic Utility Classes

Contents:

If you've been reading this book sequentially, you've read all about the core Java language constructs, including the object-oriented aspects of the language and the use of threads. Now it's time to shift gears and talk about the Java Application Programming Interface (API), the collection of classes that comes with every Java implementation. The Java API encompasses all the public methods and variables in the classes that comprise the core Java packages, listed in Table 7.1. This table also lists the chapters in this book that describe each of the packages.

Table 7.1: Packages of the Java API

Package	Contents	Chapter(s)
`java.lang`	Basic language classes	4, 5, 6, 7
`java.io`	Input and output	8
`java.util`	Utilities and collections classes	7
`java.text`	International text classes	7
`java.net`	Sockets and URLs	9
`java.applet`	The applet API	10
`java.awt`	The Abstract Windowing Toolkit	10, 11, 12, 13, 14
`java.awt.image`	AWT image classes	13, 14
`java.beans`	Java Beans API	
`java.rmi`	RMI classes	
`java.security`	Encryption and signing	
`java.sql`	JDBC classes	

As you can see in Table 7.1, we've already examined some of the classes in `java.lang` in earlier chapters on the core language constructs. Starting with this chapter, we'll throw open the Java toolbox and begin examining the rest of the classes in the API.

We'll begin our exploration with some of the fundamental language classes in `java.lang`, including strings and math utilities. Figure 7.1 shows the class hierarchy of the `java.lang` package.

Figure 7.1: The java.lang package

[Graphic: Figure 7-1]

We cover some of the classes in `java.util`, such as classes that support date and time values, random numbers, vectors, and hashtables. Figure 7.2 shows the class hierarchy of the `java.util` package.

Figure 7.2: The java.util package

[Graphic: Figure 7-2]

7.1 Strings

In this section, we take a closer look at the Java `String` class (or more specifically, `java.lang.String`). Because strings are used so extensively throughout Java (or any programming language, for that matter), the Java `String` class has quite a bit of functionality. We'll test drive most of the important features, but before you go off and write a complex parser or regular expression library, you should probably refer to a Java class reference manual for additional details.

Strings are immutable; once you create a `String` object, you can't change its value. Operations that would otherwise change the characters or the length of a string instead return a new `String` object that copies the needed parts of the original. Because of this feature, strings can be safely shared. Java makes an effort to consolidate identical strings and string literals in the same class into a shared string pool.

String Constructors

To create a string, assign a double-quoted constant to a `String` variable:

```
String quote = "To be or not to be";
```

Java automatically converts the string literal into a `String` object. If you're a C or C++ programmer, you may be wondering if `quote` is null-terminated. This question doesn't make any sense with Java strings. The `String` class actually uses a Java character array internally. It's `private` to the `String` class, so you can't get at the characters and change them. As always, arrays in Java are real objects that know their own length, so `String` objects in Java don't require special terminators (not even internally). If you need to know the length of a `String`, use the `length()` method:

```
int length = quote.length();
```

Strings can take advantage of the only overloaded operator in Java, the `+` operator, for string concatenation. The following code produces equivalent strings:

```
String name = "John " + "Smith";
String name = "John ".concat("Smith");
```

Literal strings can't span lines in Java source files, but we can concatenate lines to produce the same effect:

```
String poem =
    "'Twas brillig, and the slithy toves\n" +
    "   Did gyre and gimble in the wabe:\n" +
    "All mimsy were the borogoves,\n" +
    "   And the mome raths outgrabe.\n";
```

Of course, embedding lengthy text in source code should now be a thing of the past, given that we can retrieve a `String` from anywhere on the planet via a URL. In Chapter 9, *Network Programming*, we'll see how to do things like:

```
String poem =
    (String) new URL
       ("http://server/~dodgson/jabberwocky.txt").getContent();
```

In addition to making strings from literal expressions, we can construct a `String` from an array of characters:

```
char [] data = { 'L', 'e', 'm', 'm', 'i', 'n', 'g' };
String lemming = new String( data );
```

Or from an array of bytes:

```
byte [] data = { 97, 98, 99 };
String abc = new String(data, "8859_5");
```

The second argument to the `String` constructor for byte arrays is the name of an encoding scheme. It's used to convert the given bytes to the string's Unicode characters. Unless you know something about Unicode, you can probably use the form of the constructor that accepts only a byte array; the default encoding scheme will be used.

Strings from Things

We can get the string representation of most things with the static `String.valueOf()` method. Various overloaded versions of this method give us string values for all of the primitive types:

```
String one = String.valueOf( 1 );
String two = String.valueOf( 2.0f );
String notTrue = String.valueOf( false );
```

All objects in Java have a `toString()` method, inherited from the `Object` class (see Chapter 5, *Objects in Java*).

For class-type references, `String.valueOf()` invokes the object's `toString()` method to get its string representation. If the reference is `null`, the result is the literal string "null":

```
String date = String.valueOf( new Date() );
System.out.println( date );
// Sun Dec 19 05:45:34 CST 1999

date = null;
System.out.println( date );
// null
```

Things from Strings

Producing primitives like numbers from `String` objects is not a function of the `String` class. For that we need the primitive wrapper classes; they are described in the next section on the `Math` class. The wrapper classes provide `valueOf()` methods that produce an object from a `String`, as well as corresponding methods to retrieve the value in various primitive forms. Two examples are:

```
int i = Integer.valueOf("123").intValue();
double d = Double.valueOf("123.0").doubleValue();
```

In the above code, the `Integer.valueOf()` call yields an `Integer` object that represents the value 123. An `Integer` object can provide its primitive value in the form of an `int` with the `intValue()` method.

Although the techniques above may work for simple cases, they will not work internationally. Let's pretend for a moment that we are programming Java in the rolling hills of Tuscany. We would follow the local customs for representing numbers and write code like the following.

```
double d = Double.valueOf("1.234,56").doubleValue();    // oops!
```

Unfortunately, this code throws a `NumberFormatException`. The `java.text` package, which we'll discuss later, contains the tools we need to generate and parse strings in different countries and languages.

The `charAt()` method of the `String` class lets us get at the characters of a `String` in an array-like fashion:

```
String s = "Newton";

for ( int i = 0; i < s.length(); i++ )     System.out.println( s.charAt( i ) );
```

This code prints the characters of the string one at a time. Alternately, we can get the characters all at once with `toCharArray()`. Here's a way to save typing a bunch of single quotes:

```
char [] abcs = "abcdefghijklmnopqrstuvwxyz".toCharArray();
```

Comparisons

Just as in C, you can't compare strings for equality with "`==`" because as in C, strings are actually references. If your

Java compiler doesn't happen to coalesce multiple instances of the same string literal to a single string pool item, even the expression `"foo" == "foo"` will return `false`. Comparisons with `<`, `>`, `<=`, and `>=` don't work at all, because Java can't convert references to integers.

Use the `equals()` method to compare strings:

```
String one = "Foo";

char [] c = { 'F', 'o', 'o' };
String two = new String ( c );

if ( one.equals( two ) )                // yes
```

An alternate version, `equalsIgnoreCase()`, can be used to check the equivalence of strings in a case-insensitive way:

```
String one = "FOO";
String two = "foo";

if ( one.equalsIgnoreCase( two ) )      // yes
```

The `compareTo()` method compares the lexical value of the `String` against another `String`. It returns an integer that is less than, equal to, or greater than zero, just like the C routine `string()`:

```
String abc = "abc";
String def = "def";
String num = "123";

if ( abc.compareTo( def ) < 0 )         // yes
if ( abc.compareTo( abc ) == 0 )        // yes
if ( abc.compareTo( num ) > 0 )         // yes
```

On some systems, the behavior of lexical comparison is complex, and obscure alternative character sets exist. Java avoids this problem by comparing characters strictly by their position in the Unicode specification.

In Java 1.1, the `java.text` package provides a sophisticated set of classes for comparing strings, even in different languages. German, for example, has vowels with umlauts (those funny dots) over them and a weird-looking beta character that represents a double-s. How should we sort these? Although the rules for sorting these characters are precisely defined, you can't assume that the lexical comparison we used above works correctly for languages other than English. Fortunately, the `Collator` class takes care of these complex sorting problems. In the following example, we use a `Collator` designed to compare German strings. (We'll talk about `Locale`s in a later section.) You can obtain a default `Collator` by calling the `Collator.getInstance()` method that has no arguments. Once you have an appropriate `Collator` instance, you can use its `compare()` method, which returns values just like `String`'s `compareTo()` method. The code below creates two strings for the German translations of "fun" and "later," using Unicode constants for these two special characters. It then compares them, using a `Collator` for the German locale; the result is that "later" (spaeter) sorts before "fun" (spass).

```
String fun = "Spa\u00df";
String later = "sp\u00e4ter";
Collator german = Collator.getInstance(Locale.GERMAN);
if (german.compare(later, fun) < 0)  // yes
```

Using collators is essential if you're working with languages other than English. In Spanish, for example, "ll" and "ch" are treated as separate characters, and alphabetized separately. A collator handles cases like these automatically.

Searching

The `String` class provides several methods for finding substrings within a string. The `startsWith()` and `endsWith()` methods compare an argument `String` with the beginning and end of the `String`, respectively:

```
String url = "http://foo.bar.com/";
if ( url.startsWith("http:") )
    // do HTTP
```

Overloaded versions of `indexOf()` search for the first occurrence of a character or substring:

```
int i = abcs.indexOf( 'p' );            // i = 15
int i = abcs.indexOf( "def" );          // i = 3
```

Correspondingly, overloaded versions of `lastIndexOf()` search for the last occurrence of a character or substring.

Editing

A number of methods operate on the `String` and return a new `String` as a result. While this is useful, you should be aware that creating lots of strings in this manner can affect performance. If you need to modify a string often, you should use the `StringBuffer` class, as I'll discuss shortly.

`trim()` is a useful method that removes leading and trailing white space (i.e., carriage return, newline, and tab) from the `String`:

```
String abc = "   abc   ";
abc = abc.trim();                       // "abc"
```

In the above example, we have thrown away the original `String` (with excess white space), so it will be garbage collected.

The `toUpperCase()` and `toLowerCase()` methods return a new `String` of the appropriate case:

```
String foo = "FOO".toLowerCase();
String FOO = foo.toUpperCase();
```

`substring()` returns a specified range of characters. The starting index is inclusive; the ending is exclusive:

```
String abcs = "abcdefghijklmnopqrstuvwxyz";
String cde = abcs.substring(2, 5);      // "cde"
```

String Method Summary

Many people complain when they discover the Java `String` class is `final` (i.e., it can't be subclassed). There is a lot of functionality in `String`, and it would be nice to be able to modify its behavior directly. Unfortunately, there is also a serious need to optimize and rely on the performance of `String` objects. As I discussed in Chapter 5, *Objects in Java*, the Java compiler can optimize `final` classes by inlining methods when appropriate. The implementation of `final` classes can also be trusted by classes that work closely together, allowing for special cooperative optimizations. If you want to make a new string class that uses basic `String` functionality, use a `String` object in your class and provide methods that delegate method calls to the appropriate `String` methods.

Table 7.2 summarizes the methods provided by the `String` class.

Table 7.2: String Methods

Method	**Functionality**
`charAt()`	Gets at a particular character in the string
`compareTo()`	Compares the string with another string
`concat()`	Concatenates the string with another string
`copyValueOf()`	Returns a string equivalent to the specified character array
`endsWith()`	Checks if the string ends with a suffix
`equals()`	Compares the string with another string
`equalsIgnoreCase()`	Compares the string with another string and ignores case
`getBytes()`	Copies characters from the string into a byte array
`getChars()`	Copies characters from the string into a character array
`hashCode()`	Returns a hashcode for the string
`indexOf()`	Searches for the first occurrence of a character or substring in the string
`intern()`	Fetches a unique instance of the string from a global shared string pool
`lastIndexOf()`	Searches for the last occurrence of a character or substring in a string
`length()`	Returns the length of the string
`regionMatches()`	Checks whether a region of the string matches the specified region of another string
`replace()`	Replaces all occurrences of a character in the string with another character
`startsWith()`	Checks if the string starts with a prefix
`substring()`	Returns a substring from the string
`toCharArray()`	Returns the array of characters from the string
`toLowerCase()`	Converts the string to uppercase
`toString()`	Converts the string to a string
`toUpperCase()`	Converts the string to lowercase

`trim()`	Removes the leading and trailing white space from the string
`valueOf()`	Returns a string representation of a value

java.lang.StringBuffer

The `java.lang.StringBuffer` class is a growable buffer for characters. It's an efficient alternative to code like the following:

```
String ball = "Hello";
ball = ball + " there.";
ball = ball + " How are you?";
```

The above example repeatedly produces new `String` objects. This means that the character array must be copied over and over, which can adversely affect performance. A more economical alternative is to use a `StringBuffer` object and its `append()` method:

```
StringBuffer ball = new StringBuffer("Hello");
ball.append(" there.");
ball.append(" How are you?");
```

The `StringBuffer` class actually provides a number of overloaded `append()` methods, for appending various types of data to the buffer.

We can get a `String` from the `StringBuffer` with its `toString()` method:

```
String message = ball.toString();
```

`StringBuffer` also provides a number of overloaded `insert()` methods for inserting various types of data at a particular location in the string buffer.

The `String` and `StringBuffer` classes cooperate, so that even in this last operation, no copy has to be made. The string data is shared between the objects, unless and until we try to change it in the `StringBuffer`.

So, when should you use a `StringBuffer` instead of a `String`? If you need to keep adding characters to a string, use a `StringBuffer`; it's designed to efficiently handle such modifications. You'll still have to convert the `StringBuffer` to a `String` when you need to use any of the methods in the `String` class. You can print a `StringBuffer` directly using `System.out.println()`because `println()` calls the `toString()` for you.

Another thing you should know about `StringBuffer` methods is that they are thread-safe, just like all public methods in the Java API. This means that any time you modify a `StringBuffer`, you don't have to worry about another thread coming along and messing up the string while you are modifying it. If you recall our discussion of synchronization in Chapter 6, *Threads*, you know that being thread-safe means that only one thread at a time can change the state of a `StringBuffer` instance.

On a final note, I mentioned earlier that strings take advantage of the single overloaded operator in Java, `+`, for concatenation. You might be interested to know that the compiler uses a `StringBuffer` to implement concatenation. Consider the following expression:

```
String foo = "To " + "be " + "or";
```

This is equivalent to:

```
String foo = new
  StringBuffer().append("To ").append("be ").append("or").toString();
```

This kind of chaining of expressions is one of the things operator overloading hides in other languages.

java.util.StringTokenizer

A common programming task involves parsing a string of text into words or "tokens" that are separated by some set of delimiter characters. The `java.util.StringTokenizer` class is a utility that does just this. The following example reads words from the string `text`:

```
String text = "Now is the time for all good men (and women)...";
StringTokenizer st = new StringTokenizer( text );

while ( st.hasMoreTokens() )  {
    String word = st.nextToken();
    ...
}
```

First, we create a new `StringTokenizer` from the `String`. We invoke the `hasMoreTokens()` and `nextToken()` methods to loop over the words of the text. By default, we use white space (i.e., carriage return, newline, and tab) as delimiters.

The `StringTokenizer` implements the `java.util.Enumeration` interface, which means that `StringTokenizer` also implements two more general methods for accessing elements: `hasMoreElements()` and `nextElement()`. These methods are defined by the `Enumeration` interface; they provide a standard way of returning a sequence of values, as we'll discuss a bit later. The advantage of `nextToken()` is that it returns a `String`, while `nextElement()` returns an `Object`. The `Enumeration` interface is implemented by many items that return sequences or collections of objects, as you'll see when we talk about hashtables and vectors later in the chapter. Those of you who have used the C `strtok()`function should appreciate how useful this object-oriented equivalent is.

You can also specify your own set of delimiter characters in the `StringTokenizer` constructor, using another `String` argument to the constructor. Any combination of the specified characters is treated as the equivalent of white space for tokenizing:

```
text = "http://foo.bar.com/";
tok = new StringTokenizer( text, "/:" );

if ( tok.countTokens() < 2 )            // bad URL
```

```
String protocol = tok.nextToken();      // protocol = "http" String host =
tok.nextToken();          // host = "foo.bar.com"
```

The example above parses a URL specification to get at the protocol and host components. The characters "/" and ":" are used as separators. The `countTokens()` method provides a fast way to see how many tokens will be returned by `nextToken()`, without actually creating the `String` objects.

An overloaded form of `nextToken()` accepts a string that defines a new delimiter set for that and subsequent reads. And finally, the `StringTokenizer` constructor accepts a flag that specifies that separator characters are to be returned individually as tokens themselves. By default, the token separators are not returned.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

8. Input/Output Facilities

Contents:

In this chapter, we'll continue our exploration of the Java API by looking at many of the classes in the `java.io` package. These classes support a number of forms of input and output; I expect you'll use them often in your Java applications. Figure 8.1 shows the class hierarchy of the `java.io` package.

We'll start by looking at the stream classes in `java.io`; these classes are all subclasses of the basic `InputStream`, `OutputStream`, `Reader`, and `Writer` classes. Then we'll examine the `File` class and discuss how you can interact with the filesystem using classes in `java.io`. Finally, we'll take a quick look at the data compression classes provided in `java.util.zip`.

8.1 Streams

All fundamental I/O in Java is based on *streams*. A stream represents a flow of data, or a channel of communication with (at least conceptually) a writer at one end and a reader at the other. When you are working with terminal input and output, reading or writing files, or communicating through sockets in Java, you are using a stream of one type or another. So you can see the forest without being distracted by the trees, I'll start by summarizing the different types of streams.

Figure 8.1: The java.io package

[Graphic: Figure 8-1]

`InputStream`/`OutputStream`

Abstract classes that define the basic functionality for reading or writing an unstructured sequence of bytes. All other byte streams in Java are built on top of the basic `InputStream` and `OutputStream`.

`Reader`/`Writer`

Abstract classes that define the basic functionality for reading or writing an unstructured sequence of characters. All other character streams in Java are built on top of `Reader` and `Writer`.

`InputStreamReader`/`OutputStreamWriter`

"Bridge" classes that convert bytes to characters and vice versa.

`DataInputStream`/`DataOutputStream`

Specialized stream filters that add the ability to read and write simple data types like numeric primitives and `String` objects.

`BufferedInputStream`/`BufferedOutputStream` /`BufferedReader`/`BufferedWriter`

Specialized streams that incorporate buffering for additional efficiency.

`PrintWriter`

A specialized character stream that makes it simple to print text.

`PipedInputStream`/`PipedOutputStream` /`PipedReader`/`PipedWriter`

"Double-ended" streams that always occur in pairs. Data written into a `PipedOutputStream` or `PipedWriter` is read from its corresponding `PipedInputStream` or `PipedReader`.

`FileInputStream`/`FileOutputStream` /`FileReader`/`FileWriter`

Implementations of `InputStream`, `OutputStream`, `Reader`, and `Writer` that read from and write to files on the local filesystem.

Streams in Java are one-way streets. The `java.io` input and output classes represent the ends of a simple stream, as shown in Figure 8.2. For bidirectional conversations, we use one of each type of stream.

Figure 8.2: Basic input and output stream functionality

[Graphic: Figure 8-2]

`InputStream` and `OutputStream` are `abstract` classes that define the lowest-level interface for all byte streams. They contain methods for reading or writing an unstructured flow of byte-level data. Because these classes are abstract, you can never create a "pure" input or output stream. Java implements subclasses of these for activities like reading and writing files, and communicating with sockets. Because all byte streams inherit the structure of `InputStream` or `OutputStream`, the various kinds of byte streams can be used interchangeably. For example, a method often takes an `InputStream` as an argument. This means the method accepts any subclass of `InputStream`. Specialized types of streams can also be layered to provide higher-level functionality, such as buffering or handling larger data types.

In Java 1.1, new classes based around `Reader` and `Writer` were added to the `java.io` package. `Reader` and `Writer` are very much like `InputStream` and `OutputStream`, except that they deal with characters instead of bytes. As true character streams, these classes correctly handle Unicode characters, which was not always the case with the byte streams. However, some sort of bridge is needed between these character streams and the byte streams of physical devices like disks and networks. `InputStreamReader` and `OutputStreamWriter` are special classes that use an *encoding scheme* to translate between character and byte streams.

We'll discuss all of the interesting stream types in this section, with the exception of `FileInputStream`, `FileOutputStream`, `FileReader`, and `FileWriter`. We'll postpone the discussion of file streams until the next section, where we'll cover issues involved with accessing the filesystem in Java.

Terminal I/O

The prototypical example of an `InputStream` object is the standard input of a Java application. Like `stdin` in C or `cin` in C++, this object reads data from the program's environment, which is usually a terminal window or a command pipe. The `java.lang.System` class, a general repository for system-related resources, provides a reference to standard input in the `static` variable `in`. `System` also provides objects for standard output and standard error in the `out` and `err` variables, respectively. The following example shows the correspondence:

```
InputStream stdin = System.in;
OutputStream stdout = System.out;
OutputStream stderr = System.err;
```

This example hides the fact that `System.out` and `System.err` aren't really `OutputStream` objects, but more specialized and useful `PrintStream` objects. I'll explain these later, but for now we can reference `out` and `err` as `OutputStream` objects, since they are a kind of `OutputStream` by inheritance.

We can read a single byte at a time from standard input with the `InputStream`'s `read()` method. If you look closely at the API, you'll see that the `read()` method of the base `InputStream` class is actually an `abstract` method. What lies behind `System.in` is an implementation of `InputStream`, so it's valid to call `read()` for this stream:

```
try {
    int val = System.in.read();
    ...
}
catch ( IOException e ) {
}
```

As is the convention in C, `read()` provides a byte of information, but its return type is `int`. A return value of `-1` indicates a normal end of stream has been reached; you'll need to test for this condition when using the simple `read()` method. If an error occurs during the read, an `IOException` is thrown. All basic input and output stream commands can throw an `IOException`, so you should arrange to catch and handle them as appropriate.

To retrieve the value as a byte, perform the cast:

```
byte b = (byte) val;
```

Of course, you'll need to check for the end-of-stream condition before you perform the cast. An overloaded form of `read()` fills a byte array with as much data as possible up to the limit of the array size and returns the number of bytes read:

```
byte [] bity = new byte [1024];
int got = System.in.read( bity );
```

We can also check the number of bytes available for reading on an `InputStream` with the `available()` method. Once we have that information, we can create an array of exactly the right size:

```
int waiting = System.in.available();
if ( waiting > 0 ) {
    byte [] data = new byte [ waiting ];
    System.in.read( data );
    ...
}
```

InputStream provides the skip() method as a way of jumping over a number of bytes. Depending on the implementation of the stream and if you aren't interested in the intermediate data, skipping bytes may be more efficient than reading them. The close() method shuts down the stream and frees up any associated system resources. It's a good idea to close a stream when you are done using it.

Character Streams

The InputStream and OutputStream subclasses of Java 1.0.2 included methods for reading and writing strings, but most of them operated by assuming that a sixteen-bit Unicode character was equivalent to an eight-bit byte in the stream. This only works for Latin-1 (ISO8859-1) characters, so the character stream classes Reader and Writer were introduced in Java 1.1. Two special classes, InputStreamReader and OutputStreamWriter, bridge the gap between the world of character streams and the world of byte streams. These are character streams that are wrapped around an underlying byte stream. An encoding scheme is used to convert between bytes and characters. An encoding scheme name can be specified in the constructor of InputStreamReader or OutputStreamWriter. Another constructor simply accepts the underlying stream and uses the system's default encoding scheme. For example, let's parse a human-readable string from the standard input into an integer. We'll assume that the bytes coming from System.in use the system's default encoding scheme.

```
try {
    InputStreamReader converter = new InputStreamReader(System.in);
    BufferedReader in = new BufferedReader(converter);

    String text = in.readLine();
    int i = NumberFormat.getInstance().parse(text).intValue();
}
catch ( IOException e ) { }
catch ( ParseException pe ) { }
```

First, we wrap an InputStreamReader around System.in. This object converts the incoming bytes of System.in to characters using the default encoding scheme. Then, we wrap a BufferedReader around the InputStreamReader. BufferedReader gives us the readLine() method, which we can use to retrieve a full line of text into a String. The string is then parsed into an integer using the techniques described in Chapter 7.

We could have programmed the previous example using only byte streams, and it would have worked for users in the United States, at least. So why go to the extra trouble of using character streams? Character streams were introduced in Java 1.1 to correctly support Unicode strings. Unicode was designed to support almost all of the written languages of the world. If you want to write a program that works in any part of the world, in any language, you definitely want to use streams that don't mangle Unicode.

So how do you decide when you need a byte stream and when you need a character stream? If you want to read or write character strings, use some variety of Reader or Writer. Otherwise a byte stream should suffice. Let's say, for example, that you want to read strings from a file that was written out by a Java 1.0.2 application. In this case you could simply create a FileReader, which will convert the bytes in the file to characters using the system's default encoding scheme. If you have a file in a specific encoding scheme, you can create an InputStreamReader with that encoding scheme and read characters from it. Another example comes from the Internet. Web servers serve files as byte streams. If you want to read Unicode strings from a file with a particular encoding scheme, you'll need an appropriate InputStreamReader wrapped around the socket's InputStream.

Stream Wrappers

What if we want to do more than read and write a mess of bytes or characters? Many of the InputStream, OutputStream, Reader, and Writer classes wrap other streams and add new features. A filtered stream takes another stream in its constructor; it delegates calls to the underlying stream while doing some additional processing of its own.

In Java 1.0.2, all wrapper streams were subclasses of FilterInputStream and FilterOutputStream. The character stream classes introduced in Java 1.1 break this pattern, but they operate in the same way. For example, BufferedInputStream extends FilterInputStream in the byte world, but BufferedReader extends Reader in the character world. It doesn't really matter--both classes accept a stream in their constructor and perform buffering. Like the byte stream classes, the character stream classes include the abstract FilterReader and FilterWriter classes, which simply pass all method calls to an underlying stream.

The FilterInputStream, FilterOutputStream, FilterReader, and FilterWriter classes themselves aren't useful; they must be subclassed and specialized to create a new type of filtering operation. For example, specialized wrapper streams like DataInputStream and DataOutputStream provide additional methods for reading and writing primitive data types.

As we said, when you create an instance of a filtered stream, you specify another stream in the constructor. The specialized stream wraps an additional layer of functionality around the other stream, as shown in Figure 8.3. Because filtered streams themselves are subclasses of the fundamental stream types, filtered streams can be layered on top of each other to provide different combinations of features. For example, you could wrap a PushbackReader around a LineNumberReader that was wrapped around a FileReader.

Figure 8.3: Layered streams

[Graphic: Figure 8-3]

Data streams

DataInputStream and DataOutputStream are filtered streams that let you read or write strings and primitive data types that comprise more than a single byte. DataInputStream and DataOutputStream implement the DataInput and DataOutput interfaces, respectively. These interfaces define the methods required for streams that read and write strings and Java primitive types in a machine-independent manner.

You can construct a DataInputStream from an InputStream and then use a method like readDouble() to read a primitive data type:

```
DataInputStream dis = new DataInputStream( System.in );
double d = dis.readDouble();
```

The above example wraps the standard input stream in a DataInputStream and uses it to read a double value. readDouble() reads bytes from the stream and constructs a double from them. All DataInputStream methods that read primitive types also read binary information.

The DataOutputStream class provides write methods that correspond to the read methods in DataInputStream. For example, writeInt() writes an integer in binary format to the underlying output stream.

The readUTF() and writeUTF() methods of DataInputStream and DataOutputStream read and write a Java String of Unicode characters using the UTF-8 "transformation format." UTF-8 is an ASCII-compatible encoding of Unicode characters commonly used for the transmission and storage of Unicode text.[1]

[1] Check out the URL http://www.stonehand.com/unicode/standard/utf8.html for more information on UTF-8.

We can use a DataInputStream with any kind of input stream, whether it be from a file, a socket, or standard input. The same applies to using a DataOutputStream, or, for that matter, any other specialized streams in java.io.

Buffered streams

The BufferedInputStream, BufferedOutputStream, BufferedReader, and BufferedWriter classes add a data buffer of a specified size to the stream path. A buffer can increase efficiency by reducing the number of physical read or write operations that correspond to read() or write() method calls. You create a buffered stream with an appropriate input or output stream and a buffer size. Furthermore, you can wrap another stream around a buffered stream so that it benefits from the buffering. Here's a simple buffered input stream:

```
BufferedInputStream bis = new BufferedInputStream(myInputStream, 4096);
...
bis.read();
```

In this example, we specify a buffer size of 4096 bytes. If we leave off the size of the buffer in the constructor, a reasonably sized one is chosen for us. On our first call to read(), bis tries to fill the entire 4096-byte buffer with data. Thereafter, calls to read() retrieve data from the buffer until it's empty.

A BufferedOutputStream works in a similar way. Calls to write() store the data in a buffer; data is actually written only when the buffer fills up. You can also use the flush() method to wring out the contents of a BufferedOutputStream before the buffer is full.

Some input streams like BufferedInputStream support the ability to mark a location in the data and later reset the stream to that position. The mark() method sets the return point in the stream. It takes an integer value that specifies the number of bytes that can be read before the stream gives up and forgets about the mark. The reset() method returns the stream to the marked point; any data read after the call to mark() is read again.

This functionality is especially useful when you are reading the stream in a parser. You may occasionally fail to parse a structure and so must try something else. In this situation, you can have your parser generate an error (a homemade ParseException) and then reset the stream to the point before it began parsing the structure:

```
BufferedInputStream input;
...
try {
    input.mark( MAX_DATA_STRUCTURE_SIZE );
    return( parseDataStructure( input ) );
}
catch ( ParseException e ) {
    input.reset();
    ...
}
```

The `BufferedReader` and `BufferedWriter` classes work just like their byte-based counterparts, but operate on characters instead of bytes.

Print streams

Another useful wrapper stream is `java.io.PrintWriter`. This class provides a suite of overloaded `print()` methods that turn their arguments into strings and push them out the stream. A complementary set of `println()` methods adds a newline to the end of the strings. `PrintWriter` is the more capable big brother of the `PrintStream` byte stream. `PrintWriter` is an unusual character stream because it can wrap either an `OutputStream` or another `Writer`. The `System.out` and `System.err` streams are `PrintStream` objects; you have already seen such streams strewn throughout this book:

```
System.out.print("Hello world...\n");
System.out.println("Hello world...");
System.out.println( "The answer is: " + 17 );
System.out.println( 3.14 );
```

In Java 1.1, the `PrintStream` class has been enhanced to translate characters to bytes using the system's default encoding scheme. Although `PrintStream` is not deprecated in Java 1.1, its constructors are. For all new development, use a `PrintWriter` instead of a `PrintStream`. Because a `PrintWriter` can wrap an `OutputStream`, the two classes are interchangeable.

When you create a `PrintWriter` object, you can pass an additional `boolean` value to the constructor. If this value is `true`, the `PrintWriter` automatically performs a `flush()` on the underlying `OutputStream` or `Writer` each time it sends a newline:

```
boolean autoFlush = true;
PrintWriter p = new PrintWriter( myOutputStream, autoFlush );
```

When this technique is used with a buffered output stream, it corresponds to the behavior of terminals that send data line by line.

Unlike methods in other stream classes, the methods of `PrintWriter` and `PrintStream` do not throw `IOException`s. Instead, if we are interested, we can check for errors with the `checkError()` method:

```
System.out.println( reallyLongString );
if ( System.out.checkError() )                // Uh oh
```

Pipes

Normally, our applications are directly involved with one side of a given stream at a time. `PipedInputStream` and `PipedOutputStream` (or `PipedReader` and `PipedWriter`), however, let us create two sides of a stream and connect them together, as shown in Figure 8.4. This provides a stream of communication between threads, for example.

To create a pipe, we use both a `PipedInputStream` and a `PipedOutputStream`. We can simply choose a side and then construct the other side using the first as an argument:

Figure 8.4: Piped streams

[Graphic: Figure 8-4]

```
PipedInputStream pin = new PipedInputStream();
PipedOutputStream pout = new PipedOutputStream( pin );
```

Alternatively :

```
PipedOutputStream pout = new PipedOutputStream( );
PipedInputStream pin = new PipedInputStream( pout );
```

In each of these examples, the effect is to produce an input stream, `pin`, and an output stream, `pout`, that are connected. Data written to `pout` can then be read by `pin`. It is also possible to create the `PipedInputStream` and the `PipedOutputStream` separately, and then connect them with the `connect()` method.

We can do exactly the same thing in the character-based world, using `PipedReader` and `PipedWriter` in place of `PipedInputStream` and `PipedOutputStream`.

Once the two ends of the pipe are connected, use the two streams as you would other input and output streams. You can use `read()` to read data from the `PipedInputStream` (or `PipedReader`) and `write()` to write data to the `PipedOutputStream` (or `PipedWriter`). If the internal buffer of the pipe fills up, the writer blocks and waits until more space is available. Conversely, if the pipe is empty, the reader blocks and waits until some data is available. Internally, the blocking is implemented with `wait()` and `notifyAll()`, as described in Chapter 6, *Threads*.

One advantage to using piped streams is that they provide stream functionality in our code, without compelling us to build new, specialized streams. For example, we can use pipes to create a simple logging facility for our application. We can send messages to the logging facility through an ordinary `PrintWriter`, and then it can do whatever processing or buffering is required before sending the messages off to their ultimate location. Because we are dealing with string messages, we use the character-based `PipedReader` and `PipedWriter` classes. The following example shows the skeleton of our logging facility:

```
import java.io.*;

class LoggerDaemon extends Thread {
    PipedReader in = new PipedReader();

    LoggerDaemon() {
        setDaemon( true );
        start();
    }

    public void run() {
        BufferedReader din = new BufferedReader( in );
        String s;

        try {
           while ( (s = din.readLine()) != null ) {
                // process line of data
                // ...
            }
        }
        catch (IOException e ) { }
    }

    PrintWriter getWriter() throws IOException {
        return new PrintWriter( new PipedWriter( in ) );
    }
}

class myApplication {
    public static void main ( String [] args ) throws IOException {
        PrintWriter out = new LoggerDaemon().getWriter();

        out.println("Application starting...");
        // ...
        out.println("Warning: does not compute!");
        // ...
    }
}
```

`LoggerDaemon` is a daemon thread, so it will die when our application exits. `LoggerDaemon` reads strings from its end of the pipe, the `PipedReader in`. `LoggerDaemon` also provides a method, `getWriter()`, that returns a `PipedWriter` that is connected to its input stream. Simply create a new `LoggerDaemon` and fetch the output stream to begin sending messages.

In order to read strings with the `readLine()` method, `LoggerDaemon` wraps a `BufferedReader` around its `PipedReader`. For convenience, it also presents its `PipedWriter` as a `PrintWriter`, rather than a simple `Writer`.

One advantage of implementing `LoggerDaemon` with pipes is that we can log messages as easily as we write text to a terminal or any other stream. In other words, we can use all our normal tools and techniques. Another advantage is that the processing happens in another thread, so we can go about our business while the processing takes place.

There is nothing stopping us from connecting more than two piped streams. For example, we could chain multiple pipes together to perform a series of filtering operations.

Strings to Streams and Back

The `StringReader` class is another useful stream class. The stream is created from a `String`; `StringReader` essentially wraps stream functionality around a `String`. Here's how to use a `StringReader`:

```
String data = "There once was a man from Nantucket...";
```

```
StringReader sr = new StringReader( data );

char T = (char)sr.read();
char h = (char)sr.read();
char e = (char)sr.read();
```

Note that you will still have to catch `IOException`s thrown by some of the `StringReader`'s methods.

The `StringReader` class is useful when you want to read data in a `String` as if it were coming from a stream, such as a file, pipe, or socket. For example, suppose you create a parser that expects to read tokens from a stream. But you want to provide a method that also parses a big string. You can easily add one using `StringReader`.

Turning things around, the `StringWriter` class lets us write to a character string through an output stream. The internal string grows as necessary to accommodate the data. In the following example, we create a `StringWriter` and wrap it in a `PrintWriter` for convenience:

```
StringWriter buffer = new StringWriter();
PrintWriter out = new PrintWriter( buffer );

out.println("A moose once bit my sister.");
out.println("No, really!");

String results = buffer.toString();
```

First we print a few lines to the output stream, to give it some data, then retrieve the results as a string with the `toString()` method. Alternately, we could get the results as a `StringBuffer` with the `getBuffer()` method.

The `StringWriter` class is useful if you want to capture the output of something that normally sends output to a stream, such as a file or the console. A `PrintWriter` wrapped around a `StringWriter` competes with `StringBuffer` as the easiest way to construct large strings piece by piece. While using a `StringBuffer` is more efficient, `PrintWriter` provides more functionality than the normal `append()` method used by `StringBuffer`.

rot13InputStream

Before we leave streams, let's try our hand at making one of our own. I mentioned earlier that specialized stream wrappers are built on top of the `FilterInputStream` and `FilterOutputStream` classes. It's quite easy to create our own subclass of `FilterInputStream` that can be wrapped around other streams to add new functionality.

The following example, `rot13InputStream`, performs a *rot13* operation on the bytes that it reads. *rot13* is a trivial algorithm that shifts alphanumeric letters to make them not quite human-readable; it's cute because it's symmetric. That is, to "un-rot13" some text, simply *rot13* it again. We'll use the `rot13InputStream` class again in the `crypt` protocol handler example in Chapter 9, *Network Programming*, so we've put the class in the `example.io` package to facilitate reuse. Here's our `rot13InputStream` class:

```
package example.io;
import java.io.*;

public class rot13InputStream extends FilterInputStream {

    public rot13InputStream ( InputStream i ) {
        super( i );
    }
    public int read() throws IOException {
        return rot13( in.read() );
    }

    private int rot13 ( int c ) {
        if ( (c >= 'A') && (c <= 'Z') )            c=(((c-'A')+13)%26)+'A';        if
( (c >= 'a') && (c <= 'z') )
            c=(((c-'a')+13)%26)+'a';
        return c;
    } }
```

The `FilterInputStream` needs to be initialized with an `InputStream`; this is the stream to be filtered. We provide an appropriate constructor for the `rot13InputStream` class and invoke the parent constructor with a call to `super()`. `FilterInputStream` contains a protected instance variable, `in`, where it stores the stream reference and makes it available to the rest of our class.

The primary feature of a `FilterInputStream` is that it overrides the normal `InputStream` methods to delegate calls to the `InputStream` in the variable `in`. So, for instance, a call to `read()` simply turns around and calls `read()` on `in` to fetch a byte. An instance of `FilterInputStream` itself could be instantiated from an `InputStream`; it would pass its method calls on to that stream and serve as a pass-through filter. To make things interesting, we can override methods of the `FilterInputStream` class and do extra work on the data as it passes through.

In our example, we have overridden the `read()` method to fetch bytes from the underlying `InputStream`, `in`, and then perform the *rot13* shift on the data before returning it. Note that the `rot13()` method shifts alphabetic characters, while simply passing all other values, including the end of stream value (`-1`). Our subclass now acts like a *rot13* filter. All other normal functionality of an `InputStream`, like `skip()` and `available()` is unmodified, so calls to these methods are answered by the underlying `InputStream`.

Strictly speaking, `rot13InputStream` only works on an ASCII byte stream, since the underlying algorithm is based on the Roman alphabet. A more generalized character scrambling algorithm would have to be based on `FilterReader` to handle Unicode correctly.

9. Network Programming

Contents:

The network is the soul of Java. Most of what is new and exciting about Java centers around the potential for new kinds of dynamic, networked applications. This chapter discusses the `java.net` package, which contains classes for communications and working with networked resources. These classes fall into two categories: the sockets API and classes for working with Uniform Resource Locators (URLs). Figure 9.1 shows all of the classes in `java.net`.

Figure 9.1: The java.net package

[Graphic: Figure 9-1]

Java's sockets interface provides access to the standard network protocols used for communications between hosts on the Internet. Sockets are the mechanism underlying all other kinds of portable networked communications. Your processes can use sockets to communicate with a server or peer applications on the Net, but you have to implement your own application-level protocols for handling and interpreting the data. Higher-level functionality, like remote procedure calls and distributed objects, are implemented with sockets.

The Java URL classes provide an API for accessing well-defined networked resources, like documents and applications on servers. The classes use an extensible set of prefabricated protocol and content handlers to perform the necessary communication and data conversion for accessing URL resources. With URLs, an application can fetch a complete file or database record from a server on the network with just a few lines of code. Applications like Web browsers, which deal with networked content, use the `URL` class to simplify the task of network programming. They also take advantage of the dynamic nature of Java, which allows handlers for new types of URLs to be added on the fly. As new types of servers and new formats for content evolve, additional URL handlers can be supplied to retrieve and interpret the data without modifying the original application.

In this chapter, I'll try to provide some practical and realistic examples of Java network programming using both APIs. Sadly, the current state of affairs is disappointing. The real release of HotJava isn't available, and Netscape Navigator imposes many restrictions on what you can do. In addition, a few standards that we need haven't been defined. Nevertheless, you can use all of Java's networking capabilities to build your own free-standing applications. I'll point out the shortcomings with Netscape Navigator and the standards scene as I go along.

9.1 Sockets

Sockets are a low-level programming interface for networked communications. They send streams of data between applications that may or may not be on the same host. Sockets originated in BSD UNIX and are, in other languages, hairy and complicated things with lots of small parts that can break off and choke little children. The reason for this is that most socket APIs can be used with almost any kind of underlying network protocol. Since the protocols that transport data across the network can have radically different features, the socket interface can be quite complex. (For a discussion of sockets in general, see *UNIX Network Programming*, by Richard Stevens [Prentice-Hall].)

Java supports a simplified object-oriented interface to sockets that makes network communications considerably easier. If you have done network programming using sockets in C or another structured language, you should be pleasantly surprised at how simple things can be when objects encapsulate the gory details. If this is the first time you've come across sockets, you'll find that talking to another application can be as simple as reading a file or getting user input. Most forms of I/O in Java, including network I/O, use the stream classes described in Chapter 8, *Input/Output Facilities*. Streams provide a unified I/O interface; reading or writing across the Internet is similar to reading or writing a file on the local system.

Java provides different kinds of sockets to support two distinct classes of underlying protocols. In this first section, we'll look at Java's `Socket` class, which uses a *connection-oriented* protocol. A connection-oriented protocol gives you the equivalent of a telephone conversation; after establishing a connection, two applications can send data back and forth; the connection stays in place even when no one is talking. The protocol ensures that no data is lost and that it always arrives in order. In the next section we'll look at the `DatagramSocket` class, which uses a *connectionless* protocol. A connectionless protocol is more like the postal service. Applications can send short messages to each other, but no attempt is made to keep the connection open between messages, to keep the messages in order, or even to guarantee that they arrive.

In theory, just about any protocol family can be used underneath the socket layer: Novell's IPX, Apple's AppleTalk, even the old ChaosNet protocols. But this isn't a theoretical world. In practice, there's only one protocol family people care about on the Internet, and only one protocol family Java supports: the Internet protocols, IP. The `Socket` class speaks TCP, and the `DatagramSocket` class speaks UDP, both standard Internet protocols. These protocols are available on any system that is connected to the Internet.

Clients and Servers

When writing network applications, it's common to talk about clients and servers. The distinction is increasingly vague, but the side that initiates the conversation is usually the *client*. The side that accepts the request to talk is usually the *server*. In the case where there are two peer applications using sockets to talk, the distinction is less important, but for simplicity we'll use the above definition.

For our purposes, the most important difference between a client and a server is that a client can create a socket to initiate a conversation with a server application at any time, while a server must prepare to listen for incoming conversations in advance. The `java.net.Socket` class represents a single side of a socket connection on either the client or server. In addition, the server uses the `java.net.ServerSocket` class to wait for connections from clients. An application acting as a server creates a `ServerSocket` object and waits, blocked in a call to its `accept()` method, until a connection arrives. When it does, the `accept()` method creates a `Socket` object the server uses to communicate with the client. A server carries on multiple conversations at once; there is only a single `ServerSocket`, but one active `Socket` object for each client, as shown in Figure 9.2.

Figure 9.2: Clients and servers, Sockets and ServerSockets

[Graphic: Figure 9-2]

A client needs two pieces of information to locate and connect to another server on the Internet: a hostname (used to find the host's network address) and a port number. The port number is an identifier that differentiates between multiple clients or servers on the same host. A server application listens on a prearranged port while waiting for connections. Clients select the port number assigned to the service they want to access. If you think of the host computers as hotels and the applications as guests, then the ports are like the guests' room numbers. For one guest to call another, he or she must know the other party's hotel name and room number.

Clients

A client application opens a connection to a server by constructing a `Socket` that specifies the hostname and port number of the desired server:

```
try {
    Socket sock = new Socket("wupost.wustl.edu", 25);
}
catch ( UnknownHostException e ) {
    System.out.println("Can't find host.");
}
catch ( IOException e ) {
    System.out.println("Error connecting to host.");
}
```

This code fragment attempts to connect a `Socket` to port 25 (the SMTP mail service) of the host wupost.wustl.edu. The client handles the possibility that the hostname can't be resolved (`UnknownHostException`) and that it might not be able to connect to it (`IOException`).

As an alternative to using a hostname, you can provide a string version of the host's IP address:

```
Socket sock = new Socket("128.252.120.1", 25);    // wupost.wustl.edu
```

Once a connection is made, input and output streams can be retrieved with the `Socket` `getInputStream()` and `getOutputStream()` methods. The following (rather arbitrary and strange) conversation illustrates sending and receiving some data with the streams. Refer to Chapter 8, *Input/Output Facilities* for a complete discussion of working with streams.

```
try {
    Socket server = new Socket("foo.bar.com", 1234);
    InputStream in = server.getInputStream();
    OutputStream out = server.getOutputStream();

    // Write a byte
    out.write(42);

    // Say "Hello" (send newline delimited string)
    PrintStream pout = new PrintStream( out );
    pout.println("Hello!");

    // Read a byte
    Byte back = in.read();

    // Read a newline delimited string
    DataInputStream din = new DataInputStream( in );
    String response = din.readLine();
    server.close();
}
catch (IOException e ) { }
```

In the exchange above, the client first creates a `Socket` for communicating with the server. The `Socket` constructor specifies the server's hostname (foo.bar.com) and a prearranged port number (1234). Once the connection is established, the client writes a single byte to the server using the `OutputStream`'s `write()` method. It then wraps a `PrintStream` around the `OutputStream` in order to send text more easily. Next, it performs the complementary operations, reading a byte from the server using `InputStream`'s `read()` and then creating a `DataInputStream` from which to get a string of text. Finally, it terminates the connection with the `close()` method. All these operations have the potential to generate `IOExceptions`; the `catch` clause is where our application would deal with these.

Servers

After a connection is established, a server application uses the same kind of `Socket` object for its side of the communications. However, to accept a connection from a client, it must first create a `ServerSocket`, bound to the correct port. Let's recreate the previous conversation from the server's point of view:

```
// Meanwhile, on foo.bar.com...
try {
    ServerSocket listener = new ServerSocket( 1234 );

    while ( !finished ) {
        Socket aClient = listener.accept();    // wait for connection

        InputStream in = aClient.getInputStream();
        OutputStream out = aClient.getOutputStream();

        // Read a byte
        Byte importantByte = in.read();

        // Read a string
        DataInputStream din = new DataInputStream( in );
        String request = din.readLine();

        // Write a byte
        out.write(43);

        // Say "Goodbye"
        PrintStream pout = new PrintStream( out );
        pout.println("Goodbye!");

        aClient.close();
    }

    listener.close();

}
catch (IOException e ) { }
```

First, our server creates a `ServerSocket` attached to port 1234. On some systems there are rules about what ports an application can use. Port numbers below 1024 are usually reserved for system processes and standard, well-known services, so we pick a port number outside of this range. The `ServerSocket` need be created only once. Thereafter we can accept as many connections as arrive.

Next we enter a loop, waiting for the `accept()` method of the `ServerSocket` to return an active `Socket` connection from a client. When a connection has been established, we perform the server side of our dialog, then close the connection and return to the top of the loop to wait for another connection. Finally, when the server application wants to stop listening for connections altogether, it calls the `close()` method of the `ServerSocket`.[1]

> [1] A somewhat obscure security feature in TCP/IP specifies that if a server socket actively closes a connection while a client is connected, it may not be able to bind (attach itself) to the same port on the server host again for a period of time (the maximum time to live of a packet on the network). It's possible to turn off this feature, and it's likely that your Java implementation will have done so.

As you can see, this server is single-threaded; it handles one connection at a time; it doesn't call `accept()` to listen for a new connection until it's finished with the current connection. A more realistic server would have a loop that accepts connections concurrently and passes them off to their own threads for processing. (Our tiny HTTP daemon in a later section will do just this.)

Sockets and security

The examples above presuppose the client has permission to connect to the server, and that the server is allowed to listen on the specified socket. This is not always the case. Specifically, applets and other applications run under the auspices of a `SecurityManager` that can impose arbitrary restrictions on what hosts they may or may not talk to, and whether they can listen for connections. The security policy imposed by the current version of Netscape Navigator allows applets to open socket connections only to the host that served them. That is, they can talk back only to the server from which their class files were retrieved. Applets are not allowed to open server sockets themselves.

Now, this doesn't meant an applet can't cooperate with its server to communicate with anyone, anywhere.

A server could run a proxy that lets the applet communicate indirectly with anyone it likes. What the current security policy prevents is malicious applets roaming around inside corporate firewalls. It places the burden of security on the originating server, and not the client machine. Restricting access to the originating server limits the usefulness of "trojan" applications that do annoying things from the client side. You won't let your proxy mail bomb people, because you'll be blamed.

The DateAtHost Client

Many networked workstations run a time service that dispenses their local clock time on a well-known port. This was a precursor of NTP, the more general Network Time Protocol. In the next example, `DateAtHost`, we'll make a specialized subclass of `java.util.Date` that fetches the time from a remote host instead of initializing itself from the local clock. (See Chapter 7, *Basic Utility Classes* for a complete discussion of the `Date` class.)

`DateAtHost` connects to the time service (port 37) and reads four bytes representing the time on the remote host. These four bytes are interpreted as an integer representing the number of seconds since the turn of the century. `DateAtHost` converts this to Java's variant of the absolute time (milliseconds since January 1, 1970, a date that should be familiar to UNIX users) and then uses the remote host's time to initialize itself:

```
import java.net.Socket;
import java.io.*;

public class DateAtHost extends java.util.Date {
    static int timePort = 37;
    static final long offset = 2208988800L; // Seconds from century to
                                            // Jan 1, 1970 00:00 GMT

    public DateAtHost( String host ) throws IOException {
        this( host, timePort );
    }

    public DateAtHost( String host, int port ) throws IOException {
        Socket sock = new Socket( host, port );
        DataInputStream din =
            new DataInputStream(sock.getInputStream());
        int time = din.readInt();
        sock.close();

        setTime( (((1L << 32) + time) - offset) * 1000 );
    } }
```

That's all there is to it. It's not very long, even with a few frills. We have supplied two possible constructors for `DateAtHost`. Normally we'll use the first, which simply takes the name of the remote host as an argument. The second, overloaded constructor specifies the hostname and the port number of the remote time service. (If the time service were running on a nonstandard port, we would use the second constructor to specify the alternate port number.) This second constructor does the work of making the connection and setting the time. The first constructor simply invokes the second (using the `this()` construct) with the default port as an argument. Supplying simplified constructors that invoke their siblings with default arguments is a common and useful technique.

The second constructor opens a socket to the specified port on the remote host. It creates a `DataInputStream` to wrap the input stream and then reads a 4-byte integer using the `readInt()` method. It's no coincidence the bytes are in the right order. Java's `DataInputStream` and `DataOutputStream` classes work with the bytes of integer types in *network byte order* (most significant to least significant). The time protocol (and other standard network protocols that deal with binary data) also uses the network byte order, so we don't need to call any conversion routines. (Explicit data conversions would probably be necessary if we were using a nonstandard protocol, especially when talking to a non-Java client or server.) After reading the data, we're finished with the socket, so we close it, terminating the connection to the server. Finally, the constructor initializes the rest of the object by calling `Date`'s `setTime()` method with the calculated time value.[2]

[2] The conversion first creates a long value, which is the unsigned equivalent of the integer `time`. It subtracts an offset to make the time relative to the epoch (January 1, 1970) rather than the century, and multiples by 1000 to convert to milliseconds.

The `DateAtHost` class can work with a time retrieved from a remote host almost as easily as `Date` is used with the time on the local host. The only additional overhead is that we have to deal with the possible `IOException` that can be thrown by the `DateAtHost` constructor:

```
try {
    Date d = new DateAtHost( "sura.net" );
    System.out.println( "The time over there is: " + d );
    int hours = d.getHours();
    int minutes = d.getMinutes();
    ...
}
catch ( IOException e ) { }
```

This example fetches the time at the host sura.net and prints its value. It then looks at some components of the time using the `getHours()` and `getMinutes()` methods of the `Date` class.

The TinyHttpd Server

Have you ever wanted your very own Web server? Well, you're in luck. In this section, we're going to build TinyHttpd, a minimal but functional HTTP daemon. TinyHttpd listens on a specified port and services simple HTTP "get file" requests. They look something like this:

```
GET /path/filename [optional stuff]
```

Your Web browser sends one or more as lines for each document it retrieves. Upon reading the request, the server tries to open the specified file and send its contents. If that document contains references to images or other items to be displayed inline, the browser continues with additional GET requests. For best performance (especially in a time-slicing environment), TinyHttpd services each request in its own thread. Therefore, TinyHttpd can service several requests concurrently.

Over and above the limitations imposed by its simplicity, TinyHttpd suffers from the limitations imposed by the fickleness of filesystem access, as discussed in Chapter 8, *Input/Output Facilities*. It's important to remember that file pathnames are still architecture dependent--as is the concept of a filesystem to begin with. This example should work, as is, on UNIX and DOS-like systems, but may require some customizations to account for differences on other platforms. It's possible to write more elaborate code that uses the environmental information provided by Java to tailor itself to the local system. (Chapter 8, *Input/Output Facilities* gives some hints about how to do this).

WARNING:

This example will serve files from your host without protection. Don't try this at work.

Now, without further ado, here's TinyHttpd:

```
import java.net.*;
import java.io.*;
import java.util.*;

public class TinyHttpd {
    public static void main( String argv[] ) throws IOException {
        ServerSocket ss = new ServerSocket(Integer.parseInt(argv[0]));
        while ( true )
            new TinyHttpdConnection( ss.accept() );
    }
}

class TinyHttpdConnection extends Thread {
    Socket sock;
    TinyHttpdConnection ( Socket s ) {
        sock = s;
        setPriority( NORM_PRIORITY - 1 );
        start();
    }

    public void run() {
        try {
            OutputStream out = sock.getOutputStream();
            String req =
                new DataInputStream(sock.getInputStream()).readLine();
            System.out.println( "Request: "+req );

            StringTokenizer st = new StringTokenizer( req );
            if ( (st.countTokens() >= 2) &&
                  st.nextToken().equals("GET") ) {
                if ( (req = st.nextToken()).startsWith("/") )
                    req = req.substring( 1 );
                if ( req.endsWith("/") || req.equals("") )
                    req = req + "index.html";

                try {
                    FileInputStream fis = new FileInputStream ( req );
                    byte [] data = new byte [ fis.available() ];
                    fis.read( data );
                    out.write( data );
                }
                catch ( FileNotFoundException e )
                    new PrintStream( out ).println("404 Not Found");
            } else
                new PrintStream( out ).println( "400 Bad Request" );

            sock.close();
        }
        catch ( IOException e )
            System.out.println( "I/O error " + e );
    }
}
```

Compile `TinyHttpd` and place it in your class path. Go to a directory with some interesting documents and start the daemon, specifying an unused port number as an argument. For example:

```
% java TinyHttpd 1234
```

You should now be able to use your Web browser to retrieve files from your host. You'll have to specify the nonstandard port number in the URL. For example, if your hostname is foo.bar.com, and you started the server as above, you could reference a file as in:

```
http://foo.bar.com:1234/welcome.html
```

`TinyHttpd` looks for files relative to its current directory, so the pathnames you provide should be relative to that location. Retrieved some files? Al'righty then, let's take a closer look.

`TinyHttpd` is comprised of two classes. The public `TinyHttpd` class contains the `main()` method of our standalone application. It begins by creating a `ServerSocket`, attached to the specified port. It then loops, waiting for client connections and creating instances of the second class, a `TinyHttpdConnection` thread, to service each request. The `while` loop waits for the `ServerSocket` `accept()` method to return a new `Socket` for each client connection. The `Socket` is passed as an argument to construct the `TinyHttpdConnection` thread that handles it.

`TinyHttpdConnection` is a subclass of `Thread`. It lives long enough to process one client connection and then dies. `TinyHttpdConnection`'s constructor does three things. After saving the `Socket` argument for its caller, it adjusts its own priority and then invokes `start()` to bring its `run()` method to life. By lowering its priority to `NORM_PRIORITY-1` (just below the default priority), we ensure that the threads servicing established connections won't block `TinyHttpd`'s main thread from accepting new requests. (On a time-slicing system, this is less important.)

The body of `TinyHttpdConnection`'s `run()` method is where all the magic happens. First, we fetch an `OutputStream` for talking back to our client. The second line reads the `GET` request from the `InputStream` into the variable `req`. This request is a single newline-terminated `String` that looks like the `GET` request we described earlier. Since this is the only time we read from this socket, it's hard to resist the urge to be terse. Alternatively, we could break that statement into three steps: getting the `InputStream`, creating the `DataInputStream` wrapper, and reading the line. The three-line version is certainly more readable and should not be noticeably slower.

We then parse the contents of `req` to extract a filename. The next few lines are a brief exercise in string manipulation. We create a `StringTokenizer` and make sure there are at least two tokens. Using `nextToken()`, we take the first token and make sure it's the word `GET`. (If both conditions aren't met, we have an error.) Then we take the next token (which should be a filename), assign it to `req` , and check whether it begins with "/". If so, we use `substring()` to strip the first character, giving us a filename relative to the current directory. If it doesn't begin with "/", the filename is already relative to the current directory. Finally, we check to see if the requested filename looks like a directory name (i.e., ends in slash) or is empty. In these cases, we append the familiar default filename *index.html*.

Once we have the filename, we try to open the specified file and load its contents into a large byte array. (We did something similar in the `ListIt` example in Chapter 8, *Input/Output Facilities*.) If all goes well, we write the data out to client on the `OutputStream`. If we can't parse the request or the file doesn't exist, we wrap our `OutputStream` with a `PrintStream` to make it easier to send a textual message. Then we return an appropriate HTTP error message. Finally, we close the socket and return from `run()`, removing our `Thread`.

Taming the daemon

The biggest problem with `TinyHttpd` is that there are no restrictions on the files it can access. With a little trickery, the daemon will happily send any file in your filesystem to the client. It would be nice if we could restrict `TinyHttpd` to files that are in the current directory, or a subdirectory. To make the daemon safer, let's add a security manager. I discussed the general framework for security managers in Chapter 7, *Basic Utility Classes*. Normally, a security manager is used to prevent Java code downloaded over the Net from doing anything suspicious. However, a security manager will serve nicely to restrict file access in a self-contained application.

Here's the code for the security manager class:

```
import java.io.*;

class TinyHttpdSecurityManager extends SecurityManager {

    public void checkAccess(Thread g) { };
    public void checkListen(int port) { };
    public void checkLink(String lib) { };
    public void checkPropertyAccess(String key) { };
    public void checkAccept(String host, int port) { };
    public void checkWrite(FileDescriptor fd) { };
    public void checkRead(FileDescriptor fd) { };

    public void checkRead( String s ) {
        if ( new File(s).isAbsolute() || (s.indexOf("..") != -1) )
            throw new
               SecurityException("Access to file : "+s+" denied.");
    }
}
```

The heart of this security manager is the `checkRead()` method. It checks two things: it makes sure that the pathname we've been given isn't an absolute path, which could name any file in the filesystem; and it makes sure the pathname doesn't have a double dot (`..`) in it, which refers to the parent of the current directory. With these two restrictions, we can be sure (at least on a UNIX or DOS-like filesystem) that we have restricted access to only subdirectories of the current directory. If the pathname is absolute or contains "`..`", `checkRead()` throws a `SecurityException`.

The other do-nothing method implementations--e.g., `checkAccess()`--allow the daemon to do its work without interference from the security manager. If we don't install a security manager, the application runs with no restrictions. However, as soon as we install any security manager, we inherit implementations of many "check" routines. The default implementations won't let you do anything; they just throw a security exception as soon as they are called. We have to open holes so the daemon can do its own work; it still has to accept connections, listen on sockets, create threads, read property lists, etc. Therefore, we override the default checks with routines that allow these things.

Now you're thinking, isn't that overly permissive? Not for this application; after all, `TinyHttpd` never tries to load foreign classes from the Net. The only code we are executing is our own, and it's assumed we won't do anything dangerous. If we were planning to execute untrusted code, the security manager would have to be more careful about what to permit.

Now that we have a security manager, we must modify `TinyHttpd` to use it. Two changes are necessary: we must install the security manager and catch the security exceptions it generates. To install the security manager, add the following code at the beginning of `TinyHttpd`'s `main()` method:

```
System.setSecurityManager( new TinyHttpdSecurityManager() );
```

To catch the security exception, add the following `catch` clause after `FileNotFoundException`'s `catch` clause:

```
catch ( SecurityException e )
    new PrintStream( out ).println( "403 Forbidden" );
```

Now the daemon can't access anything that isn't within the current directory or a subdirectory. If it tries to, the security manager throws an exception and prevents access to the file. The daemon then returns a standard HTTP error message to the client.

`TinyHttpd` still has room for improvement. First, it consumes a lot of memory by allocating a huge array to read the entire contents of the file all at once. A more realistic implementation would use a buffer and send large amounts of data in several passes. `TinyHttpd` also fails to deal with simple things like directories. It wouldn't be hard to add a few lines of code (again, refer to the `ListIt` example in Chapter 8, *Input/Output Facilities*) to read a directory and generate linked HTML listings like most Web servers do.

10. Understand the Abstract Windowing Toolkit

Contents:

The Abstract Windowing Toolkit (AWT), or "another windowing toolkit," as some people affectionately call it, provides a large collection of classes for building graphical user interfaces in Java. With AWT, you can create windows, draw, work with images, and use components like buttons, scrollbars, and pull-down menus in a platform independant way. The `java.awt` package contains the AWT GUI classes. The `java.awt.image` package provides some additional tools for working with images.

AWT is the largest and most complicated part of the standard Java distribution, so it shouldn't be any surprise that we'll take several chapters (five, to be precise) to discuss it. Here's the lay of the land:

- Chapter 10, *Understand the Abstract Windowing Toolkit* covers the basic concepts you need to understand how AWT builds user interfaces.
- In Chapter 11, *Using and Creating GUI Components*, we discuss the basic components from which user interfaces are built: lists, text fields, checkboxes, and so on.
- Chapter 12, *Layout Managers* discusses layout managers, which are responsible for arranging components within a display.
- Chapter 13, *Drawing With the AWT* discusses the fundamentals of drawing, including simple image displays.
- Chapter 14, *Working With Images*, the last chapter to discuss the AWT in detail, covers the image generation and processing tools that are in the `java.awt.image` package. We'll throw in audio for good measure.

We can't cover the full functionality of AWT in this book; if you want complete coverage, see the Java AWT Reference (O'Reilly). Instead, we'll cover the basics of the tools you are most likely to use and show some examples of what can be done with some of the more advanced features. Figure 10.1 shows the user interface portion of the `java.awt` package.

Figure 10.1: User-interface classes of the java.awt package

[Graphic: Figure 10-1]

As its name suggests, AWT is an abstraction. Its classes and functionality are the same for all Java implementations, so Java applications built with AWT should work in the same way on all platforms. You could choose to write your code on under Windows NT/95, and then run it on an X Window System, or a Macintosh. To achieve platform independence, AWT uses interchangeable toolkits that interact with the host windowing system to display user-interface components, thus shielding your application code from the details of the environment it's running in. Let's say you ask AWT to create a button. When your application or applet runs, a toolkit appropriate to the host environment renders the button appropriately: on Windows, you can get a button that looks like other Windows buttons; on a Macintosh, you can get a Mac button; and so on.

Working with user-interface components in AWT is meant to be easy. While the low-level (possibly native) GUI toolkits may be complex, you won't have to work with them directly unless you want to port AWT to a new platform or provide an alternative "look and feel" for the built-in components. When building a user interface for your application, you'll be working with prefabricated components. It's easy to assemble a collection of user-interface components (buttons, text areas, etc.), and arrange them inside containers to build complex layouts. You can also use simple components as building blocks for making entirely new kinds of interface gadgets that are completely portable and reusable.

AWT uses layout managers to arrange components inside containers and control their sizing and positioning. Layout managers define a strategy for arranging components instead of relying on absolute positioning. For example, you can define a user interface with a collection of buttons and text areas and be reasonably confident it will always display correctly. It doesn't matter that Windows, UNIX, and the Macintosh render your buttons and text areas differently; the layout manager should still position them sensibly with respect to each other.

Unfortunately, the reality is that most of the complaints about Java center around AWT. AWT is very different from what many people are used to and lacks some of the advanced features other GUI environments provide (at least for now). It's also true that most of the bugs in current implementations of Java lie in the AWT toolkits. As bugs are fixed and developers become accustomed to AWT, we would expect the number of complaints to diminish. Java 1.1 is a big improvement over previous versions. But at the time of this writing, there are some rough edges.

10.1 GUI Concepts in Java

Chapter 11, *Using and Creating GUI Components* contains examples using most of the components in the `java.awt` package. But before we dive into those examples, we need to spend a bit of time talking about the concepts AWT uses for creating and handling user interfaces. This material should get you up to speed on GUI concepts and on how they are used in Java.

Components

A component is the fundamental user-interface object in Java. Everything you see on the display in a Java application is an AWT component. This includes things like windows, drawing canvases, buttons, checkboxes, scrollbars, lists, menus, and text fields. To be used, a component must usually be placed in a Container. Container objects group components, arrange them for display, and associate them with a particular display device. All components are derived from the abstract `java.awt.Component` class, as you saw in Figure 10.1. For example, the `Button` class is a subclass of the `Component` class, which is derived directly from `Object`.

For the sake of simplicity, we can split the functionality of the `Component` class into two categories: appearance and behavior. The `Component` class contains methods and variables that control an object's general appearance. This includes basic attributes such as whether or not it's visible, its current size and location, and certain common graphical defaults like font and color. The `Component` class also contains methods implemented by specific subclasses to produce the actual graphics the object displays. When a component is first displayed, it's associated with a particular display device. The `Component` class encapsulates access to its display area on that device. This includes methods for accessing graphics and for working with off-screen drawing buffers for the display.

By a `Component`'s behavior, we usually mean the way it responds to user-driven events. When the user performs an action (like pressing the mouse button) within a component's display area, an AWT thread delivers an event object that describes "what happened." The event is delivered to objects that have registered themselves as "listeners" for that type of event from that component. For example, when the user clicks on a button, the button delivers an `ActionEvent`. To receive those events, an object registers with the button as an `ActionListener`.

Events are delivered by invoking designated event-handler methods within the receiving object (the "listener"). Objects prepare themselves to receive events by implementing methods for the types of events in which they are interested and then registering as listeners with the sources of the events. There are specific types of events that cover different categories of component and user interaction. For example, `MouseEvent`s describe activities of the mouse within a component's area, `KeyEvent`s describe key presses, and functionally higher level events such as `ActionEvent`s indicate that a user interface component has done its job.

Although events are crucial to the workings of AWT, they aren't limited to building user interfaces. Events are an important interobject communications mechanism that may be used by completely nongraphical parts of an application as well. They are particularly important in the context of Java Beans, which use events as an extremely general notification mechanism. We will describe events thoroughly in this chapter because they are so fundamental to the way in which user interfaces function in Java, but it's good to keep the bigger picture in mind.

Containers often take on certain responsibilities for the components that they hold. Instead of having every component handle events for its own bit of the user interface, a container may register itself or another object to receive the events for its child components, and "glue" those events to the correct application logic.

A component informs its container when it does something that might affect other components in the container, such as changing its size or visibility. The container can then tell the layout manager that it is time to rearrange the child components.

Containers in Java are themselves a kind of component. Because all components share this structure, container objects can manage and arrange `Component` objects without knowing what they are and what they are doing. Components can be swapped and replaced with new versions easily and combined into composite user-interface objects that can be treated as individual components. This lends itself well to building larger, reusable user-interface items.

Peers

We have just described a nice system in which components govern their own appearance, and events are delivered to objects that are "listening" to those components. Unfortunately, getting data out to a display medium and receiving events from input devices involve crossing the line from Java to the real world. The real world is a nasty place full of architecture dependence, local peculiarities, and strange physical devices like mice, trackballs, and '69 Buicks.

At some level, our components will have to talk to objects that contain native methods to interact with the host operating environment. To keep this interaction as clean and well-defined as possible, Java uses a set of *peer* interfaces. The peer interface makes it possible for a pure Java-language AWT component to use a corresponding real component--the peer object--in the native environment. You won't generally deal directly with peer interfaces or the objects behind them; peer handling is encapsulated within the `Component` class. It's important to understand the architecture, though, because it imposes some limitations on what you can do with components.

For example, when a component such as a `Button` is first created and displayed on the screen, code in the `Component` class asks an AWT `Toolkit` class to create a corresponding peer object, as shown in Figure 10.2. The `Toolkit` is a *factory* that knows how to create objects in the native display system; Java uses this factory design pattern to provide an abstraction that separates the implementation of component objects from their functionality. The `Toolkit` object contains methods for making instances of each type of component peer. (As a developer, you will probably never work with a native user-interface directly.) `Toolkit`s can be swapped and replaced to provide new implementations of the components without affecting the rest of Java.

Figure 10.2: A toolkit creating a peer object

[Graphic: Figure 10-2]

Figure 10.2 shows a `Toolkit` producing a peer object for a `Button`. When you add a button to a container, the container calls the `Button`'s `addNotify()` method. In turn, `addNotify()` calls the `Toolkit`'s `createButton()` method to make the `Button`'s peer object in the real display system. Thereafter, the component class keeps a reference to the peer object and delegates calls to its methods.

The `java.awt.peer` package, shown in Figure 10.3, parallels the `java.awt` package and contains an interface for each type of component. For example, the `Button` component has a `ButtonPeer` interface, which defines the capabilities of a button.

Figure 10.3: The java.awt.peer package

[Graphic: Figure 10-3]

The peer objects themselves can be built in whatever way is necessary, using a combination of Java and native code. (We will discuss the implementation of peers a bit more in the AWT performance section of this chapter.) A Java-land button doesn't know or care how the real-world button is implemented or what additional capabilities it may have; it knows only about the existence of the methods defined in the `ButtonPeer` interface. Figure 10.4 shows a call to the `setLabel()` method of a `Button` object, which results in a call to the corresponding `setLabel()` method of the native button object.

Figure 10.4: Invoking a method in the peer interface

[Graphic: Figure 10-4]

In this case, the only action a button peer must be able to perform is to set its label text; `setLabel()` is the only method in the ButtonPeer interface. How the native button acts, responds to user input, etc. is entirely up to it. It might turn green when pressed or make a "ka-chunk" sound. The component in Java-land has no control over these aspects of the native button's behavior--and this has important implications. This abstraction allows AWT to use native components from whatever platform it resides on. However, it also means that a lot of a component's functionality is locked away where we can't get to it. We'll see that we can usually intercept events before the peer object has a chance to act on them, but we usually can't change much of the object's basic behavior.

A component gets its peer when it's added to a container. Containers are associated with display devices through Toolkit objects, and thus control the process of peer creation. We'll talk more the ramifications of this when we discuss addNotify() later. (See "Component peers and addNotify()".)

The Model/View/Controller Framework

Before we continue our discussion of GUI concepts, I want to make a brief aside and talk about the Model/View/Controller (MVC) framework. MVC is a method of building reusable components that logically separates the structure, representation, and behavior of a component into separate pieces. MVC is primarily concerned with building user-interface components, but the basic ideas can be applied to many design issues; its principles can be seen throughout Java. Java doesn't implement all of MVC, whose origins are in Smalltalk, but MVC's influence is apparent throughout the language.

The fundamental idea behind MVC is the separation of the data model for an item from its presentation. For example, we can draw different representations (e.g., bar graphs, pie charts) of the data in a spreadsheet. The data is the "model"; the particular representation is the "view." A single model can have many views that show different representations of the data. The behavior of a user-interface component usually changes its model and affects how the component is rendered as a view. If we were to create a button component for example, its data model could be as simple as a boolean value for whether it's up or down. The behavior for handling mouse-press events would alter the model, and the display would examine that data when it draws the on-screen representation.

The way in which AWT objects communicate, by passing events from sources to listeners, is part of this MVC concept of separation. Event listeners are "observers" and event sources are "observables." When an observable changes or performs a function, it notifies all of its observers of the activity.[1]

> [1] Although they are not used by AWT, Java provides generic Observer class and Observable interface in the java.util package. (In practice, these are more a design hint than of day to day usefulness.)

This model of operation is also central to the way in which Java works with graphics, as you'll see in Chapter 11, *Using and Creating GUI Components*. Image information from a producer, such as a graphics engine or video stream, is distributed to consumers that can represent different views of the data. Consumers register with a producer and receive updates as the image is created or when the image has changed.

The factory concept used by the Toolkit objects is related to MVC; factories use Java interfaces to separate the implementation of an object from its behavior. An object that implements an interface doesn't have to fit into a particular class structure; it needs only to provide the methods defined by the interface. Thus, an AWT Toolkit is a factory that produces native user-interface components that correspond to Java components. The native components don't need to match AWT's class structure, provided they implement the appropriate interface.

Painting and Updating

Components can be asked to draw themselves at any time. In a more procedural programming environment, you might expect a component would be involved in drawing only when first created or when it changes its appearance. In Java, components act in a way that is more closely tied to the underlying behavior of the display environment. For example, when you obscure a component with a window and then reexpose it, an AWT thread asks the component to redraw itself.

AWT asks a component to draw itself by calling its `paint()` method. `paint()` may be called at any time, but in practice, it's called when the object is first made visible, whenever it changes its appearance, and whenever some tragedy in the display system messes up its area. Because `paint()` can't make any assumptions about why it was called, it must redraw the component's entire display.

However, redrawing the whole component is unnecessary if only a small part changes, especially in an anticipated way. In this case, you'd like to specify what part of the component has changed, and redraw that part alone. Painting a large portion of the screen is time consuming, and can cause flickering that is especially annoying if you're redrawing the object frequently, as with animation. When a component realizes it needs to redraw itself, it should ask AWT to schedule a call to its `update()` method. `update()` can do drawing of its own, but often, it simply defines a clipping region--by calling `clipRect()`--on its graphics context; to limit the extent of the painted area and then calling `paint()` explicitly. A simple component doesn't have to implement its own `update()` method, but that doesn't mean the method doesn't exist. In this case, the component gets a default version of `update()` that simply clears the component's area and calls `paint()`.

A component never calls its `update()` method directly. Instead, when a component requires redrawing, it schedules a call to `update()` by invoking `repaint()`. The `repaint()` method asks AWT to schedule the component for repainting. At some point in the future, a call to `update()` occurs. AWT is allowed to manage these requests in whatever way is most efficient. If there are too many requests to handle, or if there are multiple requests for the same component, AWT can reschedule a number of repaint requests into a single call to `update()`. This means that you can't predict exactly when `update()` will be called in response to a `repaint()`; all you can expect is that it happens at least once, after you request it.

Normally, calling repaint() is an implicit request to be updated as soon as possible. There is another form of `repaint()` that allows you to specify a time period within which you would like an update, giving the system more flexibility in scheduling the request. An application can use this method to govern its refresh rate. For example, the rate at which you render frames for an animation might vary, depending on other factors (like the complexity of the image). You could impose an effective maximum frame rate by calling repaint() with a time (the inverse of the frame rate) as an argument. If you then happen to make more than one repaint request within that time period, AWT is not obliged to physically repaint for each one. It can simply condense them to carry out a single update within the time you have specified.

Both `paint()` and `update()` take a single argument: a `Graphics` object. The `Graphics` object represents the component's graphics context. It corresponds to the area of the screen on which the component can draw and provides the methods for performing primitive drawing and image manipulation. We'll look at the `Graphics` class in detail in Chapter 11, *Using and Creating GUI Components*.

All components paint and update themselves using this mechanism. However, you really care about it only when doing your own drawing, and in practice, you should be drawing only on a `Canvas`, `Panel`, `Applet`, or your own subclasses of Component. Other kinds of objects, like buttons and scrollbars, have lots of behavior built into their peers. You may be able to draw on one of these objects, but unless you specifically catch the appropriate events and redraw (which could get complicated), your handiwork is likely to disappear.

`Canvas`es, `Panel`s, and lightweight components (which we will discuss fully later in this chapter) are "blank slates" for you to implement your own behavior and appearance. For example, by itself, the AWT `Canvas` has no outward appearance; it takes up space and has a background color, but otherwise, it's empty. By subclassing `Canvas` and adding your own code, you can create a more complicated object like a graph or a flying toaster. A lightweight component is even "emptier" than that. It doesn't have a real `Toolkit` peer for its implementation; you get to specify all of the behavior and appearance yourself. We'll talk more about using `Canvas` and lightweight components to create new kinds of GUI objects later in this chapter.

A `Panel` is like a `Canvas`, but it's also a `Container`, so that it can hold other user-interface components. In the same way, a lightweight container is a simple extension of the AWT `Container` class. (More about that when we talk about containers below.)

Enabling and Disabling Components

Standard AWT components can be turned on and off by calling the `enable()` and `disable()` methods. When a component like a `Button` or `TextField` is disabled, it becomes "ghosted" or "greyed-out" and doesn't respond to user input.

For example, let's see how to create a component that can only be used once. This requires getting ahead of the story; I won't explain some aspects of this example until later. Earlier, I said that a `Button` generates an `ActionEvent` when it is pressed. This event is delivered to the listeners' `actionPerformed()` method. The code below disables whatever component generated the event:

```
public boolean void actionPerformed(ActionEvent e ) {
    ...
    ((Component)e.getSource()).disable();
}
```

This code calls `getSource()` to find out which component generated the event. We cast the result to `Component` because we don't necessarily know what kind of component we're dealing with; it might not be a button, because other kinds of components can generate action events. Once we have our component, we disable it.

You can also disable an entire container. Disabling a `Panel`, for instance, disables all the components it contains. Unfortunately, disabling components and containers is handled by the AWT Toolkit at a low level. It is currently not possible to have custom (pure Java) components notified when their native containers are disabled. This flaw should be corrected in a future release.

Focus, please

In order to receive keyboard events, a component has to have keyboard *focus*. The component with the focus is simply the currently selected input component. It receives all keyboard event information until the focus changes. A component can ask for focus with the `Component`'s `requestFocus()` method. Text components like `TextField` and `TextArea` do this automatically whenever you click the mouse in their area. A component can find out when it gains or loses focus through the `FocusListener` interface (see the table of events below). If you want to create your own text-oriented component, you could implement this behavior yourself. For instance, you might request focus when the mouse is clicked in your component's area. After receiving focus, you could change the cursor or do something else to highlight the component.

Many user interfaces are designed so that the focus automatically jumps to the "next available" component when the user presses the TAB key. This behavior is particularly common in forms; users often expect to be able to tab to the next text entry field. AWT handles automatic focus traversal for you when it is applicable. You can get control over the behavior through the `transferFocus()` and `isFocusTraversable()` methods of `Component`. `transferFocus()` passes the focus to the next appropriate component. You can use `transferFocus()` to control the order of tabbing between components by overriding it in the container and implementing your own policy. `isFocusTraversable()` returns a boolean value specifying whether or not the component should be considered eligible for receiving a transfer focus. Your components can override this method to determine whether or not they can be "tabbed to."

Other Component Methods

The `Component` class is very large; it has to provide the base level functionality for all of the various kinds of Java GUI objects. We don't have room to document every method of the component class here, but we'll flesh out our discussion by covering some more of the important ones.

`Container getParent()`

> Return the container that holds this component.

`String getName() / void setName(String name)`

> Get or assign the String name of this component. Giving a component a name is useful for debugging. The name shows up when you do a `toString()`.

`setVisible(boolean visible)`

> Make the component visible or invisible, within its container. If you change the components, visibility, remember to call `validate()` on the container; this causes the layout manager to lay out the container again.

```
Color getForeground() / void setForeground(Color c)
Color getBackground() / void setBackground(Color c)
```

> Get and set the foreground and background colors for this component. The foreground color of any component is the default color used for drawing. For example, it is the color used for text in a text field; it is also the default drawing color for the `Graphics` object passed to the component's `paint()` method. The background color is used to fill the component's area when it is cleared by the default implementation of `update()`.

`Font getFont() / void setFont(Font f)`

Get or set the Font for this component. (Fonts are discussed in Chapter 13, *Drawing With the AWT*.) You can set the Font on text components like TextField and TextArea. For Canvases, Panels, and lightweight components, this will also be the default font used for drawing text on the Graphics context passed to paint().

FontMetrics getFontMetrics(Font font)

Find out the characteristics of a font when rendered on this component. FontMetrics allow you to find out the dimensions of text when rendered in that font.

Dimension getSize() / void setSize(int width, int height)

Get and set the current size of the component. Remember to call validate() on the component's container if you change its size (see Containers below). There are other methods in Component to set its location, but normally this is the job of a layout manager.

Cursor getCursor() / void setCursor(Cursor cursor)

Get or set the type of cursor (mouse pointer) used when the mouse is over this component's area. For example:

```
Component myComponent = ...;
Cursor crossHairs = Cursor.getPredefinedCursor( Cursor.CROSSHAIR_CURSOR );
myComponent.setCursor( crossHairs );
```

Containers

Now that you understand components a little better, our discussion of containers should be easy. A container is a kind of component that holds and manages other AWT components. If you look back to Figure 10.1, you can see the part of the java.awt class hierarchy that descends from Container.

The most useful Container types are Frame, Panel, and Applet. A Frame is a top-level window on your display. Frame is derived from Window, which is pretty much the same, but lacks a border. A Panel is a generic container element used to group components inside of Frames and other Panels. The Applet class is a kind of Panel that provides the foundation for applets that run inside Web browsers. As a Panel, an Applet has the ability to contain other user-interface components. All these classes are subclasses of the Container class; you can also use the Container class directly, like a Panel, to hold components inside of another container. This is called a "lightweight container," and is closely related to lightweight components. We'll discuss lightweight components and containers later in this chapter.

Because a Container is a kind of Component, it has all of the methods of the Component class, including the graphical and event-related methods we're discussing in this chapter. But a container also maintains a list of "child" components, which are the components it manages, and therefore has methods for dealing with those components. By themselves, most components aren't very useful until they are added to a container and displayed. The add() method of the Container class adds a component to the container. Thereafter, this component can be displayed in the container's area and positioned by its layout manager. You can also remove a component from a container with the remove() method.

Layout managers

A *layout manager* is an object that controls the placement and sizing of components within the display area of a container. A layout manager is like a window manager in a display system; it controls where the components go and how big they are. Every container has a default layout manager, but you can easily install a new one by calling the container's `setLayout()` method.

AWT comes with a few layout managers that implement common layout schemes. The default layout manager for a `Panel` is a `FlowLayout`, which tries to place objects at their preferred size from left to right and top to bottom in the container. The default for a `Frame` is a `BorderLayout`, which places a limited number of objects at named locations like "North," "South," and "Center." Another layout manager, the `GridLayout`, arranges components in a rectangular grid. The most general (and difficult to use) layout manager is `GridBagLayout`, which lets you do the kinds of things you can do with HTML tables. We'll get into the details of all of these layout managers in Chapter 12, *Layout Managers*.

As I mentioned above, you normally call `add()` to add a component to a container. There is an overloaded version of `add()` that you may need, depending on what layout manager you're using. Often you'll use the version of `add()` that takes a single `Component` as an argument. However, if you're using a layout manager that uses "constraints," like `BorderLayout` or GridBagLayout, you need to specify additional information about where to put the new component. For that you can use the version that takes a constraint object:

```
add( Component component, Object constraint);
```

For example, to add a component to the top of a `BorderLayout`, you might say:

```
add( newComponent, "North");
```

In this case, the constraint object is the string "North." The `GridBagLayout` uses a much more complex constraint object to specify positioning.

Insets

Insets specify a container's margins; the space specified by the container's insets won't be used by a layout manager. Insets are described by an `Insets` object, which has four `int` fields: `top`, `bottom`, `left`, and `right`. You normally don't need to worry about the insets, the container will set them automatically, taking into account extras like the menu bar that may appear at the top of a frame. However, you should modify the insets if you're doing something like adding a decorative border (for example, a set of "index tabs" at the top of a container) that reduces the space available for components. To change the insets, you override the component's `getInsets()` method, which returns an `Insets` object. For example:

```
//reserve 50 pixels at the top, 5 at the sides and 10 at the bottom
public Insets getInsets() {
    return new Insets (50,5,10,5);
}
```

Z-ordering (stacking components)

In most layout schemes, components are not allowed to overlap, but they can. If they do, the order in which components were added to a container matters. When components overlap they are "stacked" in the order in which they were added: the first component added to the container is on top, the last is on the bottom. To give you more control over stacking, two additional forms of the `add()` method take an additional integer argument that lets you specify the component's exact position in the container's stacking order.

validate( ) and layout( )

A layout manager arranges the components in a container only when asked to. Several things can mess up a container after it's initially laid out:

- Changing its size
- Resizing or moving one of its child components
- Adding, showing, removing, or hiding a child component

Any of these actions causes the container to be marked invalid. Saying that a container is invalid simply means it needs to have its child components readjusted by its layout manager. This is accomplished by calling the `Container`'s `validate()` method. `validate()` then turns around and calls the `Container`'s `doLayout()` method, which asks the layout manager to do its job. In addition, `validate()` also notes that the `Container` has been fixed (i.e., it's valid again) and looks at each child component of the container, recursively validating any containers that are also messed up.

So if you have an applet that contains a small `Panel`--say a keypad holding some buttons--and you change the size of the `Panel` by calling its `resize()` method, you should also call `validate()` on the applet. The applet's layout manager may then reposition or resize the keypad within the applet. It also automatically calls `validate()` for the keypad, so that it can rearrange its buttons to fit inside its new area.

There are two things you should note. First, all components, not just containers, maintain a notion of when they are valid or invalid. But most components (e.g., buttons) don't do anything special when they're validated. If you have a custom component that wants to be notified when it is resized, it might be best to make it a container (perhaps a lightweight container) and do your work in the `doLayout()` method.

Next, child containers are validated only if they are invalid. That means that if you have an invalid component nested inside a valid component and you validate a container above them both, the invalid component may never be reached. However, the `invalidate()` method that marks a container as dirty automatically marks parent containers as well, all the way up the container hierarchy. So that situation should never happen.

Component peers and addNotify()

A component gets its peer when it's added to a container. Containers are associated with display devices through `Toolkit` objects, and thus control the process of peer creation. This means that you can't ask certain questions about a component before it's placed in a container. For example, you can't find out about a component's size or its default font until the component knows where it's being displayed (until it has its peer).

You probably also shouldn't be able to ask a component with no peer about other resources controlled by the peer, such as off screen graphics areas and font metrics. Java's developers apparently thought this restriction too onerous so container-less components are associated with the "default" toolkit that can answer some of these kinds of inquiries. In practice, the default toolkit is usually able to provide the right answer, because with current implementations of Java the default toolkit is probably the only toolkit available. This approach may cause problems in the future, if Java's developers add the ability for different containers to have different toolkits.

The same issue (the existence of a component's peer) also comes up when you are making your own kinds of components and need access to some of these peer resources before you can complete the setup. For example, suppose that you want to set the size or some other feature of your component based on the default font used. You can't complete this setup in your constructor, because the peer doesn't exist yet. The solution to all of these problems is proper use of the `addNotify()` method. As its name implies, `addNotify()` can be used to get notification when the peer is created. You can override it to do your own work, as long as you remember to call `super.addNotify()` to complete the peer creation. For example:

```
class FancyLabel  {
    FancyLabel() {
        // No peer yet...
    }
    public void addNotify() {
        super.addNotify();  // complete the peer creation
        // Complete setup based on Fonts
        // and other peer resources.
    }
}
```

Managing Components

There are a few additional tools of the `Container` class that we should mention.

`Component[] getComponents()`

Returns the container's components in an array.

`void list(PrintWriter out, int indent)`

Generates a list of the components in this container and writes them to the specified `PrintWriter`.

`Component getComponentAt(int x, int y)`

Tells you what component is at the specified coordinates in the container's coordinate system.

Listening for Components

Finally, an important tool to be aware of is the `ContainerListener` interface. It lets you receive an event whenever a component is added to or removed from a container. (It lets you hear the tiny cries of the component as it is imprisoned in its container or torn away.) You can use the `ContainerListener` interface to automate the process of setting up components when they are added to your container. For instance, your container might need to register other kinds of event listeners with its components to track the mouse or handle certain kinds of actions.

Windows and Frames

Windows and frames are the "top level" containers for Java components. A `Window` is simply a plain, graphical screen that displays in your windowing system. Windows have no frills; they are mainly suitable for making "splash" screens and dialogs--things that limit the user's control. `Frame`, on the other hand, is a subclass of `Window` that have a border and can hold a menu-bar. Frames are under the control of your window manager, so you can normally drag a Frame around on the screen and resize it, using the normal controls for your environment. Figure 10.5 shows a `Frame` on the left and a `Window` on the right.

Figure 10.5: A typical frame and window

[Graphic: Figure 10-5]

All other components and containers in Java must be held, at some level, inside of a `Window` or `Frame`. Applets, as we've mentioned a few times, are a kind of `Panel`. Even applets must be housed in a Java frame or window, though normally you don't see an applet's parent frame because it is part of (or simply is) the browser or appletviewer displaying the applet.

A `Frame` is the only `Component` that can be displayed without being added to or attached to another `Container`. After creating a `Frame`, you can call the `show()` method to display it. Let's create a standalone equivalent of our `HelloWeb` applet from Chapter 2, *A First Applet*:

Figure 10.6: Standalone equivalent of the HelloWeb applet

[Graphic: Figure 10-6]

```
class HelloWebApp {
    public static void main( String [] args ) {
        Frame myFrame = new Frame("The Title");
        myFrame.add("Center", new Label("Hello Web!", Label.CENTER) );
        myFrame.pack();
        myFrame.show();
    }
}
```

Here we've got our minimal, graphical, standalone Java application. The `Frame` constructor can take a `String` argument that supplies a title, displayed in the `Frame`'s title bar. (Another approach would be to create the `Frame` with no title, and call `setTitle()` to supply the title later.) After creating the `Frame`, we add our `Label` to it and then call `pack()`, which prepares the `Frame` for display. `pack()` does a couple of things, but its most important effect in this case is that it sets the size of the `Frame` to the smallest needed to hold all of its components. Specifically, `pack()` calls:

```
setSize( preferredSize() );
```

Next, we call `show()` to get the `Frame` onto the screen. The `show()` method returns immediately, without blocking. Fortunately, our application does not exit while the `Frame` is showing. To get rid of a `Frame`, call the `dispose()` method. If you want to hide the `Frame` temporarily, call `setVisible(false)`. You can check to see if a `Frame` is showing with the `isShowing()` method.

In this example, we let `pack()` set the size of the `Frame` for us before we `show()` it. If we hadn't, the `Frame` would have come up at an undefined size. If we instead want the `Frame` to be a specific size (not just hugging its child components) we could simply call `setSize()` instead of `pack()`.

```
...
myFrame.setSize( 300, 300 );
myFrame.show();
```

Other Methods for Controlling Frames

The `setLocation()` method of the `Component` class can be used on a `Frame` or `Window` to set its position on the screen. The x and y coordinates are considered relative to the screen's origin (the top left corner).

You can use the `toFront()` and `toBack()` methods, respectively, to pull a `Frame` or `Window` to the front of other windows, or push it to the background. By default, a user is allowed to resize a `Frame`, but you can prevent resizing by calling `setResizable(false)` before showing the `Frame`.

On most systems, frames can be "iconfied"; that is, they can be represented by a little icon image. You can get and set a frame's icon image by calling `getIconImage()` and `setIconImage()`. Remember that as with all components, you can set the cursor by calling the `setCursor()` method.

Using Windows

Windows and frames have a slightly convoluted relationship. We said above that `Frame` is a subclass of `Window`. However, if you look, you'll see that to create a `Window` you have to have a `Frame` available to serve as its parent. The `Window` constructor takes a `Frame` as an argument.

```
Window myWindow = new Window( myFrame );
```

The rationale for this is long and boring. Suffice it to say that this limitation will probably go away in the future.

Prepacking Windows and Frames

Earlier we said that calling `pack()` on a `Frame` sets the frame's size to the preferred size of its layout. However, the `pack()` method is not simply equivalent to a call to `setSize()`. `pack()` is often called before any of the frame's components have their peers. Therefore, calling `pack()` forces the container to choose its `Toolkit` and to create the peers of any components that have been added to it. After that is done, the layout manager can reliably determine its preferred size.

For a large frame with lots of components, packing the frame is a convenient way to do this setup work in advance, before the frame is displayed. Whether or not this is useful depends on whether you'd rather have your application start up faster, or pop up its frames faster, once it is running.

AWT Performance and Lightweight Components

Java's developers initially decided to implement the standard AWT components with a "mostly native" Toolkit. As we described above, that means that most of the important functionality of these classes is delegated to peer objects, which live in the native operating system. Using native peers allows Java to take on the look and feel of the local operating environment. Macintosh users see Mac applications, PC users see Windows' windows, and Unix users can have their Motif motif; warm fuzzy feelings abound. Java's chameleon-like ability to blend into the native environment is considered by many to be an integral part of platform independance. However, there are a few important downsides to this arrangement.

First, as we mentioned earlier, using native peer implementations makes it much more difficult (if not impossible) to subclass these components to specialize or modify their behavior. Most of their behavior comes from the native peer, and therefore can't be overidden or extended easily. As it turns out, this is not a terrible problem because of the ease with which we can make our own components in Java; we will give you an idea of how to start in Chapter 11, *Using and Creating GUI Components*. It is also true that a sophisticated new component, like an HTML viewer, would benefit little in deriving from a more primitive text viewing component like `TextArea`.

Next, porting the native code makes it much more difficult to bring Java to a new platform. For the user, this can only mean one thing: bugs. Quite simply, while the Java language itself has been quite stable, the cross platform behavior of the AWT has been an Achilles' heel. Although the situation is steadily improving, the lack of large, commercial quality Java applications until relatively recently testifies to the difficulties involved. At this time, new development has been saturated with Java for well over a year (a decade in Net time) and very few real applications are with us.

Finally, we come to a somewhat counterintuitive problem with the use of native peers. In most current implementations of Java, the native peers are quite "heavy" and consume a lot of resources. You might expect that relying on native code would be much more efficient than creating the components in Java. However, it can take a long time to instantiate a large number of GUI elements when each requires the creation of a native peer from the toolkit. And in some cases you may find that once they are created, they don't perform as well as the pure Java equivalents that you can create yourself.

An extreme example would be a spreadsheet that uses an AWT `TextField` for each cell. Creating hundreds of `TextFieldPeer` objects would be something between slow and impossible. While simply saying "don't do that" might be a valid answer, this begs the question: how do you create large applications with complex GUIs? Java would not be a very interesting environment if it was only limited to simple tasks. One solution, taken by development environments like Sun's JavaWorkshop, is to use "wrapper" classes for the standard AWT components; the wrapper controls when peer objects are created. Another attack on the problem has been to create "lightweight" components that are written entirely in Java, and therefore don't require native code.

Using Lightweight Components and Containers

A "lightweight" component is simply a component that is implemented entirely in Java. You implement all of its appearance by drawing in the `paint()` and `update()` methods; you implement its behavior by catching user events (usually at a low level) and possibly generating new events. Lightweight components can be used to create new kinds of gadgets, in the same way you might use a `Canvas` or a `Panel`. But they avoid some of the performance penalties inherent in the use of peers, and, perhaps more importantly, they provide more flexibility in their appearance. A lightweight component can have a transparent background, allowing its container to "show through" its own area. It is also more reasonable to have another component or container overlap or draw into a lightweight component's area.

You create a lightweight component by subclassing the `Component` and `Container` classes directly. That is, instead of writing:

```
class myCanvas extends Canvas { ... }
```

you write:

```
class myCanvas extends Container { ... } // lightweight
```

That's often all you need to do to create a lightweight component. When the lightweight component is put into a container, it doesn't get a native peer. Instead, it gets a `LightweightPeer` that serves as a place holder and identifies the component as lightweight and in need of special help. The container then takes over the responsibilities that would otherwise be handled by a native peer: namely, low-level delivery of events and paint requests. The container receives mouse movement events, key strokes, paint requests, etc., for the lightweight component. It then sorts out the events that fall within the component's bounds and dispatches them to it. Similarly, it translates paint requests that overlap the lightweight component's area and forwards them to it.

Figure 10.7: Sending a paint() request to a component

[Graphic: Figure 10-7]

Figure 10.7 shows a component receiving a `paint()` request via its container. This makes it easy to see how a lightweight component can have a transparent background. The component is actually drawing directly onto its container's graphics context. Conversely, anything that the container drew on its background is visible in the lightweight component. For an ordinary container, this will simply be the container's background color. But you can do much cooler things too. (See the PictureButton example at the end of the next chapter.) All of the normal rules still apply; your lightweight component's `paint()` method should render the component's entire image (assume that the container has obliterated it), but your `update()` method can assume that whatever drawing it has done previously is still intact.

Just as you can create a lightweight component by subclassing `Component`, you can create a lightweight container by subclassing `Container`. A lightweight container can hold any components, including other lightweight components and containers. In this case, event handling and paint requests are managed by the first "regular" container in the container hierarchy. (There has to be one somewhere, if you think about it.) This brings us to the cardinal rule of subclassing containers, which is:

"Always call `super.paint()` if you override a container's `paint()` method."

If you don't, the container won't be able to manage lightweight components properly.

To summarize, lightweight components are very flexible, pure Java components that are managed by their container and have a transparent background by default. Lightweight components do not rely on native peers from the AWT toolkit to provide their implementations and so they can not readily take on the look and feel of the local platform. In a sense, a lightweight component is just a convenient way to package an extension to a container's painting and event handling methods. But, again, all of this happens automatically, behind the scenes; you can create and use lightweight components as you would any other kind of component.

We'll see examples of lightweight components and containers in the next chapter.

11. Using and Creating GUI Components

Contents:

The last chapter discussed a lot of concepts: how Java's user interface facility is put together, and how the larger pieces work. You should understand what components and containers are, how you use them to create a display, what events are, how components use them to communicate with the rest of your application, and what layout managers are. In other words, we've covered a lot of material that's "good for you."

Now that we're through with the general concepts and background, we'll get to the fun stuff: how to do things with AWT. We will cover all the components that the AWT package supplies, how to use these components in applets and applications, and how to build your own components. We will have lots of code and lots of pretty examples to look at. Here's a list of the components we cover:

- `Button` and `Label`
- Text components: `TextArea` and `TextField`
- `List`
- `Menu` and `Choice`

- PopupMenu
- Checkbox and checkbox grouping
- Scrollbar and ScrollPane
- Dialog and FileDialog

When we discuss how to create your own components, we'll cover these issues:

- Extending canvas
- Lightweight components
- Making components that fire events

11.1 Buttons and Labels

We'll start with the simplest components, buttons, and labels. Frankly, there isn't much to say about them. If you've seen one button, you've seen them all; and you've already seen buttons in the applets of Chapter 2 (HelloWeb3 and HelloWeb4). A button generates an ActionEvent when the user presses it. To receive these events, your program registers an ActionListener, which must implement the actionPerformed() method. The argument passed to actionPerformed() is the event itself. Rather than rehash this material, I'll refer you to Chapter 2.

So much for review. There's one more thing worth saying about buttons, which applies to any component that generates an action event. Java lets us specify an "action command" for buttons (and other components, like menu items, that can generate action events). The action command is less interesting than it sounds. It is just a String that serves to identify the component that sent the event. By default, the action command of a Button is the same as the text of its label; it is included in action events, so you can use it to figure out which button an event came from. To get the action command from an action event, call the event's getActionCommand() method. The following code checks whether the user pressed the "Yes" button:

```
public void actionPerformed(ActionEvent e){
    if (e.getActionCommand().equals("Yes") {
        //the user pressed "Yes"; do something
        ...
    }
}
```

You can change the action command by calling the button's `setActionCommand()` method. The code below changes the button `b`'s action command to "confirm":

```
myButton.setActionCommand("confirm");
```

It's a good idea to get used to setting action commands explicitly, because they prevent your code from breaking when you or some other developer "internationalizes" it. If you rely on the button's label, your code will stop working as soon as that label changes; a French user might see the label "Oui" rather than "Yes." By setting the action command, you eliminate one source of bugs; for example, the button `myButton` above will always generate the action command "confirm," regardless of what its label says.

There's even less to be said about Label components. They're just text strings, housed in a component. There aren't any special events associated with labels; about all you can do is specify the text's alignment, which controls the position of the text within the area that the label occupies when displayed. The following code creates some labels with different alignments:

```
Label l1 = new Label("Lions"); //label with default alignment (CENTER)
Label l2 = new Label("Tigers", LEFT); //left aligned label
Label l3 = new Label (); //label with no text, default alignment
l3.setText("and Bears"); //assigning text to l3
l3.setAlignment(RIGHT); //setting l3's alignment
```

Now we've built three labels, using all three constructors and several of the class's methods. To display the labels, you only have to add them to a container by calling the container's `add()` method.

The other characteristics you might like to set on labels, like changing their font or color, are accomplished using the methods of the Component class Chapter 10, *Understand the Abstract Windowing Toolkit* For example, you can call `setFont()` and `setColor()` on a label, as with any other component.

Given that labels are so simple, why do we need them at all? Why not just call `drawString()` whenever we need text? Remember that a `Label` is a `Component`. That's important; it means that labels have the normal complement of methods for setting fonts and colors that we mentioned above, as well as the ability to be managed sensibly by a layout manager. Therefore, they're much more flexible.

Speaking of layouts--if you use the setText() method to change the text of your label, its size will probably change. So you should remember to call validate() on its container, to lay things out again.[1]

[1] At least as of Java 1.1, labels aren't very smart. Simply validating the container isn't enough. I had to explicitly invalidate the label first.

```
label.setText(...);
label.invalidate();
validate();  // on the container holding the label
```

This ought to be considered a bug.

12. Layout Managers

Contents:

A layout manager arranges the child components of a container, as shown in Figure 12.1. It positions and sets the size of components within the container's display area according to a particular layout scheme. The layout manager's job is to fit the components into the available area, while maintaining the proper spatial relationships between the components. AWT comes with a few standard layout managers that will collectively handle most situations; you can make your own layout managers if you have special requirements.

Figure 12.1: LayoutManager at work

[Graphic: Figure 12-1]

Every container has a default layout manager; therefore, when you make a new container, it comes with a `LayoutManager` object of the appropriate type. You can install a new layout manager at any time with the `setLayout()` method. Below, we set the layout manager of a container to a `BorderLayout`:

```
setLayout ( new BorderLayout() );
```

Notice that we call the `BorderLayout` constructor, but we don't even save a reference to the layout manager. This is typical; once you have installed a layout manager, it does its work behind the scenes, interacting with the container. You rarely call the layout manager's methods directly, so you don't usually need a reference (a notable exception for `CardLayout`). However, you do need to know what the layout manager is going to do with your components as you work with them.

As I explained earlier, the `LayoutManager` is consulted whenever a container's `doLayout()` method is called (usually when it is validated), to reorganize the contents. It does its job by calling the `setLocation()` and `setBounds()` methods of the individual child components to arrange them in the container's display area. A container is layed out the first time it is displayed, and thereafter whenever the container's `validate()` method is called. Containers that are a subclass of the `Window` class (which include `Frame`) are automatically validated whenever they are packed or resized. Calling `pack()` sets the window's size so it is as small as possible while holding all its components at their preferred sizes.

Every component determines three important pieces of information used by the layout manager in placing and sizing it: a minimum size, a maximum size, and a preferred size. These are reported by the `getMinimumSize()`, `getMaximumSize()`, and `getPreferredSize()`, methods of `Component`, respectively. For example, a plain `Button` object can normally be sized to any proportions. However, the button's designer can provide a preferred size for a good-looking button. The layout manager might use this size when there are no other constraints, or it might ignore it, depending on its scheme. Now, if we give the button a label, the button may need a minimum size in order to display itself properly. The layout manager might show more respect for the button's minimum size and guarantee that it has at least that much space. Similarly, a particular component might not be able to display itself properly if it is too large (perhaps it has to scale up an image); it can use `getMaximumSize()` to report the largest size it considers acceptable.[1]

> [1] Unfortunately, the current set of layout managers doesn't do anything with the maximum size. This may change in a future release.

The preferred size of a `Container` object has the same meaning as for any other type of component. However, since a `Container` may hold its own components and want to arrange them in its own layout, its preferred size is a function of its layout manager. The layout manager is therefore involved in both sides of the issue. It asks the components in its container for their preferred (or minimum) sizes in order to arrange them. Based on those values it also calculates the preferred size that is reported by its own container to that container's parent.

When a layout manager is called to arrange its components, it is working within a fixed area. It usually begins by looking at its container's dimensions, and the preferred or minimum sizes of the child components. It then doles out screen area and sets the sizes of components according to its scheme. You can override the `getMinimumSize()`, `getMaximumSize()`, and `getPreferredSize()` methods of a component, but you should do this only if you are actually specializing the component, and it has new needs. If you find yourself fighting with a layout manager because it's changing the size of one of your components, you are probably using the wrong kind of layout manager or not composing your user interface properly. Remember that it's possible to use a number of `Panel` objects in a given display, where each one has its own `LayoutManager`. Try breaking down the problem: place related components in their own `Panel` and then arrange the panels in the container. When that becomes too complicated, you can choose to use a constraint based layout manager like `GridBagLayout`, which we'll discuss later in this chapter.

12.1 FlowLayout

`FlowLayout` is a simple layout manager that tries to arrange components with their preferred sizes, from left to right and top to bottom in the display. A `FlowLayout` can have a specified justification of `LEFT`, `CENTER`, or `RIGHT`, and a fixed horizontal and vertical padding. By default, a flow layout uses `CENTER` justification, meaning that all components are centered within the area allotted to them. `FlowLayout` is the default for `Panel` components like `Applet`.

The following applet adds five buttons to the default `FlowLayout`; the result is shown in Figure 12.2.

Figure 12.2: A flow layout

[Graphic: Figure 12-2]

```
import java.awt.*;

public class Flow extends java.applet.Applet {
    public void init() {
        // Default for Applet is FlowLayout
        add( new Button("One") );
        add( new Button("Two") );
        add( new Button("Three") );
        add( new Button("Four") );
        add( new Button("Five") );
    }
}
```

If the applet is small enough, some of the buttons spill over to a second or third row.

13. Drawing With the AWT

Contents:

If you've read the last few chapters and seen the examples in the tutorial in Chapter 2, *A First Applet*, then you've probably picked up the basics of how graphical operations are performed in Java. Up to this point, we have done some simple drawing and even displayed an image or two. In this chapter, we will finally give graphics programming its due and go into depth about drawing techniques and the tools for working with images in Java. In the next chapter, we'll explore image processing tools in more detail and we'll look at the classes that let you generate images pixel by pixel on the fly.

13.1 Basic Drawing

The classes you'll use for drawing come from the `java.awt` package, as shown in Figure 13.1.[1].

> [1] The current set of drawing tools has many limitations. In the near future, JavaSoft will be releasing packages for advanced 2D graphics, which will have much greater capabilities. A 3D package is also planned. See Chapter 1, *Yet Another Language?* for information about likely future Java enhancements.

Figure 13.1: Graphics classes of the java.awt package

[Graphic: Figure 13-1]

An instance of the `java.awt.Graphics` class is called a *graphics context*. It represents a drawable surface such as a component's display area or an off-screen image buffer. A graphics context provides methods for performing all basic drawing operations on its area, including the painting of image data. We call the `Graphics` object a graphics context because it also holds contextual information about the drawing area. This information includes parameters like the drawing area's clipping region, painting color, transfer mode, and text font. If you consider the drawing area to be a painter's canvas, you might think of a graphics context as an easel that holds a set of tools and marks off the work area.

There are four ways you normally acquire a `Graphics` object. Roughly, from most common to least, they are:

- From AWT, as the result of a painting request. In this case, AWT acquires a new graphics context for the appropriate area and passes it to your component's `paint()` or `update()` method.

- Directly from an off-screen image buffer. In this case, we ask the image buffer for a graphics context directly. We'll use this when we discuss techniques like double buffering.

- By copying an existing `Graphics` object. Duplicating a graphics object can be useful for more elaborate drawing operations; different copies of a `Graphics` object draw into the same area on the screen, but can have different attributes and clipping regions.

- Directly from an on-screen component. It's possible to ask a component to give you a `Graphics` object for its display area. However, this is almost always a mistake; if you feel tempted to do this, think about why you're trying to circumvent the normal `paint()`/`repaint()` mechanism.

Each time a component's `update()` or `paint()` method is called, AWT provides the component with a new `Graphics` object for drawing in the display area. This means that attributes we set during one painting session, such as drawing color or clipping region, are reset the next time `paint()` or `update()` is called. (Each call to `paint()` starts with a tidy new easel.) For the most common attributes, like foreground color, background color, and font, we can set defaults in the component itself. Thereafter, the graphics contexts for painting in that component come with those properties initialized appropriately.

If we are working in a component's `update()` method, we can assume our on-screen artwork is still intact, and we need only to make whatever changes are needed to bring the display up to date. One way to optimize drawing operations in this case is by setting a clipping region, as we'll see shortly. If our `paint()` method is called, however, we have to assume the worst and redraw the entire display.

Drawing Methods

Methods of the `Graphics` class operate in a standard coordinate system. The origin of a newly created graphics context is the top left pixel of the component's drawing area, as shown in Figure 13.2.

Figure 13.2: Graphics coordinate system

[Graphic: Figure 13-2]

The diagram above illustrates the default coordinate system. The point (0,0) is at the top left corner of the drawing area; the point (width, height) is just outside the drawing area at the bottom right corner. The point at the bottom right corner within the drawing area has coordinates (width-1, height-1). This gives you a drawing area that is `width` pixels wide and `height` pixels high.

The coordinate system can be translated (shifted) with the `translate()` method to specify a new point as the origin. The drawable area of the graphics context can be limited to a region with the `setClip()` method.

The basic drawing and painting methods should seem familiar to you if you've done any graphics programming. The following applet, `TestPattern`, exercises most of the simple shape drawing commands; it's shown in Figure 13.3.

Figure 13.3: The TestPattern applet

[Graphic: Figure 13-3]

```
import java.awt.*;
import java.awt.event.*;
public class TestPattern extends java.applet.Applet {
    int theta = 45;
    public void paint( Graphics g ) {
        int Width = size().width;
        int Height = size().height;
        int width = Width/2;
        int height = Height/2;
        int x = (Width - width)/2;
        int y = (Height- height)/2;
        int [] polyx =  { 0, Width/2, Width, Width/2 };
        int [] polyy =  { Height/2, 0, Height/2, Height };
        Polygon poly = new Polygon( polyx, polyy, 4 );

        g.setColor( Color.black );
        g.fillRect( 0, 0, size().width, size().height );
        g.setColor( Color.yellow );
        g.fillPolygon( poly );
        g.setColor( Color.red );
        g.fillRect( x, y, width, height );
        g.setColor( Color.green );
        g.fillOval( x, y, width, height );
        g.setColor( Color.blue );
        int delta = 90;
        g.fillArc( x, y, width, height, theta, delta );
        g.setColor( Color.white );
        g.drawLine( x, y, x+width, x+height );
    }
    public void init() {
        addMouseListener( new MouseAdapter() {
            public void mousePressed( MouseEvent e ) {
                theta = (theta + 10) % 360;
                repaint();
            }
        } );
    }
}
```

`TestPattern` draws a number of simple shapes and responds to mouse clicks by rotating the filled arc and repainting. Compile it and give it a try. If you click repeatedly on the applet, you may notice that everything flashes when it repaints. `TestPattern` is not very intelligent about redrawing; we'll examine some better techniques in the upcoming section on drawing techniques.

With the exception of `fillArc()` and `fillPolygon()`, each method takes a simple `x`, `y` coordinate for the top left corner of the shape and a `width` and `height` for its size. We have picked values that draw the shapes centered, at half the width and height of the applet.

The most interesting shape we've have drawn is the `Polygon`, a yellow diamond. A `Polygon` object is specified by two arrays that contain the `x` and `y` coordinates of each vertex. In our example, the coordinates of the points in the polygon are (`polyx[0]`, `polyy[0]`), (`polyx[1]`, `polyy[1]`), and so on. There are simple drawing methods in the `Graphics` class that take two arrays and draw or fill the polygon, but we chose to create a `Polygon` object and draw it instead. The reason is that the `Polygon` object has some useful utility methods that we might want to use later. A `Polygon` can, for instance, give you its bounding box and tell you if a given point lies within its area.

AWT also provides a `Shape` interface, which is implemented by different kinds of two dimensional objects. Currently, it is only implemented by the `Rectangle` and `Polygon` classes, but it may be a sign of things to come, particularly when JavaSoft releases the extended 2D drawing package. The `setClip()` method of the `Graphics` class takes a `Shape` as an argument, but for the time being, it only works if that `Shape` is a `Rectangle`.

The `fillArc()` method requires six integer arguments. The first four specify the bounding box for an oval--just like the `fillOval()` method. The final two arguments specify what portion of the oval we want to draw, as a starting angle and an offset. Both the starting angle and the offset are specified in degrees. Zero degrees is at three o'clock; a positive angle is clockwise. For example, to draw the right half of a circle, you might call:

```
g.fillArc(0, 0, radius * 2, radius * 2, -90, 180);
```

See the Dial example in Chapter 11, *Using and Creating GUI Components* (widgets?) for an example of some trigonometric gymnastics with arcs().

Table 13.1 shows the shape-drawing methods of the `Graphics` class. As you can see, for each of the `fill()` methods in the example, there is a corresponding `draw()` method that renders the shape as an unfilled line drawing.

Table 13.1: Shape Drawing Methods in the Graphics Class

Method	**Description**
`draw3DRect()`	Draws a highlighted, 3D rectangle
`drawArc()`	Draws an arc
`drawLine()`	Draws a line
`drawOval()`	Draws an oval
`drawPolygon()`	Draws a polygon, connecting endpoints
`drawPolyline()`	Draws a line connecting a polygon's points
`drawRect()`	Draws a rectangle
`drawRoundRect()`	Draws a rounded-corner rectangle
`fill3DRect()`	Draws a filled, highlighted, 3D rectangle
`fillArc()`	Draws a filled arc
`fillOval()`	Draws a filled oval
`fillPolygon()`	Draws a filled polygon
`fillRect()`	Draws a filled rectangle

`fillRoundRect()`	Draws a filled, rounded-corner rectangle

`draw3Drect()` automatically chooses colors by "darkening" the current color. So you should set the color to something other than black, which is the default (maybe gray or white); if you don't, you'll just get black on both sides. For an example, see the `PictureButton` in Chapter 11, *Using and Creating GUI Components*.

There are a few important drawing methods missing from Table 13.1. For example, the `drawString()` method, which draws text, and the `drawImage()` method, which draws an image. We'll discuss these methods in detail in later sections.

14. Working With Images

Contents:

14.1 Image Processing

Up to this point, we've confined ourselves to working with the high-level drawing commands of the `Graphics` class and using images in a hands-off mode. In this section, we'll clear up some of the mystery surrounding images and see how they are produced and used. The classes in the `java.awt.image` package handle image processing; Figure 14.1 shows the classes in this package.

Figure 14.1: The java.awt.image package

[Graphic: Figure 14-1]

First, we'll return to our discussion about image observers and see how we can get more control over image data as it's processed asynchronously by AWT components. Then we'll open the hood and have a look at image production. If you're interested in creating sophisticated graphics, such as rendered images or video streams, this will teach you about the foundations of image construction in Java.[1]

Objects that work with image data fall into one of three categories: image-data producers, image-data consumers, and image-status observers. Image producers implement the `ImageProducer` interface. They create pixel data and distribute it to one or more consumers. Image consumers implement a corresponding `ImageConsumer` interface. They eat the pixel data and do something useful with it, such as display it on screen or analyze its contents. Image observers, as I mentioned earlier, implement the `ImageObserver` interface. They are effectively nosy neighbors of image consumers that watch as the image data arrives.

Image producers generate the information that defines each pixel of an image. A pixel has both a color and a transparency; the transparency specifies how pixels underneath the image show through. Image producers maintain a list of registered consumers for the image and send them this pixel data in one or more passes, as the pixels are generated. Image producers give the consumers other kinds of information as well, such as the image's dimensions. The producer also notifies the consumer when it has reached a boundary of the image. For a static image, such as GIF or JPEG data, the producer signals when the entire image is complete, and production is finished. For a video source or animation, the image producer could generate a continuous stream of pixel data and mark the end of each frame.

An image producer delivers pixel data and other image-attribute information by invoking methods in its consumers, as shown in Figure 14.2. This diagram illustrates an image producer sending pixel data to three consumers by invoking their `setPixels()` methods.

Figure 14.2: Image observers, producers, and consumers

[Graphic: Figure 14-2]

Each consumer represents a view of the image. A given consumer might prepare the image for display on a particular medium, or it might simply serve as a filter and pass the image data to another consumer down the line.

Figure 14.2 also shows an image observer, watching the status of one of the consumers. The observer is notified as new portions of the image and new attributes are ready. Its job is to track this information and let another part of the application know its status. As I discussed earlier, the image observer is essentially a callback that is notified asynchronously as the image is built. The default `Component` class image observer that we used in our previous examples called `repaint()` for us each time a new section of the image was available, so that the screen was updated more or less continuously as the data arrived. A different kind of image observer might wait for the entire image before telling the application to display it; yet another observer might update a loading meter showing how far the image loading had progressed.

[1] You will also want to pay attention to the forthcoming Java Media API. Java Media will support plug-n-play streaming media.

Implementing an ImageObserver

To be an image observer, you have to implement the single method, `imageUpdate()`, defined by the `java.awt.image.ImageObserver` interface:

```
public boolean imageUpdate(Image image, int flags, int x, int y,
                           int width, int height)
```

`imageUpdate()` is called by the consumer, as needed, to pass the observer information about the construction of its view of the image. Essentially, any time the image changes, the consumer tells the observer so that the observer can perform any necessary actions, like repainting. `image` holds a reference to the `Image` object the consumer is processing. `flags` is an integer whose bits specify what information about the image is now available. The values of the flags are defined as `static` identifiers in the `ImageObserver` interface, as shown in Table 14.1.

Table 14.1: ImageObserver Information Flags

Flag	Description
`HEIGHT`	The height of the image is ready
`WIDTH`	The width of the image is ready
`FRAMEBITS`	A frame is complete
`SOMEBITS`	An arbitrary number of pixels have arrived
`ALLBITS`	The image is complete
`ABORT`	The image loading has been aborted
`ERROR`	An error occurred during image processing; attempts to display the image will fail

The flags determine which of the other parameters, `x`, `y`, `width`, and `height`, hold valid data and what they mean. To test whether a particular flag in the `flags` integer is set, we have to resort to some binary shenanigans. The following class, `MyObserver`, implements the `ImageObserver` interface and prints its information as it's called:

```
import java.awt.*;
import java.awt.image.*;

class MyObserver implements ImageObserver {

    public boolean imageUpdate( Image image, int flags, int x, int y,
                                int width, int height) {

        if ( (flags & HEIGHT) !=0 )
            System.out.println("Image height = " + height );

        if ( (flags & WIDTH ) !=0 )
            System.out.println("Image width = " + width );

        if ( (flags & FRAMEBITS) != 0 )
            System.out.println("Another frame finished.");

        if ( (flags & SOMEBITS) != 0 )
            System.out.println("Image section :"
                         + new Rectangle( x, y, width, height ) );
        if ( (flags & ALLBITS) != 0 ) {
            System.out.println("Image finished!");
            return false;
        }

        if ( (flags & ABORT) != 0 )  {
            System.out.println("Image load aborted...");
            return false;
        }

        return true;
    }
}
```

The `imageUpdate()` method of `MyObserver` is called by the consumer periodically, and prints simple status messages about the construction of the image. Notice that `width` and `height` play a dual role. If `SOMEBITS` is set, they represent the size of the chunk of the image that has just been delivered. If `HEIGHT` or `WIDTH` is set, however, they represent the overall image dimensions. Just for amusement, we have used the `java.awt.Rectangle` class to help us print the bounds of rectangular region.

`imageUpdate()` returns a `boolean` value indicating whether or not it's interested in future updates. If the image is finished or aborted, `imageUpdate()` returns `false` to indicate it isn't interested in further updates. Otherwise, it returns `true`.

The following example uses `MyObserver` to print information about an image as AWT loads it:

```
import java.awt.*;

public class ObserveImage extends java.applet.Applet {
    Image img;
    public void init() {
        img = getImage( getClass().getResource(getParameter("img")) );
        MyObserver mo = new MyObserver();
        img.getWidth( mo );
        img.getHeight( mo );
        prepareImage( img, mo );
    }
}
```

After requesting the `Image` object with `getImage()`, we perform three operations on it to kick-start the loading process. `getWidth()` and `getHeight()` ask for the image's width and height. If the image hasn't been loaded yet, or its size can't be determined until loading is finished, our observer will be called when the data is ready. `prepareImage()` asks that the image be readied for display on the component. It's a general mechanism for getting AWT started loading, converting, and possibly scaling the image. If the image hasn't been otherwise prepared or displayed, this happens asynchronously, and our image observer will be notified as the data is constructed.

You may be wondering where the image consumer is, since we never see a call to `imageUpdate()`. That's a good question, but for now I'd like you to take it on faith that the consumer exists. As you'll see later, image consumers are rather mysterious objects that tend to hide beneath the surface of image-processing applications. In this case, the consumer is hiding deep inside the implementation of `Applet`.

You should be able to see how we could implement all sorts of sophisticated image loading and tracking schemes. The two most obvious strategies, however, are to draw an image progressively, as it's constructed, or to wait until it's complete and draw it in its entirety. We have already seen that the `Component` class implements the first scheme. Another class, `java.awt.MediaTracker`, is a general utility that tracks the loading of a number of images or other media types for us. We'll look at it next.

Using a MediaTracker

`java.awt.MediaTracker` is a utility class that simplifies life if we have to wait for one or more images to be loaded before they're displayed. A `MediaTracker` monitors the preparation of an image or a group of images and lets us check on them periodically, or wait until they are completed. `MediaTracker` uses the `ImageObserver` interface internally to receive image updates.

The following applet, `LoadMe`, uses a `MediaTracker` to wait while an image is prepared. It shows a "Loading..." message while it's waiting. (If you are retrieving the image from a local disk or very fast network, this might go by quickly, so pay attention.)

```
import java.awt.*;
public class TrackImage extends java.applet.Applet implements Runnable {
    Image img;
    final int MAIN_IMAGE = 0;
    MediaTracker tracker;
    boolean show = false;
    Thread runme;
    String message = "Loading...";
    public void init() {
        img = getImage( getClass().getResource(getParameter("img")) );
        tracker = new MediaTracker(this);
        tracker.addImage( img, MAIN_IMAGE );
    }
    public void start() {
        if ( !tracker.checkID( MAIN_IMAGE ) ) {
            runme = new Thread( this );
            runme.start();
        }
    }
    public void stop() {
        runme.stop();
        runme = null;
    }
    public void run() {
        repaint();
        try {
            tracker.waitForID( MAIN_IMAGE );
        } catch( InterruptedException e) { }
        if ( tracker.isErrorID( MAIN_IMAGE ) )
            message= "Error";
        else
            show = true;
        repaint();
    }
    public void paint( Graphics g ) {
        if ( show )
            g.drawImage( img, 0, 0, this );
        else {
            g.drawRect( 0, 0, getSize().width-1, getSize().height-1);
            g.drawString( message, 20, 20 );
        }
    }
}
```

From its `init()` method, `LoadMe` requests its image and creates a `MediaTracker` to manage it. Later, after the applet is started, `LoadMe` fires up a thread to wait while the image is loaded. Note that we don't do this in `init()` because it would be rude to do anything time-consuming there; it would take up time in an AWT thread that we don't own. In this case, waiting in `init()` would be especially bad because `paint()` would never get called and our "loading" message wouldn't be displayed; the applet would just hang until the image loaded. It's often better to create a new thread for initialization and display a startup message in the interim.

When we construct a `MediaTracker`, we give it a reference to our component (`this`). After creating a `MediaTracker`, we assign it images to manage. Each image is associated with an integer identifier we'll use later for checking on its status. Multiple images can be associated with the same identifier, letting us manage them as a group. The value of the identifier is also used to prioritize loading when waiting on multiple sets of images; lower IDs have higher priority. In this case, we want to manage only a single image, so we created one identifier called `MAIN_IMAGE` and passed it as the ID for our image in the call to `addImage()`.

In our applet's `start()` method, we call the `MediaTracker`'s `checkID()` routine with the ID of the image to see if it's already been loaded. If it hasn't, the applet fires up a new thread to fetch it. The thread executes the `run()` method, which simply calls the `MediaTracker` `waitforID()` routine and blocks on the image, waiting for it to finish loading. The `show` flag tells `paint()` whether to display our status message or the actual image. We do a `repaint()` immediately upon entering `run()` to display the "Loading..." status, and again upon exiting to change the display. We test for errors during image preparation with `isErrorID()` and change the status message if we find one.

This may seem like a lot of work to go through, just to put up a status message while loading a single image. `MediaTracker` is more valuable when we are working with many images that have to be available before we can begin parts of our application. It saves us from implementing a custom `ImageObserver` for every application. In the future, `MediaTracker` should also be able to track the status of audio clips and other kinds of media (as its name suggests).

Producing Image Data

What if we want to make our own image data? To be an image producer, we have to implement the five methods defined in the `ImageProducer` interface:

- `addConsumer()`
- `startProduction()`
- `isConsumer()`
- `removeConsumer()`
- `requestTopDownLeftRightResend()`

Four methods of `ImageProducer` simply deal with the process of registering consumers. `addConsumer()` takes an `ImageConsumer` as an argument and adds it to the list of consumers. Our producer can then start sending image data to the consumer whenever it's ready. `startProduction()` is identical to `addConsumer()`, except that it asks the producer to start sending data as soon as possible. The difference might be that a given producer would send the current frame of data or initiate construction of a frame immediately, rather than waiting until its next cycle. `isConsumer()` tests whether a particular consumer is already registered, and `removeConsumer()` removes a consumer from the list. We'll see shortly that we can perform these kinds of operations easily with a `Vector`; see Chapter 7, *Basic Utility Classes* for a complete discussion of `Vector` objects.

An `ImageProducer` also needs to know how to use the `ImageConsumer` interface of its clients. The final method of the `ImageProducer` interface, `requestTopDownLeftRightResend()`, asks that the image data be resent to the consumer, in order, from beginning to end. In general, a producer can generate pixel data and send it to the consumer in any order that it likes. The `setPixels()` method of the `ImageConsumer` interface takes parameters telling the consumer what part of the image is being delivered on each call. A call to `requestTopDownLeftRightResend()` asks the producer to send the pixel data again, in order. A consumer might do this so that it can use a higher quality conversion algorithm that relies on receiving the pixel data in sequence. It's important to note that the producer is allowed to ignore this request; it doesn't have to be able to send the data in sequence.

Color models

Everybody wants to work with color in their application, but using color raises problems. The most important problem is simply how to represent a color. There are many different ways to encode color information: red, green, blue (RGB) values; hue, saturation, value (HSV); hue, lightness, saturation (HLS); and more. In addition, you can provide full color information for each pixel, or you can just specify an index into a color table (palette) for each pixel. The way you represent a color is called a *color model*. AWT provides tools for two broad groups of color models: *direct* and *indexed*.

As you might expect, you need to specify a color model in order to generate pixel data; the `abstract` class `java.awt.image.ColorModel` represents a color model. A `ColorModel` is one of the arguments to the `setPixels()` method an image producer calls to deliver pixels to a consumer. What you probably wouldn't expect is that you can use a different color model every time you call `setPixels()`. Exactly why you'd do this is another matter. Most of the time, you'll want to work with a single color model; that model will probably be the default direct color model. But the additional flexibility is there if you need it.

By default, the core AWT components use a direct color model called ARGB. The A stands for "alpha,", which is the historical name for transparency. RGB refers to the red, green, and blue color components that are combined to produce a single, composite color. In the default ARGB model, each pixel is represented by a 32-bit integer that is interpreted as four 8-bit fields; in order, the fields represent the transparency (A), red, green, and blue components of the color, as shown in Figure 14.3.

Figure 14.3: ARGB color encoding

[Graphic: Figure 14-3]

To create an instance of the default ARGB model, call the `static getRGBdefault()` method in `ColorModel`. This method returns a `DirectColorModel` object; `DirectColorModel` is a subclass of `ColorModel`. You can also create other direct color models by calling a `DirectColorModel` constructor, but you shouldn't need to unless you have a fairly exotic application.

In an indexed color model, each pixel is represented by a smaller amount of information: an index into a table of real color values. For some applications, generating data with an indexed model may be more convenient. If you have an 8-bit display or smaller, using an indexed model may be more efficient, since your hardware is internally using an indexed color model of some form.

While AWT provides `IndexedColorModel` objects, we won't cover them in this book. It's sufficient to work with the `DirectColorModel`. Even if you have an 8-bit display, the Java implementation on your platform should accommodate the hardware you have and, if necessary, dither colors to fit your display. Java also produces transparency on systems that don't natively support it by dithering colors.

Creating an image

Let's take a look at producing some image data. A picture may be worth a thousand words, but fortunately, we can generate a picture in significantly fewer than a thousand words of Java. If we're interested in producing a static image with just one frame, we can use a utility class that acts as an `ImageProducer` for us.

`java.awt.image.MemoryImageSource` is a simple utility class that implements the `ImageProducer` interface; we give it pixel data in an array and it sends that data to an image consumer. A `MemoryImageSource` can be constructed for a given color model, with various options to specify the type and positioning of its data. We'll use the simplest form, which assumes an ARGB color model.

The following applet, `ColorPan`, creates an image from an array of integers holding ARGB pixel values:

```
import java.awt.*;
import java.awt.image.*;
public class ColorPan extends java.applet.Applet {
    Image img;
    int width, height;
    int [] pixData;
    public void init() {
        width = getSize().width;
        height = getSize().height;
        pixData = new int [width * height];
        int i=0;
        for (int y = 0; y < height; y++) {
            int red = (y * 255) / (height - 1);
            for (int x = 0; x < width; x++) {
                int green = (x * 255) / (width - 1);
                int blue = 128;
                int alpha = 255;
                pixData[i++] = (alpha << 24) | (red << 16) |
                               (green << 8 ) | blue;
            }
        }
    }
    public void paint( Graphics g ) {
        if ( img == null )
            img = createImage( new MemoryImageSource(width, height,
                                          pixData, 0, width));
        g.drawImage( img, 0, 0, this );
    }
}
```

Give it a try. The size of the image is determined by the size of the applet when it starts up. What you should get is a very colorful box that pans from deep blue at the upper left-hand corner to bright yellow at the bottom right with green and red at the other extremes. (You'll have to imagine something more colorful than the black and white image above.)

We create the pixel data for our image in the `init()`method, and then use `MemoryImageSource` to create and display the image in `paint()`. The variable `pixData` is a one-dimensional array of integers that holds 32-bit ARGB pixel values. In `init()` we loop over every pixel in the image and assign it an ARGB value. The alpha (transparency) component is always 255, which means the image is opaque. The blue component is always 128, half its maximum intensity. The red component varies from 0 to 255 along the y axis; likewise, the green component varies from 0 to 255 along the x axis. The line below combines these components into an ARGB value:

```
pixData[i++] = (alpha << 24) | (red << 16) | (green << 8 ) | blue;
```

The bitwise left-shift operator (`<<`) should be familiar to C programmers. It simply shoves the bits over by the specified number of positions. The alpha value takes the top byte of the integer, followed by the red, green, and blue values.

When we construct the `MemoryImageSource` as a producer for this data, we give it five parameters: the width and height of the image to construct (in pixels), the `pixData` array, an offset into that array, and the width of each scan line (in pixels). We'll start with the first element (offset 0) of `pixData`; the width of each scan line and the width of the image are the same. The array `pixData` has `width * height` elements, which means it has one element for each pixel.

We create the actual image once, in `paint()`, using the `createImage()` method that our applet inherits from `Component`. In the double-buffering and off-screen drawing examples, we used `createImage()` to give us an empty off-screen image buffer. Here we use `createImage()` to generate an image from a specified `ImageProducer`. `createImage()` creates the `Image` object and receives pixel data from the producer to construct the image. Note that there's nothing particularly special about `MemoryImageSource`; we could use any object that implements the image-producer interface inside of `createImage()`, including one we wrote ourselves. Once we have the image, we can draw it on the display with the familiar `drawImage()` method.

You can use `MemoryImageSource` to produce complex, pixel-by-pixel graphics or render images from arbitrary sources. It produces static images, though; when it reaches the end of its pixel data, its job is done. To generate a stream of image data or update pixel values, we need a more persistent image producer.

Updating a MemoryImageSource

`MemoryImageSource` can also be used to generate a sequence of images, or to update an image dynamically. In Java 1.1, this is probably the easiest way to build your own low-level animation software. This example simulates the static on a television screen. It generates successive frames of random black and white pixels and displays each frame when it is complete. The figure below shows one frame of random static, followed by the code:

[Graphic: Figure from the text]

```
import java.awt.*;
import java.awt.image.*;
public class StaticGenerator
        extends java.applet.Applet
        implements Runnable {
    int arrayLength, pixels[];
    MemoryImageSource source;
    Image image;
    int width, height;
    public void init() {
        width = getSize().width; height = getSize().height;
        arrayLength = width * height;
        pixels = new int [arrayLength];
        source = new MemoryImageSource(width, height, pixels, 0, width);
        source.setAnimated(true);
        image = createImage(source);
        new Thread(this).start();
    }
    public void run() {
        while (true) {
            try {
                Thread.sleep(1000/24);
            } catch( InterruptedException e ) { /* die */ }
            for (int x = 0; x < width; x++)
                for (int y = 0; y < height; y++)  {
                    boolean rand = Math.random() > 0.5;
                    pixels[y*width+x] =
                        rand ? Color.black.getRGB() : Color.white.getRGB();
                }
            // Push out the new data
            source.newPixels(0, 0, width, height);
        }
    }
    public void paint( Graphics g ) {
        g.drawImage(image, 0, 0, this);
    }
}
```

The `init()` method sets up the `MemoryImageSource` that produces the sequence of images. It first computes the size of the array needed to hold the image data. It then creates a `MemoryImageSource` object that produces images the width and height of the display, using the default color model (the constructor we use assumes that we want the default). We start taking pixels from the beginning of the pixel array, and scan lines in the array have the same width as the image. Once we have created the `MemoryImageSource`, we call its `setAnimated()` method to tell it that we will be generating an image sequence. Then we use the source to create an `Image` that will display our sequence.

We next start a thread that generates the pixel data. For every element in the array, we get a random number, and set the pixel to black if the random number is greater than 0.5. Because `pixels` is an `int` array, we can't assign `Color` objects to it directly; we use `getRGB()` to extract the color components from the black and white `Color` constants. When we have filled the entire array with data, we call the `newPixels()` method, which delivers the new data to the image.

That's about all there is. We provide a very uninteresting `paint()` method, that just calls `drawImage()` to put the current state of the image on the screen. Whenever `paint()` is called, we see the latest collection of static. The image observer, which is the `Applet` itself, schedules a call to `paint()` whenever anything interesting has happened to the image. It's worth noting how simple it is to create this animation. Once we have the `MemoryImageSource`, we use it to create an image that we treat like any other image. The code that generates the image sequence can be arbitrarily complex--certainly in any reasonable example, it would be more complex than our (admittedly cheesy) static. But that complexity never infects the simple task of getting the image on the screen and updating it.

Image Producers and Consumers

In this section we'll create an image producer that generates a stream of image frames rather than just a static image. Unfortunately, it would take too many lines of code to generate anything really interesting, so we'll stick with a simple modification of our `ColorPan` example. After all, figuring out what to display is your job; I'm primarily concerned with giving you the necessary tools. After this, you should have the needed tools to implement more interesting applications.

A word of advice: if you find yourself writing image producers, you're probably making your life excessively difficult. Most situations can be handled by the dynamic `MemoryImageSource` technique that we just demonstrated. Before going to the trouble of writing an image producer, convince yourself that there isn't a simpler solution. Even if you never write an image producer yourself, it's good (like Motherhood and Apple Pie) to understand how Java's image rendering tools work.

Image consumers

First, we have to know a little more about the image consumers we'll be feeding. An image consumer implements the seven methods that are defined in the `ImageConsumer` interface. Two of these methods are overloaded versions of the `setPixels()` method that accept the actual pixel data for a region of the image. They are identical except that one takes the pixel data as an array of integers, and the other uses an array of bytes. (An array of bytes is natural when you're using an indexed color model because each pixel is specified by an index into a color array.) A call to `setPixels()` looks something like the following:

```
setPixels(x, y, width, height, colorModel, pixels, offset, scanLength);
```

`pixels` is the one-dimensional array of bytes or integers that holds the pixel data. Often, you deliver only part of the image with each call to `setPixels()`. The `x`, `y`, `width`, and `height` values define the rectangle of the image for which pixels are being delivered. `x` and `y` specify the upper left-hand corner of the chunk you're delivering, relative to the upper left-hand corner of the image as a whole. `width` specifies the width in pixels of the chunk; `height` specifies the number of scan lines in the chunk. `offset` specifies the point in `pixels` at which the data being delivered in this call to `setPixels()` starts.

Finally, scanLength indicates the width of the entire image, which is not necessarily the same as width. The pixels array must be large enough to accommodate width*length+offset elements; if it's larger, any leftover data is ignored.

We haven't said anything yet about the colorModel argument to setPixels(). In our previous example, we drew our image using the default ARGB color model for pixel values; the version of the MemoryImageSource constructor that we used supplied the default color model for us. In this example, we also stick with the default model, but this time we have to specify it explicitly. The remaining five methods of the ImageConsumer interface accept general attributes and framing information about the image:

- setHints()
- setDimensions()
- setProperties()
- setColorModel()
- imageComplete()

Before delivering any data to a consumer, the producer should call the consumer's setHints() method to pass it information about how pixels will be delivered. Hints are specified in the form of flags defined in the ImageConsumer interface. The flags are described in Table 14.2. The consumer uses these hints to optimize the way it builds the image; it's also free to ignore them.

Table 14.2: ImageConsumer setHints() Flags

Flag	**Description**
RANDOMPIXELORDER	The pixels are delivered in random order
TOPDOWNLEFTRIGHT	The pixels are delivered from top to bottom, left to right
COMPLETESCANLINES	Each call to setPixels() delivers one or more complete scan lines
SINGLEPASS	Each pixel is delivered only once
SINGLEFRAME	The pixels define a single, static image

setDimensions() is called to pass the width and height of the image when they are known.

setProperties() is used to pass a hashtable of image properties, stored by name. This method isn't particularly useful without some prior agreement between the producer and consumer about what properties are meaningful. For example, image formats such as GIF and TIFF can include additional information about the image. These image attributes could be delivered to the consumer in the hashtable.

setColorModel() is called to tell the consumer which color model will be used to process most of the pixel data. However, remember that each call to setPixels() also specifies a ColorModel for its group of pixels. The color model specified in setColorModel() is really only a hint that the consumer can use for optimization. You're not required to use this color model to deliver all (or for that matter, any) of the pixels in the image.

The producer calls the consumer's imageComplete() method when it has completely delivered the image or a frame of an image sequence. If the consumer doesn't wish to receive further frames of the image, it should unregister itself from the producer at this point. The producer passes a status flag formed from the flags shown in Table 14.3.

Table 14.3: ImageConsumer imageComplete() Flags

Flag	Description
STATICIMAGEDONE	A single static image is complete
SINGLEFRAMEDONE	One frame of an image sequence is complete
IMAGEERROR	An error occurred while generating the image

As you can see, the ImageProducer and ImageConsumer interfaces provide a very flexible mechanism for distributing image data. Now let's look at a simple producer.

A sequence of images

The following class, ImageSequence, shows how to implement an ImageProducer that generates a sequence of images. The images are a lot like the ColorPan image we generated a few pages back, except that the blue component of each pixel changes with every frame. This image producer doesn't do anything you couldn't do with a MemoryImageSource. It reads ARGB data from an array, and consults the object that creates the array to give it an opportunity to update the data between each frame.

This is a complex example, so before diving into the code, let's take a broad look at the pieces. The ImageSequence class is an image producer; it generates data and sends it to image consumers to be displayed. To make our design more modular, we define an interface called FrameARGBData that describes how our rendering code provides each frame of ARGB pixel data to our producer. To do the computation and provide the raw bits, we create a class called ColorPanCycle that implements FrameARGBData. This means that ImageSequence doesn't care specifically where the data comes from; if we wanted to draw different images, we could just drop in another class, provided that the new class implements FrameARGBData. Finally, we create an applet called UpdatingImage that includes two image consumers to display the data.

Here's the ImageSequence class:

```
import java.awt.image.*;
import java.util.*;
public class ImageSequence extends Thread implements ImageProducer {
    int width, height, delay;
    ColorModel model = ColorModel.getRGBdefault();
    FrameARGBData frameData;
    private Vector consumers = new Vector();
    public void run() {
        while ( frameData != null ) {
            frameData.nextFrame();
            sendFrame();
            try {
                sleep( delay );
            } catch ( InterruptedException e ) {}
        }
    }
    public ImageSequence(FrameARGBData src, int maxFPS ) {
        frameData = src;
        width = frameData.size().width;
        height = frameData.size().height;
        delay = 1000/maxFPS;
        setPriority( MIN_PRIORITY + 1 );
    }
    public synchronized void addConsumer(ImageConsumer c) {
        if ( isConsumer( c ) )
            return;
        consumers.addElement( c );
        c.setHints(ImageConsumer.TOPDOWNLEFTRIGHT |
                 ImageConsumer.SINGLEPASS );
        c.setDimensions( width, height );
        c.setProperties( new Hashtable() );
        c.setColorModel( model );
    }
    public synchronized boolean isConsumer(ImageConsumer c) {
        return ( consumers.contains( c ) );
    }
    public synchronized void removeConsumer(ImageConsumer c) {
        consumers.removeElement( c );
    }
    public void startProduction(ImageConsumer ic) {
        addConsumer(ic);
    }
    public void requestTopDownLeftRightResend(ImageConsumer ic) { }
    private void sendFrame() {
        for ( Enumeration e = consumers.elements(); e.hasMoreElements();  ) {
            ImageConsumer c = (ImageConsumer)e.nextElement();
            c.setPixels(0, 0, width, height, model, frameData.getPixels(), 0, width);
            c.imageComplete(ImageConsumer.SINGLEFRAMEDONE);
        }
    }
}
```

The bulk of the code in `ImageSequence` creates the skeleton we need for implementing the `ImageProducer` interface. `ImageSequence` is actually a simple subclass of `Thread` whose `run()` method loops, generating and sending a frame of data on each iteration. The `ImageSequence` constructor takes two items: a `FrameARGBData` object that updates the array of pixel data for each frame, and an integer that specifies the maximum number of frames per second to generate. We give the thread a low priority (`MIN_PRIORITY+1`) so that it can't run away with all of our CPU time.

Our `FrameARGBData` object implements the following interface:

```
interface FrameARGBData {
    java.awt.Dimension size();
    int [] getPixels();
    void nextFrame();
}
```

In `ImageSequence`'s `run()` method, we call `nextFrame()` to compute the array of pixels for each frame. After computing the pixels, we call our own `sendFrame()` method to deliver the data to the consumers. `sendFrame()` calls `getPixels()` to retrieve the updated array of pixel data from the `FrameARGBData` object. `sendFrame()` then sends the new data to all of the consumers by invoking each of their `setPixels()` methods and signaling the end of the frame with `imageComplete()`. Note that `sendFrame()` can handle multiple consumers; it iterates through a `Vector` of image consumers. In a more realistic implementation, we would also check for errors and notify the consumers if any occurred.

The business of managing the `Vector` of consumers is handled by `addConsumer()` and the other methods in the

ImageProducer interface. addConsumer() adds an item to consumers. A Vector is a perfect tool for this task, since it's an automatically extendable array, with methods for finding out how many elements it has, whether or not a given element is already a member, and so on.

addConsumer() also gives the consumer hints about how the data will be delivered by calling setHints(). This image provider always works from top to bottom and left to right, and makes only one pass through the data. addConsumer() next gives the consumer an empty hashtable of image properties. Finally, it reports that most of the pixels will use the default ARGB color model (we initialized the variable model to ColorModel.getRGBDefault()). In this example, we always start sending image data on the next frame, so startProduction() simply calls addConsumer().

We've discussed the mechanism for communications between the consumer and producer, but I haven't yet told you where the data comes from. We have a FrameARGBData interface that defines how to retrieve the data, but we don't yet have an object that implements the interface. The following class, ColorPanCycle, implements FrameARGBData; we'll use it to generate our pixels:

```
import java.awt.*;
class ColorPanCycle implements FrameARGBData {
    int frame = 0, width, height;
    private int [] pixels;
    ColorPanCycle ( int w, int h ) {
        width = w;
        height = h;
        pixels = new int [ width * height ];
        nextFrame();
    }
    public synchronized int [] getPixels() {
        return pixels;
    }
    public synchronized void nextFrame() {
        int index = 0;
        for (int y = 0; y < height; y++) {
            for (int x = 0; x < width; x++) {
                int red = (y * 255) / (height - 1);
                int green = (x * 255) / (width - 1);
                int blue = (frame * 10) & 0xff;
                pixels[index++] =
                    (255 << 24) | (red << 16) | (green << 8) | blue;
            }
        }
        frame++;
    }
    public Dimension size() {
        return new Dimension ( width, height );
    }
}
```

ColorPanCycle is like our previous ColorPan example, except that it adjusts each pixel's blue component each time nextFrame() is called. This should produce a color cycling effect; as time goes on, the image becomes more blue.

Now let's put the pieces together by writing an applet that displays a sequence of changing images: UpdatingImage. In fact, we'll do better than displaying one sequence. To prove that ImageSequence really can deal with multiple consumers, UpdatingImage creates two components that display different views of the image. Once the mechanism has been set up, it's surprising how little code you need to add additional displays.

```
import java.awt.*;
import java.awt.image.*;
public class UpdatingImage extends java.applet.Applet {
    ImageSequence seq;
    public void init() {
        seq = new ImageSequence( new ColorPanCycle(100, 100), 10);
        setLayout( null );
        add( new ImageCanvas( seq, 50, 50 ) );
        add( new ImageCanvas( seq, 100, 100 ) );
        seq.start();
    }
    public void stop() {
        if ( seq != null ) {
            seq.stop();
            seq = null;
        }
    }
}
class ImageCanvas extends Canvas {
    Image img;
    ImageProducer source;
    ImageCanvas ( ImageProducer p, int w, int h ) {
        source = p;
        setSize( w, h );
    }
    public void update( Graphics g ) {
        paint(g);
    }
    public void paint( Graphics g ) {
        if ( img == null )
            img = createImage( source );
        g.drawImage( img, 0, 0, getSize().width, getSize().height, this );
    }
}
```

UpdatingImage constructs a new ImageSequence producer with an instance of our ColorPanCycle object as its frame source. It then creates two ImageCanvas components that create and display the two views of our animation. ImageCanvas is a subclass of Canvas; it takes an ImageProducer and a width and height in its constructor and creates and displays an appropriately scaled version of the image in its paint() method. UpdatingImage places the smaller view on top of the larger one for a sort of "picture in picture" effect.

If you've followed the example to this point, you're probably wondering where in the heck is the image consumer. After all, we spent a lot of time writing methods in ImageSequence for the consumer to call. If you look back at the code, you'll see that an ImageSequence object gets passed to the ImageCanvas constructor, and that this object is used as an argument to createImage(). But nobody appears to call addConsumer(). And the image producer calls setPixels() and other consumer methods; but it always digs a consumer out of its Vector of registered consumers, so we never see where these consumers come from.

In UpdatingImage, the image consumer is behind the scenes, hidden deep inside the Canvas--in fact, inside the Canvas' peer. The call to createImage() tells its component (i.e., our canvas) to become an image consumer. Something deep inside the component is calling addConsumer() behind our backs and registering a mysterious consumer, and that consumer is the one the producer uses in calls to setPixels() and other methods. We haven't implemented any ImageConsumer objects in this book because, as you might imagine, most image consumers are implemented in native code, since they need to display things on the screen. There are others though; the java.awt.image.PixelGrabber class is a consumer that returns the pixel data as a byte array. You might use it to save an image. You can make your own consumer do anything you like with pixel data from a producer. But in reality, you rarely need to write an image consumer yourself. Let them stay hidden; take it on faith that they exist.

Now for the next question: How does the screen get updated? Even though we are updating the consumer with new data, the new image will not appear on the display unless the applet repaints it periodically. By now, this part of the machinery should be familiar: what we need is an image observer. Remember that all components are image observers (i.e., the class Component implements ImageObserver). The call to drawImage() specifies our ImageCanvas as its image observer. The default Component class-image-observer functionality then repaints our image whenever new pixel data arrives.

In this example, we haven't bothered to stop and start our applet properly; it continues running and wasting CPU time even when it's invisible. There are two strategies for stopping and restarting our thread. We can destroy the thread and create a new one, which would require recreating our ImageCanvas objects, or we could suspend and resume the active thread. As discussed in Chapter 6, *Threads*, neither option is particularly difficult.

Filtering Image Data

As I said above, you rarely need to write an image consumer. However, there is one kind of image consumer that's worth knowing about. In this final section on images, we'll build a simple image filter. An image filter is simply a class that performs some work on image data before passing the data to another consumer.

The ColorSep applet acquires an image; uses an image filter to separate the image into red, green, and blue components; and displays the three resulting images. With this applet and a few million dollars, you could build your own color separation plant.

```
import java.awt.*;
import java.awt.image.*;
public class ColorSep extends java.applet.Applet {
    Image img, redImg, greenImg, blueImg;
    public void init() {
        img = getImage( getClass().getResource( getParameter("img")) );
        redImg = createImage(new FilteredImageSource(img.getSource(),
                                        new ColorMaskFilter( Color.red )));
        greenImg = createImage(new FilteredImageSource(img.getSource(),
                                        new ColorMaskFilter( Color.green )));
        blueImg = createImage(new FilteredImageSource(img.getSource(),
                                        new ColorMaskFilter( Color.blue )));
    }
    public void paint( Graphics g ) {
        int width = getSize().width, height = getSize().height;
        g.drawImage( redImg, 0, 0, width/3, height, this );
        g.drawImage( greenImg, width/3, 0, width/3, height, this );
        g.drawImage( blueImg, 2*width/3, 0, width/3, height, this );
    }
}
class ColorMaskFilter extends RGBImageFilter {
    Color color;
    ColorMaskFilter( Color mask ) {
        color = mask;
        canFilterIndexColorModel = true;
    }
    public int filterRGB(int x, int y, int pixel ) {
        return
            255 << 24 |
            (((pixel & 0xff0000) >> 16) * color.getRed()/255) << 16 |
            (((pixel & 0xff00) >> 8) * color.getGreen()/255) << 8 |
            (pixel & 0xff) * color.getBlue()/255 ;
    }
}
```

The FilteredImageSource and RGBImageFilter classes form the basis for building and using image filters. A FilteredImageSource is an image producer (like MemoryImageSource) that is constructed from an image and an ImageFilter object. It fetches pixel data from the image and feeds it through the image filter before passing the data along. Because FilteredImageSource is an image producer, we can use it in our calls to createImage().

But where's the consumer? FilteredImageSource obviously consumes image data as well as producing it. The image consumer is still mostly hidden, but is peeking out from under its rock. Our class ColorMaskFilter extends RGBImageFilter, which in turn extends ImageFilter. And ImageFilter is (finally!) an image consumer. Of course, we still don't see the calls to addConsumer(), and we don't see an implementation of setPixels(); they're hidden in the ImageFilter sources and inherited by ColorMaskFilter.

So what does ColorMaskFilter actually do? Not much. ColorMaskFilter is a simple subclass of RGBImageFilter that implements one method, filterRGB(), through which all of the pixel data are fed. Its constructor saves a mask value we use for filtering. The filterRGB() method accepts a pixel value, along with its x and y coordinates, and returns the filtered version of the pixel. In ColorMaskFilter, we simply multiply the color components by the mask color to get the proper effect. A more complex filter, however, might use the coordinates to change its behavior based on the pixel's position.

One final detail: the constructor for ColorMaskFilter sets the flag canFilterIndexColorModel. This flag is inherited from RGBImageFilter. It means our filter doesn't depend on the pixel's position. In turn, this means it can filter the colors in a color table. If we were using an indexed color model, filtering the color table would be much faster than filtering the individual pixels.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

Glossary

abstract

> The `abstract` keyword is used to declare abstract methods and classes. An abstract method has no implementation defined; it is declared with arguments and a return type as usual, but the body enclosed in curly braces is replaced with a semicolon. The implementation of an abstract method is provided by a subclass of the class in which it is defined. If an abstract method appears in a class, the class is also abstract.

API (Application Programming Interface)

> An API consists of the functions and variables programmers are use in their applications. The Java API consists of all `public` and `protected` methods of all `public` classes in the `java.applet`, `java.awt`, `java.awt.image`, `java.awt.peer`, `java.io`, `java.lang`, `java.net`, and `java.util` packages.

applet

> An embedded Java application that runs in the context of an applet viewer, such as a Web browser.

<applet> tag

> HTML tag that specifies an applet run within a Web document.

applet viewer

> An application that implements the additional structure needed to run and display Java applets. An applet viewer can be a Web browser like HotJava or Netscape Navigator, or a separate program like Sun's *appletviewer*.

application

A Java program that runs standalone; i.e., it doesn't require an applet viewer.

AWT (Abstract Windowing Toolkit)

Java's platform-independent windowing, graphics, and user-interface toolkit.

boolean

A primitive Java data type that contains a truth value. The two possible values of a `boolean` variable are `true` and `false`.

byte

A primitive Java data type that's an 8-bit two's-complement signed number (in all implementations).

callback

A behavior that is defined by one object and then later invoked by another object when a particular event occurs.

cast

A technique that explicitly converts one data type to another.

catch

The `catch` statement introduces an exception-handling block of code following a `try` statement. The `catch` keyword is followed by an exception type and argument name in parentheses, and a block of code within curly braces.

char

A primitive Java data type; a variable of type `char` holds a single 16-bit Unicode character.

class

a) An encapsulated collection of data and methods to operate on the data. A class may be instantiated to produce an object that's an instance of the class.

b) The `class` keyword is used to declare a class, thereby defining a new object type. Its syntax is similar to the `struct` keyword in C.

class loader

An object in the Java security model that is responsible for loading Java binary classes from the network into the local interpreter. A class loader keeps its classes in a separate namespace, so that loaded classes cannot interact with system classes and breach system security.

class method

A method declared `static`. Methods of this type are not passed implicit `this` references and may refer only to class variables and invoke other class methods of the current class. A class method may be invoked through the class name, rather than through an instance of the class.

class path

The directory path specifying the location of compiled Java class files on the local system.

class variable

A variable declared `static`. Variables of this type are associated with the class, rather than with a particular instance of the class. There is only one copy of a static variable, regardless of the number of instances of the class that are created.

client

The application that initiates a conversation as part of a networked client/server application. See server.

compilation unit

The source code for a Java class. A compilation unit normally contains a single class definition, and in most current development environments is just a file with a *.java* extension.

compiler

A program that translates source code into executable code.

component

> Any of the GUI primitives implemented in the `java.awt` package as subclasses of `Component`. The classes `Button`, `Choice`, and `TextField` (among many others) are components.

composition

> Using objects as part of another, more complex object. When you compose a new object, you create complex behavior by delegating tasks to the internal objects. Composition is different from inheritance, which defines a new object by changing or refining the behavior of an old object. See inheritance.

constructor

> A method that is invoked automatically when a new instance of a class is created. Constructors are used to initialize the variables of the newly created object. The constructor method has the same name as the class.

container

> One of the `java.awt` classes that "contain" GUI components. Components in a container appear within the boundaries of the container. The classes `Dialog`, `Frame`, `Panel`, and `Window` are containers.

content handler

> A class that recognizes the content type of particular data, parses it, and converts it to an appropriate object.

datagram

> A packet of data sent to a receiving computer without warning, error checking, or other control information.

data hiding

> See encapsulation.

double

A Java primitive data type;a `double` value is a 64-bit (double-precision) floating-point number.

encapsulation

An object-oriented programming technique that makes an object's data `private` or `protected` (i.e., hidden) and allows programmers to access and manipulate that data only through method calls. Done well, encapsulation reduces bugs and promotes reusability and modularity of classes. This technique is also known as data hiding.

event

A user's action, such as a mouse click or key press.

exception

A signal that some unexpected condition has occurred in the program. In Java, exceptions are objects that are subclasses of `Exception` or `Error` (which themselves are subclasses of `Throwable`). Exceptions in Java are "raised" with the `throw` keyword and received with the `catch` keyword. See `throw`, `throws`, and `catch`.

extends

The `extends` keyword is used in a `class` declaration to specify the superclass of the class being defined. The class being defined has access to all the `public` and `protected` variables and methods of the superclass (or, if the class being defined is in the same package, it has access to all non-`private` variables and methods). If a class definition omits the `extends` clause, its superclass is taken to be `java.lang.Object`.

final

The `final` keyword is a modifier that may be applied to classes, methods, and variables. It has a similar, but not identical meaning in each case. When `final` is applied to a class, it means that the class may never be subclassed. `java.lang.System` is an example of a `final` class. When `final` is applied to a variable, the variable is a constant; i.e., it can't be modified.

finalize

`finalize` is not actually a Java keyword, but a reserved method name. The finalizer is called when an object is no longer being used (i.e., when there are no further references to it), but before the object's memory is actually reclaimed by the system. A finalizer should perform cleanup tasks and free system resources not handled by Java's garbage-collection system.

finally

This keyword introduces the `finally` block of a `try`/`catch`/`finally` construct. `catch` and `finally` blocks provide exception handling and routine cleanup for code in a `try` block. The `finally` block is optional, and appears after the `try` block, and after zero or more `catch` blocks. The code in a `finally` block is executed once, regardless of how the code in the `try` block executes. In normal execution, control reaches the end of the `try` block and proceeds to the `finally` block, which generally performs any necessary cleanup.

float

A Java primitive data type; a `float` value is a 32-bit (single-precision) floating-point number represented in IEEE 754 format.

garbage collection

The process of reclaiming the memory of objects no longer in use. An object is no longer in use when there are no references to it from other objects in the system and no references in any local variables on the method call stack.

GC

An abbreviation for garbage collection or garbage collector (or occasionally "graphics context").

graphics context

A drawable surface represented by the `java.awt.Graphics` class. A graphics context contains contextual information about the drawing area and provides methods for performing drawing operations in it.

GUI (graphical user interface)

A GUI is a user interface constructed from graphical push buttons, text fields, pull-down menus, dialog boxes, and other standard interface components. In Java, GUIs are implemented with the classes in the `java.awt` package.

hashcode

An arbitrary-looking identifying number used as a kind of signature for an object. A hashcode stores an object in a hashtable. See hashtable.

hashtable

> An object that is like a dictionary or an associative array. A hashtable stores and retrieves elements using key values called hashcodes. See hashcode.

hostname

> The name given to an individual computer attached to the Internet.

HotJava

> A WWW browser written in Java that is capable of downloading and running Java applets.

ImageConsumer

> An interface for receiving image data from an image source. Image consumers are usually implemented by the `awt.peer` interface, so they are largely invisible to programmers.

ImageObserver

> An interface in the `java.awt.image` package that receives information about the status of an image being constructed by a particular `ImageConsumer`.

ImageProducer

> An interface in the `java.awt.image` package that represents an image source (i.e., a source of pixel data).

implements

> The `implements` keyword is used in class declarations to indicate that the class implements the named interface or interfaces. The `implements` clause is optional in class declarations; if it appears, it must follow the `extends` clause (if any). If an `implements` clause appears in the declaration of a non-`abstract` class, every method from each specified interface must be implemented by the class or by one of its superclasses.

import

> The `import` statement makes Java classes available to the current class under an abbreviated name. (Java classes are always available by their fully qualified name, assuming the appropriate class file can be found relative to the `CLASSPATH` environment variable and that the class file is

readable. `import` doesn't make the class available; it just saves typing and makes your code more legible). Any number of `import` statements may appear in a Java program. They must appear, however, after the optional `package` statement at the top of the file, and before the first class or interface definition in the file.

inheritance

An important feature of object-oriented programming that involves defining a new object by changing or refining the behavior of an existing object. That is, an object implicitly contains all the non-`private` variables of its superclass and can invoke all the non-`private` methods of its superclass. Java supports single inheritance of classes and multiple inheritance of interfaces.

instance

An object. When a class is instantiated to produce an object, we say the object is an instance of the class.

instance method

A non-`static` method of a class. Such a method is passed an implicit `this` reference to the object that invoked it. See also class method and `static`.

instanceof

`instanceof` is a Java operator that returns `true` if the object on its left-hand side is an instance of the class (or implements the interface) specified on its right-hand side. `instanceof` returns `false` if the object is not an instance of the specified class or does not implement the specified interface. It also returns `false` if the specified object is `null`.

instance variable

A non-`static` variable of a class. Copies of such variables occur in every instance of the created class. See also class variable and `static`.

int

A primitive Java data type that's a 32-bit two's-complement signed number (in all implementations).

interface

The `interface` keyword is used to declare an interface. More generally, an interface defines a list of methods that enables a class to implement the interface itself.

interpreter

The module that decodes and executes Java bytecode.

ISO8859-1

An 8-bit character encoding standardized by the ISO. This encoding is also known as Latin-1 and contains characters from the Latin alphabet suitable for English and most languages of western Europe.

ISO10646

A 4-byte character encoding that includes all of the world's national standard character encodings. Also known as UCS. The 2-byte Unicode character set maps to the range 0x00000000 to 0x0000FFFF of ISO 10646.

Java WorkShop

Sun's Web browser-based tool written in Java for the development of Java applications.

JDK (Java Development Kit)

A package of software distributed by Sun Microsystems for Java developers. It includes the Java interpreter, Java classes, and Java development tools: compiler, debugger, disassembler, appletviewer, stub file generator, and documentation generator.

JavaScript

A language for creating dynamic Web pages developed by Netscape. From a programmer's point of view, it's unrelated to Java, although some of its capabilities are similar. Internally, there may be a relationship, but even that is unclear.

layout manager

An object that controls the arrangement of components within the display area of a container. The `java.awt` package contains a number of layout managers that provide different layout styles.

Latin-1

A nickname for ISO8859-1.

local variable

A variable that is declared inside a single method. A local variable can be seen only by code within that method.

long

A primitive Java data type that's a 64-bit two's-complement signed number (in all implementations).

method

The object-oriented programming term for a function or procedure.

method overloading

Providing definitions of more than one method with the same name but with different argument lists or return values. When an overloaded method is called, the compiler determines which one is intended by examining the supplied argument types.

method overriding

Defining a method that exactly matches (i.e., same name, same argument types, and same return type) a method defined in a superclass. When an overridden method is invoked, the interpreter uses "dynamic method lookup" to determine which method definition is applicable to the current object.

modifier

A keyword placed before a class, variable, or method that alters the item's accessibility, behavior, or semantics. See `abstract`, `final`, `native`, `private`, `private protected`, `protected`, `public`, `static`, and `synchronized`.

Model/View/Controller (MVC) framework

A user-interface design that originated in Smalltalk. In MVC, the data for a display item is called the "model." A "view" displays a particular representation of the model, and a "controller" provides user interaction with both. Java incorporates many MVC concepts.

NaN (not-a-number)

This is a special value of the `double` and `float` data types that represents an undefined result of a mathematical operation, such as zero divided by zero.

native

`native` is a modifier that may be applied to method declarations. It indicates that the method is implemented (elsewhere) in C, or in some other platform-dependent fashion. A `native` method should have a semicolon instead of a body. A `native` method cannot be `abstract`, but all other method modifiers may be used with `native` methods.

native method

A method that is implemented in a native language on a host platform, rather than being implemented in Java. Native methods provide access to such resources as the network, the windowing system, and the host filesystem.

new

`new` is a unary operator that creates a new object or array (or raises an `OutOfMemoryException` if there is not enough memory available).

null

`null` is a special value that indicates a variable doesn't refer to any object. The value `null` may be assigned to any class or interface variable. It cannot be cast to any integral type, and should not be considered equal to zero, as in C.

object

An instance of a class. A class models a group of things; an object models a particular member of that group.

package

The `package` statement specifies which package the code in the file is part of. Java code that is part of a particular package has access to all classes (`public` and non-`public`) in the package, and all non-`private` methods and fields in all those classes. When Java code is part of a named package, the compiled class file must be placed at the appropriate position in the `CLASSPATH` directory hierarchy before it can be accessed by the Java interpreter or other utilities. If the `package` statement is omitted from a file, the code in that file is part of an unnamed default package. This is convenient for small test programs, or during development because it means the code can be interpreted from the current directory.

<param> tag

HTML tag used within `<applet>` ... `</applet>` to specify a named parameter and string value to an applet within a Web page.

peer

The actual implementation of a GUI component on a specific platform. Peer components reside within a `Toolkit` object. See `Toolkit`.

primitive type

One of the Java data types: `boolean`, `char`, `byte`, `short`, `int`, `long`, `float`, `double`. Primitive types are manipulated, assigned, and passed to methods "by value" (i.e., the actual bytes of the data are copied). See also reference type.

private

The `private` keyword is a visibility modifier that can be applied to method and field variables of classes. A `private` field is not visible outside its class definition.

private protected

When the `private` and `protected` visibility modifiers are both applied to a variable or method in a class, they indicate the field is visible only within the class itself and within subclasses of the class. Note that subclasses can access only `private protected` fields within themselves or within other objects that are subclasses; they cannot access those fields within instances of the superclass.

protected

The `protected` keyword is a visibility modifier that can be applied to method and field variables of classes. A `protected` field is visible only within its class, within subclasses, or within the package of which its class is a part. Note that subclasses in different packages can access only `protected` fields within themselves or within other objects that are subclasses; they cannot access protected fields within instances of the superclass.

protocol handler

> Software that describes and enables the use of a new protocol. A protocol handler consists of two classes: a `StreamHandler` and a `URLConnection`.

public

> The `public` keyword is a visibility modifier that can be applied to classes and interfaces and to the method and field variables of classes and interfaces. A `public` class or interface is visible everywhere. A non-`public` class or interface is visible only within its package. A `public` method or variable is visible everywhere its class is visible. When none of the `private`, `protected` or `public` modifiers is specified, a field is visible only within the package of which its class is a part.

reference type

> Any object or array. Reference types are manipulated, assigned, and passed to methods "by reference." In other words, the underlying value is not copied; only a reference to it is. See also primitive type.

root

> The base of a hierarchy, such as a root class, whose descendants are subclasses. The `java.lang.Object` class serves as the root of the Java class hierarchy.

SecurityManager

> The Java class that defines the methods the system calls to check whether a certain operation is permitted in the current environment.

server

> The application that accepts a request for a conversation as part of a networked client/server application. See client.

shadow

> To declare a variable with the same name as a variable defined in a superclass. We say the variable "shadows" the superclass's variable. Use the `super` keyword to refer to the shadowed variable, or refer to it by casting the object to the type of the superclass.

short

A primitive Java data type that's a 16-bit two's-complement signed number (in all implementations).

socket

An interface that listens for connections from clients on a data port and connects the client data stream with the receiving application.

static

The `static` keyword is a modifier applied to method and variable declarations within a class. A `static` variable is also known as a class variable as opposed to non-`static` instance variables. While each instance of a class has a full set of its own instance variables, there is only one copy of each `static` class variable, regardless of the number of instances of the class (perhaps zero) that are created. `static` variables may be accessed by class name or through an instance. Non-`static` variables can be accessed only through an instance.

stream

A flow of data, or a channel of communication. All fundamental I/O in Java is based on streams.

String

A class used to represent textual information. The `String` class includes many methods for operating on string objects. Java overloads the + operator for string concatenation.

subclass

A class that extends another. The subclass inherits the `public` and `protected` methods and variables of its superclass. See `extends`.

super

The keyword `super` refers to the same value as `this`: the instance of the class for which the current method (these keywords are valid only within non-`static` methods) was invoked. While the type of `this` is the type of the class in which the method appears, the type of `super` is the type of the superclass of the class in which the method appears. `super` is usually used to refer to superclass variables shadowed by variables in the current class. Using `super` in this way is equivalent to casting `this` to the type of the superclass.

superclass

A class extended by some other class. The superclass's `public` and `protected` methods and variables are available to the subclass. See `extends`.

synchronized

The `synchronized` keyword is used in two related ways in Java: as a modifier and as a statement. First, it is a modifier applied to class or instance methods. It indicates that the method modifies the internal state of the class or the internal state of an instance of the class in a way that is not thread-safe. Before running a `synchronized` class method, Java obtains a lock on the class, to ensure that no other threads can modify the class concurrently. Before running a `synchronized` instance method, Java obtains a lock on the instance that invoked the method, ensuring that no other threads can modify the object at the same time.

Java also supports a `synchronized` statement that serves to specify a "critical section" of code. The `synchronized` keyword is followed by an expression in parentheses, and a statement or block of statements. The expression must evaluate to an object or array. Java obtains a lock on the specified object or array before executing the statements.

TCP

Transmission Control Protocol. A connection-oriented, reliable protocol. One of the protocols on which the Internet is based.

this

Within an instance method or constructor of a class, `this` refers to "this object"--the instance currently being operated on. It is useful to refer to an instance variable of the class that has been shadowed by a local variable or method argument. It is also useful to pass the current object as an argument to static methods or methods of other classes.

There is one additional use of `this`: when it appears as the first statement in a constructor method, it refers to one of the other constructors of the class.

thread

A single, independent stream of execution within a program. Since Java is a "multithreaded" programming language, more than one thread may be running within the Java interpreter at a time. Threads in Java are represented and controlled through the `Thread` object.

throw

The `throw` statement signals that an exceptional condition has occurred by throwing a specified exception object. This statement stops program execution and resumes it at the nearest containing `catch` statement that can handle the specified exception object. Note that the `throw` keyword must be followed by an exception object, not an exception class.

throws

The `throws` keyword is used in a method declaration to list the exceptions the method can throw. Any exceptions a method can raise that are not subclasses of `Error` or `RuntimeException` must either be caught within the method or declared in the method's `throws` clause.

Toolkit

The property of the Java API that defines the look and feel of the user interface on a specific platform.

try

The `try` keyword indicates a block of code to which subsequent `catch` and `finally` clauses apply. The `try` statement itself performs no special action. See the entries for `catch` and `finally` for more information on the `try`/`catch`/`finally` construct.

UCS (universal character set)

A synonym for ISO10646.

UDP

User Datagram Protocol. A connectionless unreliable protocol. UDP describes a network data connection based on datagrams with little packet control.

Unicode

A 16-bit character encoding that includes all of the world's commonly used alphabets and ideographic character sets in a "unified" form (i.e., a form from which duplications among national standards have been removed). ASCII and Latin-1 characters may be trivially mapped to Unicode characters. Java uses Unicode for its `char` and `String` types.

UTF-8 (UCS transformation format 8-bit form)

An encoding for Unicode characters (and more generally, UCS characters) commonly used for transmission and storage. It is a multibyte format in which different characters require different numbers of bytes to be represented.

vector

A dynamic array of elements.

verifier

A theorem prover that steps through the Java byte-code before it is run and makes sure that it is well-behaved. The byte-code verifier is the first line of defense in Java's security model.

1. Introduction

Contents:

The phenomenon that is Java continues to capture new supporters every day. What began as a programming environment for writing fancy animation applets that could be embedded in web browsers is growing up to be a sophisticated platform for delivering all kinds of portable, distributed applications. If you are already an experienced Java programmer, you know just how powerful the portability of Java is. If you are just now discovering Java, you'll be happy to know that the days of porting applications are over. Once you write a Java application, it can run on UNIX workstations, PCs, and Macintosh computers, as well as on many other supported platforms.

This book is a complete programmer's reference to the "fundamental classes" in the Java programming environment. The fundamental classes in the Java Development Kit (JDK) provide a powerful set of tools for creating portable applications; they are an important component of the toolbox used by every Java programmer. This reference covers the classes in the `java.lang`, `java.io`, `java.net`, `java.util`, `java.lang.reflect`, `java.math`, `java.text`, and `java.util.zip` packages. This chapter offers an overview of the fundamental classes in each of these packages.

This reference assumes you are already familiar with the Java language and class libraries. If you aren't, *Exploring Java*, by Pat Niemeyer and Josh Peck, provides a general introduction, and other books in the O'Reilly Java series provide detailed references and tutorials on specific topics. Note that the material herein does not cover the classes that comprise the Abstract Window Toolkit (AWT): the AWT is covered by a companion volume, the *Java AWT Reference*, by John Zukowski. In addition, this book does not cover any of the new "enterprise" APIs in the core 1.1 JDK, such as the classes in the `java.rmi`, `java.sql`, and `java.security` packages. These packages will be covered by forthcoming books on distributed computing and database programming. See the Preface for a complete list of titles in the O'Reilly Java series.

You should be aware that this book covers two versions of Java: 1.0.2 and 1.1. Version 1.1 of the Java Development Kit (JDK) was released in February 1997. This release includes many improvements and additions to the fundamental Java classes; it represents a major step forward in the evolution of Java. Although Java 1.1 has a number of great new features, you may not want to switch to the new version right away, especially if you are writing mostly Java applets. You'll need to keep an eye on the state of Java support in browsers to help you decide when to switch to Java 1.1. Of course, if you are writing Java applications, you can take the plunge today.

This chapter points out new features of Java 1.1 as they come up. However, there is one "feature" that deserves mention that doesn't fit naturally into an overview. As of Java 1.1, classes, methods, and constructors available in Java 1.0.2 can be deprecated in favor of new classes, methods, and constructors in Java 1.1. The Java 1.1 compiler issues a warning whenever you use a deprecated entity.

1.1 The java.lang Package

The `java.lang` package contains classes and interfaces essential to the Java language. For example, the `Object` class is the ultimate superclass of all other classes in Java. `Object` defines some basic methods for thread synchronization that are inherited by all Java classes. In addition, `Object` defines basic methods for equality testing, hashcode generation, and string conversion that can be overridden by subclasses when appropriate.

The `java.lang` package also contains the `Thread` class, which controls the operation of each thread in a multithreaded application. A `Thread` object can be used to start, stop, and suspend a thread. A `Thread` must be associated with an object that implements the `Runnable` interface; the `run()` method of this interface specifies what the thread actually does. See Chapter 3, *Threads*, for a more detailed explanation of how threads work in Java.

The `Throwable` class is the superclass of all error and exception classes in Java, so it defines the basic functionality of all such classes. The `java.lang` package also defines the standard error and exception classes in Java. The error and exception hierarchies are rooted at the `Error` and `Exception` subclasses of `Throwable`. See Chapter 4, *Exception Handling*, for more information about the exception-handling mechanism.

The `Boolean`, `Character`, `Byte`, `Double`, `Float`, `Integer`, `Long`, and `Short` classes encapsulate the Java primitive data types. `Byte` and `Short` are new in Java 1.1, as is the `Void` class.

All of these classes are necessary to support the new Reflection API and class literals in Java 1.1 The `Class` class also has a number of new methods in Java 1.1 to support reflection.

All strings in Java are represented by `String` objects. These objects are immutable. The `StringBuffer` class in `java.lang` can be used to work with mutable text strings. Chapter 2, *Strings and Related Classes*, offers a more detailed description of working with strings in Java.

See Chapter 12, *The java.lang Package*, for complete reference material on all of the classes in the `java.lang` package.

2. Strings and Related Classes

Contents:

As with most programming languages, strings are used extensively throughout Java, so the Java API has quite a bit of functionality to help you manipulate strings. This chapter describes the following classes:

- The `java.lang.String` class represents all textual strings in Java. A `String` object is immutable; once you create a `String` object, there is no way to change the sequence of characters it represents or the length of the string.
- The `java.lang.StringBuffer` class represents a variable-length, mutable sequence of characters. With a `StringBuffer` object, you can insert characters anywhere in the sequence and add characters to the end of the sequence.
- The `java.util.StringTokenizer` class provides support for parsing a string into a sequence of words, or tokens.

2.1 String

You can create a `String` object in Java simply by assigning a string literal to a `String` variable:

```
String quote = "To be or not to be";
```

All string literals are compiled into `String` objects. Although the Java compiler does not generally treat expressions involving object references as compile-time constants, references to `String` objects created from string literals are treated as compile-time constants.

Of course, there are many other ways to create a `String` object. The `String` class has a number of constructors that let you create a `String` from an array of bytes, an array of characters, another `String` object, or a `StringBuffer` object.

If you are a C or C++ programmer, you may be wondering if `String` objects are null-terminated. The answer is no, and, in fact, the question is irrelevant. The `String` class actually uses a character array internally. Since arrays in Java are actual objects that know their own length, a `String` object also knows its length and does not require a special terminator. Use the `length()` method to get the length of a `String` object.

Although `String` objects are immutable, the `String` class does provide a number of useful methods for working with strings. Any operation that would otherwise change the characters or the length of the string returns a new `String` object that copies the necessary portions of the original `String`.

The following methods access the contents of a `String` object:

- `substring()` creates a new `String` object that contains a sub-sequence of the sequence of characters represented by a `String` object.

- `charAt()` returns the character at a given position in a `String` object.

- `getChars()` and `getBytes()` return a range of characters in a `char` array or a `byte` array.

- `toCharArray()` returns the entire contents of a `String` object as a `char` array.

You can compare the contents of `String` objects with the following methods:

- `equals()` returns `true` if two `String` objects have the exact same contents, while `equalsIgnoreCase()` returns `true` if two objects have the same contents ignoring differences between upper- and lowercase versions of the same character.

- `regionMatches()` determines if two sub-strings contain the same sequence of characters.

- `startsWith()` and `endsWith()` determine if a `String` object begins or ends with a particular sequence of characters.

- `compareTo()` determines if the contents of one `String` object are less than, equal to, or greater than the contents of another `String` object.

Use the following methods to search for characters in a string:

- `indexOf()` searches forward through a string for a given character or string.
- `lastIndexOf()` searches backwards through a string for a given character or string.

The following methods manipulate the contents of a string and return a new, related string:

- `concat()` returns a new `String` object that is the concatenation of two `String` objects.
- `replace()` returns a new `String` object that contains the same sequence of characters as the original string, but with a given character replaced by another given character.
- `toLowerCase()` and `toUpperCase()` return new `String` objects that contain the same sequence of characters as the original string, but converted to lower- or uppercase.
- `trim()` returns a new `String` object that contains the same character sequence as the original string, but with leading and trailing white space and control characters removed.

The `String` class also defines a number of `static` methods named `valueOf()` that return string representations of primitive Java data types and objects. The `Object` class defines a `toString()` method, and, since `Object` is the ultimate superclass of every other class, every class inherits a basic `toString()` method. Any class that has a string representation should override the `toString()` method to produce the appropriate string.

3. Threads

Contents:

Threads provide a way for a Java program to do multiple tasks concurrently. A thread is essentially a flow of control in a program and is similar to the more familiar concept of a process. An operating system that can run more than one program at the same time uses processes to keep track of the various programs that it is running. However, processes generally do not share any state, while multiple threads within the same application share much of the same state. In particular, all of the threads in an application run in the same address space, sharing all resources except the stack. In concrete terms, this means that threads share field variables, but not local variables.

When multiple processes share a single processor, there are times when the operating system must stop the processor from running one process and start it running another process. The operating system must execute a sequence of events called a *context switch* to transfer control from one process to another. When a context switch occurs, the operating system has to save a lot of information for the process that is being paused and load the comparable information for the process being resumed. A context switch between two processes can require the execution of thousands of machine instructions. The Java virtual machine is responsible for handling context switches between threads in a Java program. Because threads share much of the same state, a context switch between two threads typically requires the execution of less than 100 machine instructions.

There are a number of situations where it makes sense to use threads in a Java program. Some programs must be able to engage in multiple activities and still be able to respond to additional input from the user. For example, a web browser should be able to respond to user input while fetching an image or playing a sound. Because threads can be suspended and resumed, they can make it easier to control multiple activities, even if the activities do not need to be concurrent. If a program models real world objects that display independent, autonomous behavior, it makes sense to use a separate thread for each object. Threads can also implement asynchronous methods, so that a calling method does not have to wait for the method it calls to complete before continuing with its own activity.

Java applets make considerable use of threads. For example, an animation is generally implemented with a separate thread. If an applet has to download extensive information, such as an image or a sound, to initialize itself, the initialization can take a long time. This initialization can be done in a separate thread to prevent the initialization from interfering with the display of the applet. If an applet needs to process messages from the network, that work generally is done in a separate thread so that the applet can continue painting itself on the screen and responding to mouse and keyboard events. In addition, if each message is processed separately, the applet uses a separate thread for each message.

For all of the reasons there are to use threads, there are also some compelling reasons not to use them. If a program uses inherently sequential logic, where one operation starts another operation and then must wait for the other operation to complete before continuing, one thread can implement the entire sequence. Using multiple threads in such a case results in a more complex program with no accompanying benefits. There is considerable overhead in creating and starting a thread, so if an operation involves only a few primitive statements, it is faster to handle it with a single thread. This can even be true when the operation is conceptually asynchronous. When multiple threads share objects, the objects must use synchronization mechanisms to coordinate thread access and maintain consistent state. Synchronization mechanisms add complexity to a program, can be difficult to tune for optimal performance, and can be a source of bugs.

3.1 Using Thread Objects

The `Thread` class in the `java.lang` package creates and controls threads in Java programs. The execution of Java code is always under the control of a `Thread` object. The `Thread` class provides a `static` method called `currentThread()` that provides a reference to the `Thread` object that controls the current thread of execution.

Associating a Method with a Thread

The first thing you need to do to make a `Thread` object useful is to associate it with a method you want it to run. Java provides two ways of associating a method with a `Thread`:

- Declare a subclass of `Thread` that defines a `run()` method.

- Pass a reference to an object that implements the `Runnable` interface to a `Thread` constructor.

For example, if you need to load the contents of a URL as part of an applet's initialization, but the applet can provide other functionality before the content is loaded, you might want to load the content in a separate thread. Here is a class that does just that:

```
import java.net.URL;
```

```
class UrlData extends Thread   {
    private Object data;
    private URL url
    public UrlData(String urlName) throws MalformedURLException {
        url = new URL(urlName);
        start();
    }
    public void run(){
        try {
            data = url.getContent();
        } catch (java.io.IOException  e) {
        }
    }
    public Object getUrlData(){
        return data;
    }
}
```

The `UrlData` class is declared as a subclass of `Thread` so that it can get the contents of the URL in a separate thread. The constructor creates a `java.net.URL` object to fetch the contents of the URL, and then calls the `start()` method to start the thread. Once the thread is started, the constructor returns; it does not wait for the contents of the URL to be fetched. The `run()` method is executed after the thread is started; it does the real work of fetching the data. The `getUrlData()` method is an access method that returns the value of the `data` variable. The value of this variable is `null` until the contents of the URL have been fetched, at which time it contains a reference to the actual data.

Subclassing the `Thread` class is convenient when the method you want to run in a separate thread does not need to belong to a particular class. Sometimes, however, you need the method to be part of a particular class that is a subclass of a class other than `Thread`. Say, for example, you want a graphical object that is displayed in a window to alternate its background color between red and blue once a second. The object that implements this behavior needs to be a subclass of the `java.awt.Canvas` class. However, at the same time, you need a separate thread to alternate the color of the object once a second.

In this situation, you want to tell a `Thread` object to run code in another object that is not a subclass of the `Thread` class. You can accomplish this by passing a reference to an object that implements the `Runnable` interface to the constructor of the `Thread` class. The `Runnable` interface requires that an object has a `public` method called `run()` that takes no arguments. When a `Runnable` object is passed to the constructor of the `Thread` class, it creates a `Thread` object that calls the `Runnable` object's `run()` method when the thread is started. The following example shows part of the code that implements an object that alternates its background color between red and blue once a second:

```
class AutoColorChange extends java.awt.Canvas implements Runnable {
    private Thread myThread;
    AutoColorChange () {
        myThread = new Thread(this);
        myThread.start();
        ...
    }
    public void run() {
        while (true) {
            setBackground(java.awt.Color.red);
            repaint();
            try {
                myThread.sleep(1000);
            } catch (InterruptedException e) {}
            setBackground(java.awt.Color.blue);
            repaint();
            try {
                myThread.sleep(1000);
            } catch (InterruptedException e) {}
        }
    }
}
```

The `AutoChangeColor` class extends `java.awt.Canvas`, alternating the background color between red and blue once a second. The constructor creates a new `Thread` by passing the current object to the `Thread` constructor, which tells the `Thread` to call the `run()` method in the `AutoChangeColor` class. The constructor then starts the new thread by calling its `start()` method, so that the color change happens asynchronously of whatever else is going on. The class has an instance variable called `myThread` that contains a reference to the `Thread` object, so that can control the thread. The `run()` method takes care of changing the background color, using the `sleep()` method of the `Thread` class to temporarily suspend the thread and calling `repaint()` to redisplay the object after each color change.

Controlling a Thread

As shown in the previous section, you start a `Thread` by calling its `start()` method. Before the `start()` method is called, the `isAlive()` method of the `Thread` object always returns `false`. When the `start()` method is called, the `Thread` object becomes associated with a scheduled thread in the underlying environment. After the `start()` method has returned, the `isAlive()` method always returns `true`. The `Thread` is now scheduled to run until it dies, unless it is suspended or in another unrunnable state.

It is actually possible for `isAlive()` to return `true` before `start()` returns, but not before start() is called. This can happen because the start() method can return either before the started Thread begins to run or after it begins to run. In other words, the method that called start() and the new thread are now running concurrently. On a multiprocessor system, the start() method can even return at the same time the started Thread begins to run.

Thread objects have a parent-child relationship. The first thread created in a Java environment does not have a parent Thread. However, after the first Thread object is created, the Thread object that controls the thread used to create another Thread object is considered to be the parent of the newly created Thread. This parent-child relationship is used to supply some default values when a Thread object is created, but it has no further significance after a Thread has been created.

Stopping a thread

A thread dies when one of the following things happens:

- The run() method called by the Thread returns.
- An exception is thrown that causes the run() method to be exited.
- The stop() method of the Thread is called.

The stop() method of the Thread class works by throwing a ThreadDeath object in the run() method of the thread. Normally, you should not catch ThreadDeath objects in a try statement. If you need to catch ThreadDeath objects to detect that a Thread is about to die, the try statement that catches ThreadDeath objects should rethrow them.

When an object (ThreadDeath or otherwise) is thrown out of the run() method for the Thread, the uncaughtException() method of the ThreadGroup for that Thread is called. If the thrown object is an instance of the ThreadDeath class, the thread dies, and the thrown object is ignored. Otherwise, if the thrown object is of any other class, uncaughtException() calls the thrown object's printStackTrace() method, the thread dies, and the thrown object is ignored. In either case, if there are other nondaemon threads running in the system, the current program continues to run.

Interrupting a thread

There are a number of methods in the Java API, such as wait() and join(), that are declared as throwing an InterruptedException. What these methods have in common is that they temporarily suspend the execution of a thread. In Java 1.1, if a thread is waiting for one of these methods to return and another thread calls interrupt() on the waiting thread, the method that is waiting throws an InterruptedException.

The interrupt() method sets an internal flag in a Thread object. Before the interrupt()

method is called, the `isInterrupted()` method of the `Thread` object always returns `false`. After the `interrupt()` method is called, `isInterrupted()` returns `true`.

Prior to version 1.1, the methods in the Java API that are declared as throwing an `InterruptedException` do not actually do so. However, the `isInterrupted()` method does function as described above. Thus, if the code in the `run()` method for a thread periodically calls `isInterrupted()`, the thread can respond to a call to `interrupt()` by shutting down in an orderly fashion.

Thread priority

One of the attributes that controls the behavior of a thread is its priority. Although Java does not guarantee much about how threads are scheduled, it does guarantee that a thread with a priority that is higher than that of another thread will be scheduled to run at least as often, and possibly more often, than the thread with the lower priority. The priority of a thread is set when the `Thread` object is created, by passing an argument to the constructor that creates the `Thread` object. If an explicit priority is not specified, the `Thread` inherits the priority of its parent `Thread` object.

You can query the priority of a `Thread` object by calling its `getPriority()` method. Similarly, you can set the priority of a `Thread` using its `setPriority()` method. The priority you specify must be greater than or equal to `Thread.MIN_PRIORITY` and less than or equal to `Thread.MAX_PRIORITY`.

Before actually setting the priority of a `Thread` object, the `setPriority()` method checks the maximum allowable priority for the `ThreadGroup` that contains the `Thread` by calling `getMaxPriority()` on the `ThreadGroup`. If the call to `setPriority()` tries to set the priority to a value that is higher than the maximum allowable priority for the `ThreadGroup`, the priority is instead set to the maximum priority. It is possible for the current priority of a `Thread` to be greater than the maximum allowable priority for the `ThreadGroup`. In this case, an attempt to raise the priority of the `Thread` results in its priority being lowered to the maximum priority.

Daemon threads

A daemon thread is a thread that runs continuously to perform a service, without having any connection with the overall state of the program. For example, the thread that runs the garbage collector in Java is a daemon thread. The thread that processes mouse events for a Java program is also a daemon thread. In general, threads that run application code are not daemon threads, and threads that run system code are daemon threads. If a thread dies and there are no other threads except daemon threads alive, the Java virtual machine stops.

A `Thread` object has a `boolean` attribute that specifies whether or not a thread is a daemon thread. The daemon attribute of a thread is set when the `Thread` object is created, by passing an argument to the constructor that creates the `Thread` object. If the daemon attribute is not explicitly specified, the `Thread` inherits the daemon attribute of its parent `Thread` object.

The daemon attribute is queried using the `isDaemon()` method; it is set using the `setDaemon()` method.

Yielding

When a thread has nothing to do, it can call the `yield()` method of its `Thread` object. This method tells the scheduler to run a different thread. The value of calling `yield()` depends largely on whether the scheduling mechanism for the platform on which the program is running is preemptive or nonpreemptive.

By choosing a maximum length of time a thread can continuously, a *preemptive* scheduling mechanism guarantees that no single thread uses more than its fair share of the processor. If a thread runs for that amount of time without yielding control to another thread, the scheduler preempts the thread and causes it to stop running so that another thread can run.

A *nonpreemptive* scheduling mechanism cannot preempt threads. A nonpreemptive scheduler relies on the individual threads to yield control of the processor frequently, so that it can provide reasonable performance. A thread explicitly yields control by calling the `Thread` object's `yield()` method. More often, however, a thread implicitly yields control when it is forced to wait for something to happen elsewhere.

Calling a `Thread` object's `yield()` method during a lengthy computation can be quite valuable on a platform that uses a nonpreemptive scheduling mechanism, as it allows other threads to run. Otherwise, the lengthy computation can prevent other threads from running. On a platform that uses a preemptive scheduling mechanism, calling `yield()` does not usually make any noticeable difference in the responsiveness of threads.

Regardless of the scheduling algorithm that is being used, you should not make any assumptions about when a thread will be scheduled to run again after it has called `yield()`. If you want to prevent a thread from being scheduled to run until a specified amount of time has elapsed, you should call the `sleep()` method of the `Thread` object. The `sleep()` method takes an argument that specifies a minimum number of milliseconds that must elapse before the thread can be scheduled to run again.

Controlling groups of threads

Sometimes is it necessary to control multiple threads at the same time. Java provides the `ThreadGroup` class for this purpose. Every `Thread` object belongs to a `ThreadGroup` object. By passing an argument to the constructor that creates the `Thread` object, the `ThreadGroup` of a thread can be set when the `Thread` object is created. If an explicit `ThreadGroup` is not specified, the `Thread` belongs to the same ThreadGroup as its parent Thread object.

4. Exception Handling

Contents:

Exception handling is a mechanism that allows Java programs to handle various exceptional conditions, such as semantic violations of the language and program-defined errors, in a robust way. When an exceptional condition occurs, an *exception* is thrown. If the Java virtual machine or run-time environment detects a semantic violation, the virtual machine or run-time environment implicitly throws an exception. Alternately, a program can throw an exception explicitly using the `throw` statement. After an exception is thrown, control is transferred from the current point of execution to an appropriate `catch` clause of an enclosing `try` statement. The `catch` clause is called an exception handler because it handles the exception by taking whatever actions are necessary to recover from it.

4.1 Handling Exceptions

The `try` statement provides Java's exception-handling mechanism. A `try` statement contains a block of code to be executed. Putting a block in a `try` statement indicates that any exceptions or other abnormal exits in the block are going to be handled appropriately. A `try` statement can have any number of optional `catch` clauses that act as exception handlers for the `try` block. A `try` statement can also have a `finally` clause. The `finally` block is always executed before control leaves the `try` statement; it cleans up after the `try` block. Note that a `try` statement must have either a `catch` clause or a `finally` clause.

Here is an example of a `try` statement that includes a `catch` clause and a `finally` clause:

```
try {
    out.write(b);
} catch (IOException e) {
    System.out.println("Output Error");
} finally {
    out.close();
}
```

If `out.write()` throws an `IOException`, the exception is caught by the `catch` clause. Regardless of whether `out.write()` returns normally or throws an exception, the `finally` block is executed, which ensures that `out.close()` is always called.

A `try` statement executes the block that follows the keyword `try`. If an exception is thrown from within the `try` block and the `try` statement has any `catch` clauses, those clauses are searched, in order, for one that can handle the exception. If a `catch` clause handles an exception, that `catch` block is executed.

However, if the `try` statement does not have any `catch` clauses that can handle the exception (or does not have any `catch` clauses at all), the exception propagates up through enclosing statements in the current method. If the current method does not contain a `try` statement that can handle the exception, the exception propagates up to the invoking method. If this method does not contain an appropriate `try` statement, the exception propagates up again, and so on. Finally, if no `try` statement is found to handle the exception, the currently running thread terminates.

A `catch` clause is declared with a parameter that specifies the type of exception it can handle. The parameter in a `catch` clause must be of type `Throwable` or one of its subclasses. When an exception occurs, the `catch` clauses are searched for the first one with a parameter that matches the type of the exception thrown or is a superclass of the thrown exception. When the appropriate `catch` block is executed, the actual exception object is passed as an argument to the `catch` block. The code within a `catch` block should do whatever is necessary to handle the exception condition.

The `finally` clause of a `try` statement is always executed, no matter how control leaves the `try` statement. Thus it is a good place to handle clean-up operations, such as closing files, freeing resources, and closing network connections.

6. I/O

Contents:

The `java.io` package contains the fundamental classes for performing input and output operations in Java. These I/O classes can be divided into four basic groups:

- Classes for reading input from a stream.
- Classes for writing output to a stream.
- Classes for manipulating files.
- Classes for serializing objects.

All fundamental I/O in Java is based on *streams*. A stream represents a flow of data, or a channel of communication. Conceptually, there is a reading process at one end of the stream and a writing process at the other end. Java 1.0 supported only byte streams, which meant that Unicode characters were not always handled correctly. As of Java 1.1, there are classes in `java.io` for both byte streams and character streams. The character stream classes, which are called *readers* and *writers*, handle Unicode characters appropriately.

The rest of this chapter describes the classes in `java.io` that read from and write to streams, as well as the classes that manipulate files. The classes for serializing objects are described in Chapter 7, *Object Serialization*.

6.1 Input Streams and Readers

The `InputStream` class is an `abstract` class that defines methods to read sequentially from a stream of bytes. Java provides subclasses of the `InputStream` class for reading from files, `StringBuffer` objects, and byte arrays, among other things. Other subclasses of `InputStream` can be chained together to provide additional logic, such as keeping track of the current line number or combining multiple input sources into one logical input stream. It is also easy to define a subclass of `InputStream` that reads from any other kind of data source.

In Java 1.1, the `Reader` class is an `abstract` class that defines methods to read sequentially from a stream of characters. Many of the byte-oriented `InputStream` subclasses have character-based `Reader` counterparts. Thus, there are subclasses of `Reader` for reading from files, character arrays, and `String` objects.

InputStream

The `InputStream` class is the `abstract` superclass of all other byte input stream classes. It defines three `read()` methods for reading from a raw stream of bytes:

```
read()
read(byte[] b)
read(byte[] b, int off, int len)
```

If there is no data available to read, these methods block until input is available. The class also defines an `available()` method that returns the number of bytes that can be read without blocking and a `skip()` method that skips ahead a specified number of bytes. The `InputStream` class defines a mechanism for marking a position in the stream and returning to it later, via the `mark()` and `reset()` methods. The `markSupported()` method returns `true` in subclasses that support these methods.

Because the `InputStream` class is `abstract`, you cannot create a "pure" `InputStream`. However, the various subclasses of `InputStream` can be used interchangeably. For example, methods often take an `InputStream` as a parameter. Such a method accepts any subclass of `InputStream` as an argument.

`InputStream` is designed so that `read(byte[])` and `read(byte[], int, int)` both call `read()`. Thus, when you subclass `InputStream`, you only need to define the `read()` method. However, for efficiency's sake, you should also override `read(byte[], int, int)` with a method that can read a block of data more efficiently than reading each byte separately.

Reader

The `Reader` class is the `abstract` superclass of all other character input stream classes. It defines nearly the same methods as `InputStream`, except that the `read()` methods deal with characters instead of bytes:

```
read()
read(char[] cbuf)
read(char[] cbuf, int off, int len)
```

The `available()` method of `InputStream` has been replaced by the `ready()` method of `Reader`, which simply returns a flag that indicates whether or not the stream must block to read the next character.

`Reader` is designed so that `read()` and `read(char[])` both call `read(char[], int, int)`. Thus, when you subclass `Reader`, you only need to define the `read(char[], int, int)` method. Note that this design is different from, and more efficient than, that of `InputStream`.

InputStreamReader

The InputStreamReader class serves as a bridge between InputStream objects and Reader objects. Although an InputStreamReader acts like a character stream, it gets its input from an underlying byte stream and uses a character encoding scheme to translate bytes into characters. When you create an InputStreamReader, specify the underlying InputStream and, optionally, the name of an encoding scheme. For example, the following code fragment creates an InputStreamReader that reads characters from a file that is encoded using the ISO 8859-5 encoding:

```
String fileName = "encodedfile.txt"; String encodingName = "8859_5";
InputStreamReader in;
try {
   x FileInputStream fileIn = new FileInputStream(fileName);
    in = new InputStreamReader(fileIn, encodingName);
} catch (UnsupportedEncodingException e1) {
    System.out.println(encodingName + " is not a supported encoding scheme.");
} catch (IOException e2) {
    System.out.println("The file " + fileName + " could not be opened.");
}
```

FileInputStream and FileReader

The FileInputStream class is a subclass of InputStream that allows a stream of bytes to be read from a file. The FileInputStream class has no explicit open method. Instead, the file is implicitly opened, if appropriate, when the FileInputStream is created. There are three ways to create a FileInputStream:

- You can create a FileInputStream by passing the name of a file to be read:

  ```
  FileInputStream f1 = new FileInputStream("foo.txt");
  ```

- You can create a FileInputStream with a File object:

  ```
  File f = new File("foo.txt");
  FileInputStream f2 = new FileInputStream(f);
  ```

- You can create a FileInputStream with a FileDescriptor object. A FileDescriptor object encapsulates the native operating system's representation of an open file. You can get a FileDescriptor from a RandomAccessFile by calling its getFD() method. You create a FileInputStream that reads from the open file associated with a RandomAccessFile as follows:

  ```
  RandomAccessFile raf;
  raf = new RandomAccessFile("z.txt","r");
  FileInputStream f3 = new FileInputStream(raf.getFD());
  ```

  The FileReader class is a subclass of Reader that reads a stream of characters from a file. The bytes in the file are converted to characters using the default character encoding scheme. If you do not want to use the default encoding scheme, you need to wrap an InputStreamReader around a FileInputStream, as shown above. You can create a FileReader from a filename, a File object, or a FileDescriptor object, as described above for `FileInputStream`.

StringReader and StringBufferInputStream

The `StringReader` class is a subclass of `Reader` that gets its input from a `String` object. The `StringReader` class supports mark-and-reset functionality via the `mark()` and `reset()` methods. The following example shows the use of `StringReader`:

```
StringReader sr = new StringReader("abcdefg");
try {
    char[] buffer = new char[3];
    sr.read(buffer);
    System.out.println(buffer);
} catch (IOException e) {
    System.out.println("There was an error while reading.");
}
```

This code fragment produces the following output:

```
abc
```

The `StringBufferInputStream` class is the byte-based relative of `StringReader`. The entire class is deprecated as of Java 1.1 because it does not properly convert the characters of the string to a byte stream; it simply chops off the high eight bits of each character. Although the `markSupported()` method of `StringBufferInputStream` returns `false`, the `reset()` method causes the next read operation to read from the beginning of the `String`.

CharArrayReader and ByteArrayInputStream

The `CharArrayReader` class is a subclass of `Reader` that reads a stream of characters from an array of characters. The `CharArrayReader` class supports mark-and-reset functionality via the `mark()` and `reset()` methods. You can create a `CharArrayReader` by passing a reference to a `char` array to a constructor like this:

```
char[] c;
...
CharArrayReader r;
r = new CharArrayReader(c);
```

You can also create a `CharArrayReader` that only reads from part of an array of characters by passing an offset and a length to the constructor. For example, to create a `CharArrayReader` that reads elements 5 through 24 of a `char` array you would write:

```
r = new CharArrayReader(c, 5, 20);
```

The `ByteArrayInputStream` class is just like `CharArrayReader`, except that it deals with bytes instead of characters. In Java 1.0, `ByteArrayInputStream` did not fully support `mark()` and `reset()`; in Java 1.1

these methods are completely supported.

PipedInputStream and PipedReader

The PipedInputStream class is a subclass of InputStream that facilitates communication between threads. Because it reads bytes written by a connected PipedOutputStream, a PipedInputStream must be connected to a PipedOutputStream to be useful. There are a few ways to connect a PipedInputStream to a PipedOutputStream. You can first create the PipedOutputStream and pass it to the PipedInputStream constructor like this:

```
PipedOutputStream po = new PipedOutputStream();
PipedInputStream pi = new PipedInputStream(po);
```

You can also create the PipedInputStream first and pass it to the PipedOutputStream constructor like this:

```
PipedInputStream pi = new PipedInputStream();
PipedOutputStream po = new PipedOutputStream(pi);
```

The PipedInputStream and PipedOutputStream classes each have a connect() method you can use to explicitly connect a PipedInputStream and a PipedOutputStream as follows:

```
PipedInputStream pi = new PipedInputStream();
PipedOutputStream po = new PipedOutputStream();
pi.connect(po);
```

Or you can use connect() as follows:

```
PipedInputStream pi = new PipedInputStream();
PipedOutputStream po = new PipedOutputStream();
po.connect(pi);
```

Multiple PipedOutputStream objects can be connected to a single PipedInputStream at one time, but the results are unpredictable. If you connect a PipedOutputStream to an already connected PipedInputStream, any unread bytes from the previously connected PipedOutputStream are lost. Once the two PipedOutputStream objects are connected, the PipedInputStream reads bytes written by either PipedOutputStream in the order that it receives them. The scheduling of different threads may vary from one execution of the program to the next, so the order in which the PipedInputStream receives bytes from multiple PipedOutputStream objects can be inconsistent.

The PipedReader class is the character-based equivalent of PipedInputStream. It works in the same way, except that a PipedReader is connected to a PipedWriter to complete the pipe, using either the appropriate constructor or the connect() method.

FilterInputStream and FilterReader

The FilterInputStream class is a wrapper class for InputStream objects. Conceptually, an object that belongs to a subclass of FilterInputStream is wrapped around another InputStream object. The constructor for this class requires an InputStream. The constructor sets the object's in instance variable to reference the specified InputStream, so from that point on, the FilterInputStream is associated with the given InputStream. All of the methods in FilterInputStream work by calling the corresponding methods in the underlying InputStream. Because the close() method of a FilterInputStream calls the close() method of the InputStream that it wraps, you do not need to explicitly close the underlying InputStream.

A FilterInputStream does not add any functionality to the object that it wraps, so by itself it is not very useful. However, subclasses of the FilterInputStream class do add functionality to the objects that they wrap in two ways:

- Some subclasses add logic to the InputStream methods. For example, the InflaterInputStream class in the java.util.zip package decompresses data automatically in the read() methods.

- Some subclasses add new methods. An example is DataInputStream, which provides methods for reading primitive Java data types from the stream.

The FilterReader class is the character-based equivalent of FilterInputStream. A FilterReader is wrapped around an underlying Reader object; the methods of FilterReader call the corresponding methods of the underlying Reader. However, unlike FilterInputStream, FilterReader is an abstract class, so you cannot instantiate it directly.

DataInputStream

The DataInputStream class is a subclass of FilterInputStream that provides methods for reading a variety of data types. The DataInputStream class implements the DataInput interface, so it defines methods for reading all of the primitive Java data types.

You create a DataInputStream by passing a reference to an underlying InputStream to the constructor. Here is an example that creates a DataInputStream and uses it to read an int that represents the length of an array and then to read the array of long values:

```
long[] readLongArray(InputStream in) throws IOException {
    DataInputStream din = new DataInputStream(in);
    int count = din.readInt();
    long[] a = new long[count];
    for (int i = 0; i < count; i++) {
        a[i] = din.readLong();
    }
    return a;
}
```

BufferedReader and BufferedInputStream

The BufferedReader class is a subclass of Reader that buffers input from an underlying Reader. A BufferedReader object reads enough characters from its underlying Reader to fill a relatively large buffer, and then it satisfies read operations by supplying characters that are already in the buffer. If most read operations read just a few characters, using a BufferedReader can improve performance because it reduces the number of read operations that the program asks the operating system to perform. There is generally a measurable overhead associated with each call to the operating system, so reducing the number of calls into the operating system improves performance. The BufferedReader class supports mark-and-reset functionality via the mark() and reset() methods.

Here is an example that shows how to create a BufferedReader to improve the efficiency of reading from a file:

```
try {
    FileReader fileIn = new FileReader("data.dat");
    BufferedReader in = new BufferedReader(fileIn);
    // read from the file
} catch (IOException e) {
    System.out.println(e);
}
```

The BufferedInputStream class is the byte-based counterpart of BufferedReader. It works in the same way as BufferedReader, except that it buffers input from an underlying InputStream.

LineNumberReader and LineNumberInputStream

The LineNumberReader class is a subclass of BufferedReader. Its read() methods contain additional logic to count end-of-line characters and thereby maintain a line number. Since different platforms use different characters to represent the end of a line, LineNumberReader takes a flexible approach and recognizes "\n", "\r", or "\r\n" as the end of a line. Regardless of the end-of-line character it reads, LineNumberReader returns only "\n" from its read() methods.

You can create a LineNumberReader by passing its constructor a Reader. The following example prints out the first five lines of a file, with each line prefixed by its number. If you try this example, you'll see that the line numbers begin at 0 by default:

```
try {
    FileReader fileIn = new FileReader("text.txt");
    LineNumberReader in = new LineNumberReader(fileIn);
    for (int i = 0; i < 5; i++)
        System.out.println(in.getLineNumber() + " " + in.readLine());
}catch (IOException e) {
    System.out.println(e);
}
```

The LineNumberReader class has two methods pertaining to line numbers. The getLineNumber() method returns the current line number. If you want to change the current line number of a LineNumberReader, use setLineNumber(). This method does not affect the stream position; it merely sets the value of the line number.

The `LineNumberInputStream` is the byte-based equivalent of `LineNumberReader`. The entire class is deprecated in Java 1.1 because it does not convert bytes to characters properly. Apart from the conversion problem, `LineNumberInputStream` works the same as `LineNumberReader`, except that it takes its input from an `InputStream` instead of a `Reader`.

SequenceInputStream

The `SequenceInputStream` class is used to sequence together multiple `InputStream` objects. Consider this example:

```
FileInputStream f1 = new FileInputStream("data1.dat");
FileInputStream f2 = new FileInputStream("data2.dat");
SequenceInputStream s = new SequenceInputStream(f1, f2);
```

This example creates a `SequenceInputStream` that reads all of the bytes from `f1` and then reads all of the bytes from `f2` before reporting that it has encountered the end of the stream. You can also cascade `SequenceInputStream` object themselves, to allow more than two input streams to be read as if they were one. You would write it like this:

```
FileInputStream f3 = new FileInputStream("data3.dat");
SequenceInputStream s2 = new SequenceInputStream(s, f3);
```

The `SequenceInputStream` class has one other constructor that may be more appropriate for wrapping more than two `InputStream` objects together. It takes an `Enumeration` of `InputStream` objects as its argument. The following example shows how to create a `SequenceInputStream` in this manner:

```
Vector v = new Vector();
v.add(new FileInputStream("data1.dat"));
v.add(new FileInputStream("data2.dat"));
v.add(new FileInputStream("data3.dat"));
Enumeration e = v.elements();
SequenceInputStream s = new SequenceInputStream(e);
```

PushbackInputStream and PushbackReader

The `PushbackInputStream` class is a `FilterInputStream` that allows data to be pushed back into the input stream and reread by the next read operation. This functionality is useful for implementing things like parsers that need to read data and then return it to the input stream. The Java 1.0 version of `PushbackInputStream` supported only a one-byte pushback buffer; in Java 1.1 this class has been enhanced to support a larger pushback buffer.

To create a `PushbackInputStream`, pass an `InputStream` to its constructor like this:

```
FileInputStream ef = new FileInputStream("expr.txt");
PushbackInputStream pb = new PushbackInputStream(ef);
```

This constructor creates a `PushbackInputStream` that uses a default one-byte pushback buffer. When you have data that you want to push back into the input stream to be read by the next read operation, you pass the data to one of the `unread()` methods.

The `PushbackReader` class is the character-based equivalent of `PushbackInputStream`. In the following example, we create a `PushbackReader` with a pushback buffer of 48 characters:

```
FileReader fileIn = new FileReader("expr.txt");
PushbackReader in = new PushbackReader(fileIn, 48);
```

Here is an example that shows the use of a `PushbackReader`:

```
public String readDigits(PushbackReader pb) {
    char c;
    StringBuffer buffer = new StringBuffer();
    try {
        while (true) {
            c = (char)pb.read();
            if (!Character.isDigit(c))
                break;
            buffer.append(c);
        }
        if (c != -1)
            pb.unread(c);
    }catch (IOException e) {}
    return buffer.toString();
}
```

The above example shows a method that reads characters corresponding to digits from a `PushbackReader`. When it reads a character that is not a digit, it calls the `unread()` method so that the nondigit can be read by the next read operation. It then returns a string that contains the digits that were read.

7. Object Serialization

Contents:

The object serialization mechanism in Java 1.1 provides a way for objects to be written as a stream of bytes and then later recreated from that stream of bytes. This facility supports a variety of interesting applications. For example, object serialization provides persistent storage for objects, whereby objects are stored in a file for later use. Also, a copy of an object can be sent through a socket to another Java program. Object serialization forms the basis for the remote method invocation mechanism in Java that facilitates distributed programs. Object serialization is supported by a number of new classes in the `java.io` package in Java 1.1.

7.1 Object Serialization Basics

If a class is designed to work with object serialization, reading and writing instances of that class is quite simple. The process of writing an object to a byte stream is called *serialization*. For example, here is how you can write a `Color` object to a file:

```
FileOutputStream out = new FileOutputStream("tmp");
ObjectOutput objOut = new ObjectOutputStream(out);
objOut.writeObject(Color.red);
```

All you need to do is create an `ObjectOutputStream` around another output stream and then pass the object to be written to the `writeObject()` method. If you are writing objects to a socket or any other destination that is time-sensitive, you should call the `flush()` method after you are finished passing objects to the `ObjectOutputStream`.

The process of reading an object from byte stream is called *deserialization*. Here is how you can read that Color object from its file:

```
FileInputStream in = new FileInputStream("tmp");
ObjectInputStream objIn = new ObjectInputStream(in);
Color c = (Color)objIn.readObject();
```

Here all you need to do is create an ObjectInputStream object around another input stream and call its readObject() method.

8. Networking

Contents:

The `java.net` package provides two basic mechanisms for accessing data and other resources over a network. The fundamental mechanism is called a socket. A socket allows programs to exchange groups of bytes called packets. There are a number of classes in `java.net` that support sockets, including `Socket`, `ServerSocket`, `DatagramSocket`, `DatagramPacket`, and `MulticastSocket`. The `java.net` package also includes a `URL` class that provides a higher-level mechanism for accessing and processing data over a network.

8.1 Sockets

A socket is a mechanism that allows programs to send packets of bytes to each other. The programs do not need to be running on the same machine, but if they are running on different machines, they do need to be connected to a network that allows the machines to exchange data. Java's socket implementation is based on the socket library that was originally part of BSD UNIX. Programmers who are familiar with UNIX sockets or the Microsoft WinSock library should be able to see the similarities in the Java implementation.

When a program creates a socket, an identifying number called a port number is associated with the socket. Depending on how the socket is used, the port number is either specified by the program or assigned by the operating system. When a socket sends a packet, the packet is accompanied by two pieces of information that specify the destination of the packet:

- A network address that specifies the system that should receive the packet.
- A port number that tells the receiving system to which socket to deliver the data.

Sockets typically work in pairs, where one socket acts as a client and the other functions as a server. A server socket specifies the port number for the network communication and then listens for data that is sent to it by client sockets. The port numbers for server sockets are well-known numbers that are known to client programs.

For example, an FTP server uses a socket that listens at port 21. If a client program wants to communicate with an FTP server, it knows to contact a socket that listens at port 21.

The operating system normally specifies port numbers for client sockets because the choice of a port number is not usually important. When a client socket sends a packet to a server socket, the packet is accompanied by the port number of the client socket and the client's network address. The server is then able to use that information to respond to the client.

When using sockets, you have to decide which type of protocol that you want it to use to transport packets over the network: a connection-oriented protocol or a connectionless protocol. With a connection-oriented protocol, a client socket establishes a connection to a server socket when it is created. Once the connection has been established, a connection-oriented protocol ensures that data is delivered reliably, which means:

- For every packet that is sent, the packet is delivered. Every time a socket sends a packet, it expects to receive an acknowledgement that the packet has been received successfully. If the socket does not receive that acknowledgement within the time it expects to receive it, the socket sends the packet again. The socket keeps trying until transmission is successful, or it decides that delivery has become impossible.

- Packets are read from the receiving socket in the same order that they were sent. Because of the way that networks work, packets may arrive at the receiving socket in a different order than they were sent. A reliable, connection-oriented protocol allows the receiving socket to reorder the packets it receives, so that they can be read by the receiving program in the same order that they were sent.

A connectionless protocol allows a best-effort delivery of packets. It does not guarantee that packets are delivered or that packets are read by the receiving program in the same order they were sent. A connectionless protocol trades these deficiencies for performance advantages over connection-oriented protocols. Here are two types of situations in which connectionless protocols are frequently preferred over connection-oriented protocols:

- When only a single packet needs to be sent and guaranteed delivery is not crucial, a connectionless protocol eliminates the overhead involved in creating and destroying a connection. For comparison purposes, the connection-oriented TCP/IP protocol uses seven packets to send a single packet, while the connectionless UDP/IP protocol uses only one. A protocol for getting the current time typically uses a connectionless protocol to request the current time from the server and to return the time to the requester.

- For extremely time-sensitive applications, such as sending audio in real time, the guarantee of reliable transmission is not an advantage and may be a disadvantage. Pausing until a missing piece of data is received can cause noticeable clicks or pauses in the audio. Techniques for sending audio over a network that use a connectionless protocol have been developed and they work noticeably better. For example, RealAudio uses a protocol that runs on top of a connectionless protocol to transmit sound over a network.

Table 8.1 shows the roles of the various socket classes in the `java.net` package.

Table 8.1: Socket Classes in java.net

	Client	**Server**
Connection-oriented Protocol	`Socket`	`ServerSocket`
Connectionless Protocol	`DatagramSocket`	`DatagramSocket`

As of Java 1.1, the `java.net` package also contains a `MulticastSocket` class that supports connectionless, multicast data communication.

Sockets for Connection-Oriented Protocols

When you are writing code that implements the server side of a connection-oriented protocol, your code typically follows this pattern:

- Create a `ServerSocket` object to accept connections.
- When the `ServerSocket` accepts a connection, it creates a `Socket` object that encapsulates the connection.
- The `Socket` is asked to create `InputStream` and `OutputStream` objects that read and write bytes to and from the connection.
- The `ServerSocket` can optionally create a new thread for each connection, so that the server can listen for new connections while it is communicating with clients.

The code that implements the client side of a connection-oriented protocol is quite simple. It creates a `Socket` object that opens a connection with a server, and then it uses that `Socket` object to communicate with the server.

Now let's look at an example. The example consists of a pair of programs that allows a client to get the contents of a file from a server. The client requests the contents of a file by opening a connection to the server and sending it the name of a file followed by a newline character. If the server is able to read the named file, it responds by sending the string `"Good:\n"` followed by the contents of the file. If the server is not able to read the named file, it responds by sending the string `"Bad:"` followed by the name of the file and a newline character. After the server has sent its response, it closes the connection.

Here's the program that implements the server side of this file transfer:

```
public class FileServer extends Thread {
    public static void main(String[] argv) {
        ServerSocket s;
        try {
```

```
        s = new ServerSocket(1234, 10);
    }catch (IOException e) {
        System.err.println("Unable to create socket");
        e.printStackTrace();
        return;
    }
    try {
        while (true) {
            new FileServer(s.accept());
        }
    }catch (IOException e) {
    }
}
private Socket socket;
FileServer(Socket s) {
    socket = s;
    start();
}
public void run() {
    InputStream in;
    String fileName = "";
    PrintStream out = null;
    FileInputStream f;
    try {
        in = socket.getInputStream();
        out = new PrintStream(socket.getOutputStream());
        fileName = new DataInputStream(in).readLine();
        f = new FileInputStream(fileName);
    }catch (IOException e) {
        if (out != null)
          out.print("Bad:"+fileName+"\n");
        out.close();
        try {
            socket.close();
        }catch (IOException ie) {
        }
        return;
    }
    out.print("Good:\n");
    // send contents of file to client.
    byte[] buffer = new byte[4096];
    try {
        int len;
        while ((len = f.read(buffer)) > 0) {
            out.write(buffer, 0, len);
        }// while
        }catch (IOException e) {
        }finally {
            try {
                in.close();
                out.close();
                socket.close();
            }catch (IOException e) {
            }
        }
    }
}
```

The `FileServer` class implements the server side of the file transfer; it is a subclass of `Thread` to make it easier to write code that can handle multiple connections at the same time. The `main()` method provides the top-level logic for the program. The first thing that `main()` does is to create a `ServerSocket` object to listen for connections. The constructor for `ServerSocket` takes two parameters: the port number for the socket and a value that specifies the maximum length of the pending connections queue. The operating system can accept connections on behalf of the socket when the server program is busy doing something other than accepting connections. If the second parameter is greater than zero, the operating system can accept up to that many connections on behalf of the socket and store them in a queue. If the second parameter is zero, however, the operating system does not accept any connections on behalf of the server program. The remainder of the `main()` method accepts a connection, creates a new instance of the `FileServer` class to process the connection, and then waits for the next connection.

Each `FileServer` object is responsible for handling a connection accepted by its `main()` method. A `FileServer` object uses a `private` variable, `socket`, to refer to the `Socket` object that allows it to communicate with the client program on the other end of the connection. The constructor for `FileServer` sets its `socket` variable to refer to the `Socket` object that is passed to it by the `main()` method and then calls its `start()` method. The `FileServer` class inherits the `start()` method from the `Thread` class; the `start()` method starts a new thread that calls the `run()` method. Because the rest of the connection processing is done asynchronously in a separate thread, the constructor can return immediately. This allows the `main()` method to accept another connection right away, instead of having to wait for this connection to be fully processed before accepting another.

The `run()` method uses the `in` and `out` variables to refer to `InputStream` and `PrintStream` objects that read from and write to the connection associated with the `Socket` object, respectively. These streams are created by calling the `getInputStream()` and `getOutputStream()` methods of the `Socket` object. The `run()` method then reads the name of the file that the client program wants to receive and creates a `FileInputStream` to read that file. If any of the methods called up to this point have detected a problem, they throw some kind of `IOException`. In this case, the server sends a response to the client that consists of the string `"Bad:"` followed by the filename and then closes the socket and returns, which kills the thread.

If everything up to this point has been fine, the server sends the string `"Good:"` and then copies the contents of the file to the socket. The copying is done by repeatedly filling a buffer with bytes from the file and writing the buffer to the socket. When the contents of the file are exhausted, the streams and the socket are closed, the `run()` method returns, and the thread dies.

Now let's take a look at the client part of this program:

```
public class FileClient {
    private static boolean usageOk(String[] argv) {
        if (argv.length != 2) {
            String msg = "usage is: " + "FileClient server-name file-name";
            System.out.println(msg);
            return false;
        }
        return true;
    }
    public static void main(String[] argv) {
        int exitCode = 0;
        if (!usageOk(argv))
          return;
        Socket s = null;
        try {
            s = new Socket(argv[0], 1234);
        }catch (IOException e) {
            String msg = "Unable to connect to server";
            System.err.println(msg);
            e.printStackTrace();
            System.exit(1);
        }
        InputStream in = null;
        try {
            OutputStream out = s.getOutputStream();
            new PrintStream(out).print(argv[1]+"\n");
            in = s.getInputStream();
            DataInputStream din = new DataInputStream(in);
            String serverStatus = din.readLine();
            if (serverStatus.startsWith("Bad")) {
                exitCode = 1;
            int ch;
            while((ch = in.read()) >= 0) {
                System.out.write((char)ch);
            }// while
        }catch (IOException e) {
        }finally {
            try {
                s.close();
            }catch (IOException e) {
            }
        }
    }
}
```

The `usageOk()` method is simply a utility method that verifies that the correct number of arguments have been passed to the client application. It outputs a help message if the number of arguments is not what is expected. It is generally a good idea to include a method like this in a Java application that uses command-line parameters.

The `main()` method does the real work of `FileClient`. After it verifies that it has the correct number of parameters, it attempts to create a socket connected to the server program running on the specified host and listening for connections on port number 1234. The socket that it creates is encapsulated by a `Socket` object. The constructor for the `Socket` object takes two arguments: the name of the machine the server program is running on and the port number. After the socket is successfully opened, the client sends the specified filename, followed by a new line character, to the server. The client then gets an `InputStream` from the socket to read what the server is sending and reads the success/failure code that the server sends back. If the request is a success, the client reads the contents of the requested file.

Note that the `finally` clause at the end closes the socket. If the program did not explicitly close the socket, it would be closed automatically when the program terminates. However, it is a good programming practice to explicitly close a socket when you are done with it.

Sockets for Connectionless Protocols

Communicating with a connectionless protocol is simpler than using a connection-oriented protocol, as both the client and the server use `DatagramSocket` objects. The code for the server-side program has the following pattern:

- Create a `DatagramSocket` object associated with a specified port number.
- Create a `DatagramPacket` object and ask the `DatagramSocket` to put the next piece of data it receives in the `DatagramPacket`.

On the client-side, the order is simply reversed:

- Create a `DatagramPacket` object associated with a piece of data, a destination network address, and a port number.
- Ask a `DatagramSocket` object to send the data associated with the `DatagramPacket` to the destination associated with the `DatagramSocket`.

Let's look at an example that shows how this pattern can be coded into a server that provides the current time and a client that requests the current time. Here's the code for the server class:

```
public class TimeServer {
    static DatagramSocket socket;
    public static void main(String[] argv) {
        try {
            socket = new DatagramSocket(7654);
        }catch (SocketException e) {
            System.err.println("Unable to create socket");
            e.printStackTrace();
            System.exit(1);
        }
        DatagramPacket datagram;
        datagram = new DatagramPacket(new byte[1], 1);
        while (true) {
            try {
                socket.receive(datagram);
                respond(datagram);
            }catch (IOException e) {
                e.printStackTrace();
            }
        }
    }
    static void respond(DatagramPacket request) {
        ByteArrayOutputStream bs;
        bs = new ByteArrayOutputStream();
        DataOutputStream ds = new DataOutputStream(bs);
        try {
            ds.writeLong(System.currentTimeMillis());
        }catch (IOException e) {
        }
        DatagramPacket response;
        byte[] data = bs.toByteArray();
        response = new DatagramPacket(data, data.length,
                              request.getAddress(), request.getPort());
        try {
            socket.send(response);
        }catch (IOException e) {
            // Give up, we've done our best.
        }
    }
}
```

The `main()` method of the `TimeServer` class begins by creating a `DatagramSocket` object that uses port number 7654. The `socket` variable refers to this `DatagramSocket`, which is used to communicate with clients. Then the `main()` method creates a `DatagramPacket` object to contain data received by the `DatagramSocket`. The two-argument constructor for `DatagramPacket` creates objects that receive data. The first argument is an array of bytes to contain the data, while the second argument specifies the number of bytes to read. When a `DatagramSocket` is asked to receive a packet into a `DatagramPacket`, only the specified number of bytes are read. Even though the client is not really sending any information to the server, we still create a `DatagramPacket` with a 1-byte buffer. In theory, all that the server needs is an empty packet that specifies the client's network address and port number, but attempting to receive a zero-byte packet does not work. When the `receive()` method of a `DatagramSocket` is called to receive a zero-byte packet, it returns immediately, rather than waiting for a packet to arrive. Finally, the server enters an infinite loop that receives requests from clients using the `receive()` method of the `DatagramSocket`, and sends responses.

The `respond()` method handles sending responses. It starts by writing the current time as a `long` value to an array of bytes. Next, the `respond()` method prepares to send the array of bytes by creating a `DatagramPacket` object that encapsulates the array and the address and port number of the client that requested the time. Notice that the constructor used to create a `DatagramPacket` object for sending a packet takes four arguments: an array of bytes, the number of bytes to send, the client's network address, and the client's port number. The address and port are retrieved from the request `DatagramPacket` with the `getAddress()` and `getPort()` methods. The `respond()` method finishes its work by actually sending the `DatagramPacket` using the `send()` method of the `DatagramSocket`.

Now here's the code for the corresponding client program:

```
public class TimeClient {
    private static boolean usageOk(String[] argv) {
        if (argv.length != 1) {
            String msg = "usage is: " + "TimeClient server-name";
            System.out.println(msg);
            return false;
        }
        return true;
    }
    public static void main(String[] argv) {
        if (!usageOk(argv))
            System.exit(1);
        DatagramSocket socket;
        try {
            socket = new DatagramSocket();
        }catch (SocketException e) {
            System.err.println("Unable to create socket");
            e.printStackTrace();
            System.exit(1);
            return;
        }
        long time;
        try {
            byte[] buf = new byte[1];
            socket.send(new DatagramPacket(buf, 1,
                               InetAddress.getByName(argv[0]), 7654));
            DatagramPacket response = new DatagramPacket(new byte[8],8);
            socket.receive(response);
            ByteArrayInputStream bs;
            bs = new ByteArrayInputStream(response.getData());
            DataInputStream ds = new DataInputStream(bs);
            time = ds.readLong();
        }catch (IOException e) {
            e.printStackTrace();
            System.exit(1);
            return;
        }
        System.out.println(new Date(time));
        socket.close();
    }
}
```

The `main()` method does the real work of `TimeClient`. After it verifies that it has the correct number of parameters with `usageOk()`, it creates a `DatagramSocket` object for communicating with the server. Note that the constructor for this `DatagramSocket` does not specify any parameters; a client `DatagramSocket` is not explicitly connected to a specific port. Then the `main()` method creates a `DatagramPacket` object to contain the request to be sent to the server. Since this `DatagramPacket` is being used to send a packet, the code uses the four-argument constructor that specifies an array of bytes, the number of bytes to send, the specified network address for a time server, and the server's port number. The `DatagramPacket` is then sent to the server with the `send()` method of the `DatagramSocket`.

Now the `main()` method creates another `DatagramPacket` to receive the response from the server. The two-argument constructor is used this time because the object is being created to receive data. After calling the `receive()` method of the `DatagramSocket` to get the response from the server, the `main()` method gets the data from the response `DatagramPacket` by calling `getData()`. The data is wrapped in a `DataInputStream` so that the data can be read as a `long` value. If everything has gone smoothly, the client finishes by printing the current time and closing the socket.

9. Security

Contents:

Java uses a "sandbox" security model to ensure that applets cannot cause security problems. The idea is that an applet can do whatever it wants within the constraints of its sandbox, but that nothing done inside the sandbox has any consequences outside of the sandbox.

9.1 SecurityManager

Java implements the sandbox model using the `java.lang.SecurityManager` class. An instance of `SecurityManager` is passed to the method `System.setSecurityManager()` to establish the security policy for an application. Before `setSecurityManager()` is called, a Java program can access any resources available on the system. After `setSecurityManager()` is called, however, the `SecurityManager` object is responsible for providing a security policy. Once a security policy has been set by calling `setSecurityManager`, the method cannot be called again. Subsequent calls simply throw a `SecurityException`.

All methods in the Java API that can access resources outside of the Java environment call a `SecurityManager` method to ask permission before doing anything. If the `SecurityManager` method throws a `SecurityException`, the exception is thrown out of the calling method, and access to the resource is denied. The `SecurityManager` class defines a number of methods for asking for permission to access specific resources. Each of these methods has a name that begins with the word "check." Table 9.1 shows the names of the `check` methods provided by the `SecurityManager` class.

Table 9.1: The Check Methods of SecurityManager

Method Name	**Permission**

`checkAccept()`	To accept a network connection
`checkAccess()`	To modify a `Thread` or `ThreadGroup`
`checkAwtEventQueueAccess()`	To access the AWT event queue
`checkConnect()`	To establish a network connection or send a datagram
`checkCreateClassLoader()`	To create a `ClassLoader` object
`checkDelete()`	To delete a file
`checkExec()`	To call an external program
`checkExit()`	To stop the Java virtual machine and exit the Java environment
`checkLink()`	To dynamically link an external library into the Java environment
`checkListen()`	To listen for a network connection
`checkMemberAccess()`	To access the members of a class
`checkMulticast()`	To use a multicast connection
`checkPackageAccess()`	To access the classes in a package
`checkPackageDefinition()`	To define classes in a package
`checkPrintJobAccess()`	To initiate a print job request
`checkPropertiesAccess()`	To get or set the `Properties` object that defines all of the system properties
`checkPropertyAccess()`	To get or set a system property
`checkRead()`	To read from a file or input stream
`checkSecurityAccess()`	To perform a security action
`checkSetFactory()`	To set a factory class that determines classes to be used for managing network connections and their content
`checkSystemClipboardAccess()`	To access the system clipboard
`checkTopLevelWindow()`	To create a top-level window on the screen
`checkWrite()`	To write to a file or output stream

The `SecurityManager` class provides implementations of these methods that always refuse the requested permission. To implement a more permissive security policy, you need to create a subclass of `SecurityManager` that implements that policy.

In Java 1.0, most browsers consider an applet to be trusted or untrusted. An untrusted applet is one that does not come from the local filesystem. An untrusted applet is treated as follows by most popular browsers:

- It can establish network connections to the network address from which it came.
- It can create new windows on the screen. However, a notice is displayed on the bottom of the window that the window was created by an untrusted applet.
- It cannot access any other external resources. In particular, untrusted applets cannot access local files.

As of Java 1.1, an applet can have a digital signature attached to it. When an applet has been signed by a trusted entity, a browser may consider the applet to be trusted and relax its security policy.

The package `java.io` contains the classes that handle fundamental input and output operations in Java. The I/O classes can be grouped as follows:

- Classes for reading input from a stream of data.
- Classes for writing output to a stream of data.
- Classes that manipulate files on the local filesystem.
- Classes that handle object serialization.

I/O in Java is based on streams. A stream represents a flow of data or a channel of communication. Java 1.0 supports only byte streams. The `InputStream` class is the superclass of all of the Java 1.0 byte input streams, while `OutputStream` is the superclass of all the byte output streams. The drawback to these byte streams is that they do not always handle Unicode characters correctly.

As of Java 1.1, `java.io` contains classes that represent character streams. These character stream classes handle Unicode characters appropriately by using a character encoding to convert bytes to characters and vice versa. The `Reader` class is the superclass of all the Java 1.1 character input streams, while `Writer` is the superclass of all character output streams.

The `InputStreamReader` and `OutputStreamWriter` classes provide a bridge between byte streams and character streams. If you wrap an `InputStreamReader` around an `InputStream` object, the bytes in the byte stream are read and converted to characters using the character encoding scheme specified by the `InputStreamReader`. Likewise, you can wrap an `OutputStreamWriter` around any `OutputStream` object so that you can write characters and have them converted to bytes.

As of Java 1.1, `java.io` also contains classes to support object serialization. Object serialization is the ability to write the complete state of an object to an output stream, and then later recreate that object by reading in the serialized state from an input stream. The `ObjectOutputStream` and `ObjectInputStream` classes handle serializing and deserializing objects, respectively.

The `RandomAccessFile` class is the only class that does not use a stream for reading or writing data. As its name implies, `RandomAccessFile` provides nonsequential access to a file for both reading and writing purposes.

The `File` class represents a file on the local file system. The class provides methods to identify and retrieve information about a file.

Figure 11.1 shows the class hierarchy for the `java.io` package. The `java.io` package defines a number of standard I/O exception classes. These exception classes are all subclasses of `IOException`, as shown in Figure 11.2.

BufferedInputStream

Name

BufferedInputStream

Synopsis

Class Name:

`java.io.BufferedInputStream`

Superclass:

`java.io.FilterInputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A BufferedInputStream object provides a more efficient way to read just a few bytes at a time from an InputStream. BufferedInputStream object use a buffer to store input from an associated InputStream. In other words, a large number of bytes are read from the underlying stream and stored in an internal buffer. A BufferedInputStream is more efficient than a regular InputStream because reading data from memory is faster than reading it from a disk or a network. All reading is done directly from the internal buffer; the disk or network needs to be accessed only occasionally to fill up the buffer.

You should wrap a BufferedInputStream around any InputStream whose read() operations may be time consuming or costly, such as a FileInputStream.

BufferedInputStream provides a way to mark a position in the stream and subsequently reset the stream to that position, using mark() and reset().

Class Summary

```
public class java.io.BufferedInputStream extends java.io.FilterInputStream {
  // Variables
  protected byte[] buf;
  protected int count;
  protected int marklimit;
  protected int markpos;
  protected int pos;
  // Constructors
  public BufferedInputStream(InputStream in);
  public BufferedInputStream(InputStream in, int size);
  // Instance Methods
  public synchronized int available();
  public synchronized void mark(int readlimit);
  public boolean markSupported();
  public synchronized int read();
  public synchronized int read(byte[] b, int off, int len);
  public synchronized void reset();
  public synchronized long skip(long n);
}
```

Variables

buf

protected byte[] buf

Description

> The buffer that stores the data from the input stream.

count

protected int count

Description

> A placeholder that marks the end of valid data in the buffer.

marklimit

protected int marklimit

Description

> The maximum number of bytes that can be read after a call to `mark()` before a call to `reset()` fails.

markpos

protected int markpos

Description

> The position of the stream when `mark()` was called. If `mark()` has not been called, this variable is `-1`.

pos

protected int pos

Description

> The current position in the buffer, or in other words, the index of the next character to be read.

Constructors

BufferedInputStream

public BufferedInputStream(InputStream in)

Parameters

`in`

The input stream to buffer.

Description

This constructor creates a `BufferedInputStream` that buffers input from the given `InputStream`, using a buffer with the default size of 2048 bytes.

public BufferedInputStream(InputStream in, int size)

Parameters

`in`

The input stream to buffer.

`size`

The size of buffer to use.

Description

This constructor creates a `BufferedInputStream` that buffers input from the given `InputStream`, using a buffer of the given size.

Instance Methods

available

public synchronized int available() throws IOException

Returns

The number of bytes that can be read without blocking.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.available()`

Description

This method returns the number of bytes that can be read without having to wait for more data to become available. The returned value is the sum of the number of bytes remaining in the object's buffer and the number returned as the result of calling the `available()` method of the underlying `InputStream` object.

mark

public synchronized void mark(int readlimit)

Parameters

`readlimit`

The maximum number of bytes that can be read before the saved position becomes invalid.

Overrides

`FilterInputStream.mark()`

Description

This method causes the `BufferedInputStream` to remember its current position. A subsequent call to `reset()` causes the object to return to that saved position, and thus reread a portion of the buffer.

markSupported

public synchronized boolean markSupported()

Returns

The `boolean` value `true`.

Overrides

`FilterInputStream.markSupported()`

Description

This method returns `true` to indicate that this class supports `mark()` and `reset()`.

read

public synchronized int read() throws IOException

Returns

The next byte of data or `-1` if the end of the stream is encountered.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read()`

Description

This method returns the next byte from the buffer. If all the bytes in the buffer have been read, the buffer is filled from the underlying `InputStream` and the next byte is returned. If the buffer does not need to be filled, this method returns immediately. If the buffer needs to be filled, this method blocks until data is available from the underlying `InputStream`, the end of the stream is reached, or an exception is thrown.

public synchronized int read(byte b[], int off, int len) throws IOException

Parameters

`b`

An array of bytes to be filled from the stream.

`off`

An offset into the byte array.

`len`

The number of bytes to read.

Returns

The actual number of bytes read or `-1` if the end of the stream is encountered immediately.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.read(byte[], int, int)`

Description

This method copies bytes from the internal buffer into the given array `b`, starting at index `off` and continuing for up to `len` bytes. If there are any bytes in the buffer, this method returns immediately. Otherwise the buffer needs to be filled; this method blocks until the data is available from the underlying `InputStream`, the end of the stream is reached, or an exception is thrown.

reset

public synchronized void reset() throws IOException

Throws

`IOException`

If there was no previous call to this `BufferedInputStream`'s mark method, or the saved position has been invalidated.

Overrides

`FilterInputStream.reset()`

Description

This method sets the position of the `BufferedInputStream` to a position that was saved by a previous call to `mark()`. Subsequent bytes read from this `BufferedInputStream` will begin from the saved position and continue normally.

skip

public synchronized long skip(long n) throws IOException

Parameters

`n`

The number of bytes to skip.

Returns

The actual number of bytes skipped.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterInputStream.skip()`

Description

This method skips `n` bytes of input. If the new position of the stream is still within the data contained in the buffer, the method returns immediately. Otherwise the `skip()` method of the underlying stream is called. A subsequent call to `read()` forces the buffer to be filled.

Inherited Methods

The package `java.lang` contains classes and interfaces that are essential to the Java language. These include:

- `Object`, the ultimate superclass of all classes in Java.
- `Thread`, the class that controls each thread in a multithreaded program.
- `Throwable`, the superclass of all error and exception classes in Java.
- Classes that encapsulate the primitive data types in Java.
- Classes for accessing system resources and other low-level entities.
- `Math`, a class that provides standard mathematical methods.
- `String`, the class that represents strings.

Because the classes in the `java.lang` package are so essential, the `java.lang` package is implicitly imported by every Java source file. In other words, you can refer to all of the classes and interfaces in `java.lang` using their simple names.

Figure 12.1 shows the class hierarchy for the `java.lang` package.

The possible exceptions in a Java program are organized in a hierarchy of exception classes. The `Throwable` class is at the root of the exception hierarchy. `Throwable` has two immediate subclasses: `Exception` and `Error`. Figure 12.2 shows the standard exception classes defined in the `java.lang` package, while Figure 12.3 shows the standard error classes defined in `java.lang`.

Figure 12.1: The java.lang package

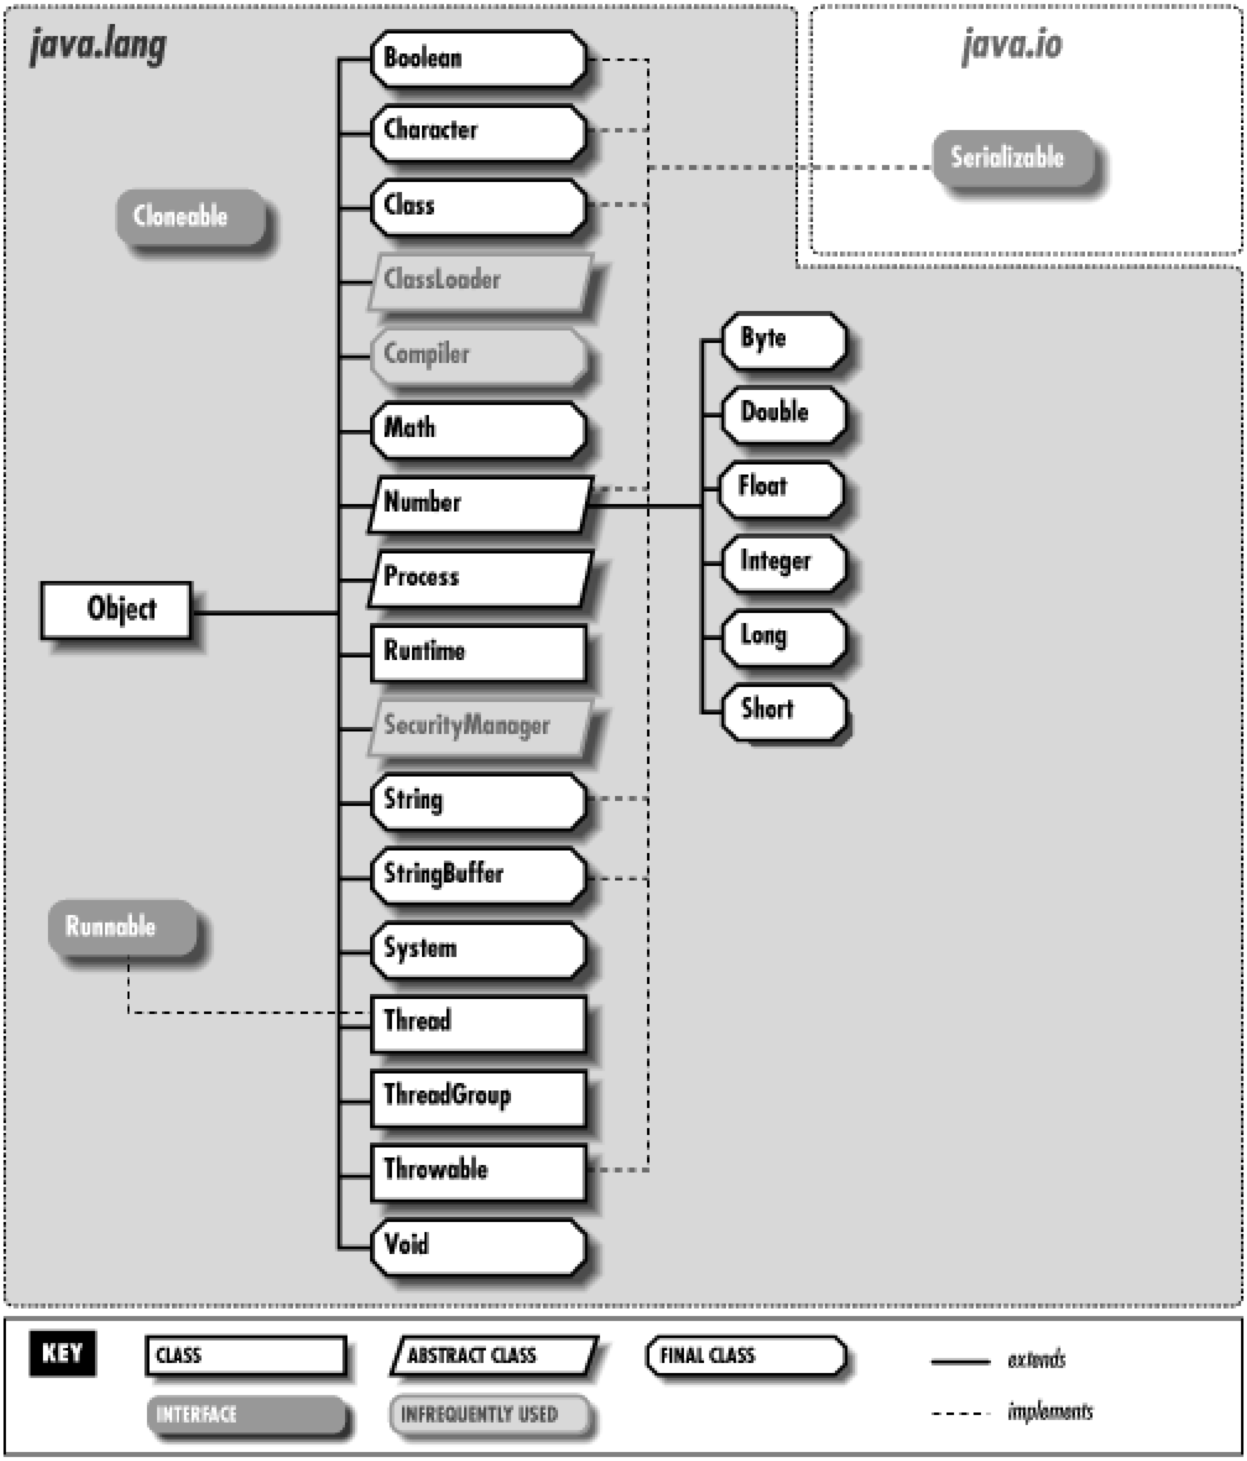

Figure 12.2: The exception classes in the java.lang package

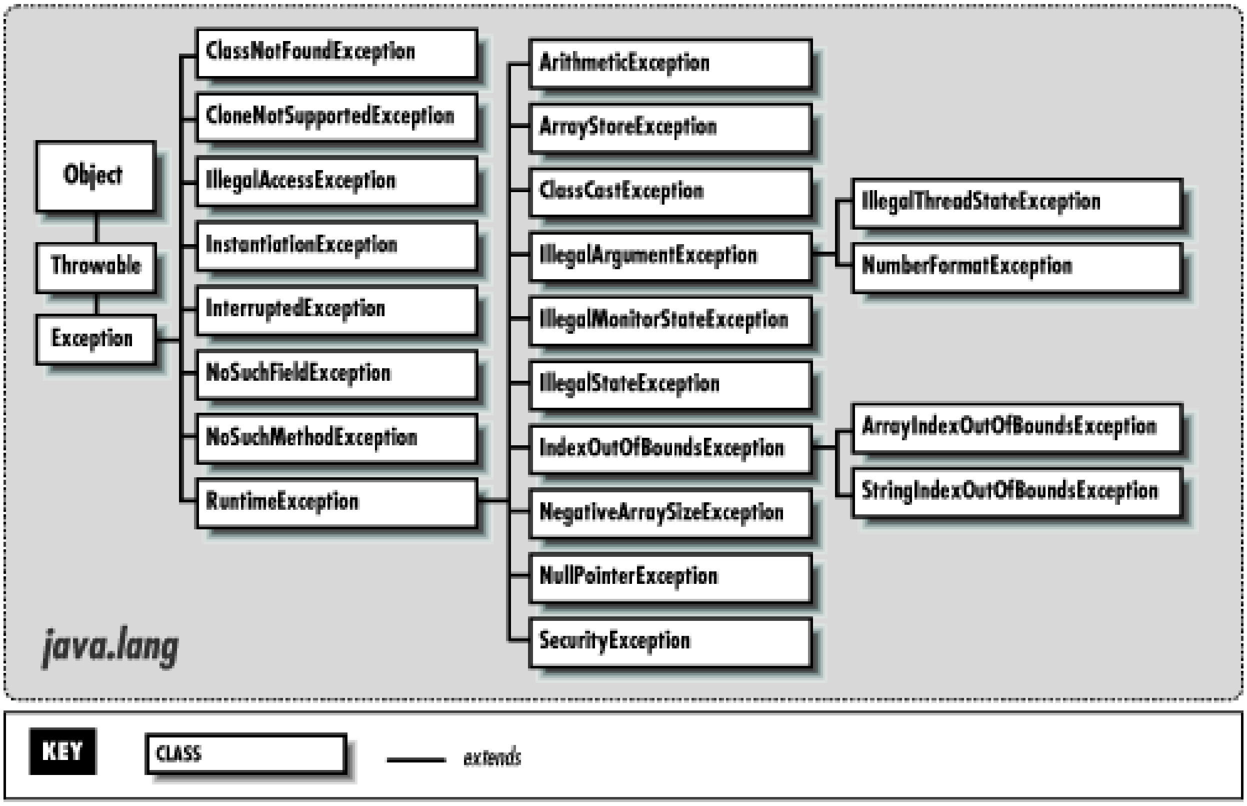

Figure 12.3: The error classes in the java.lang package

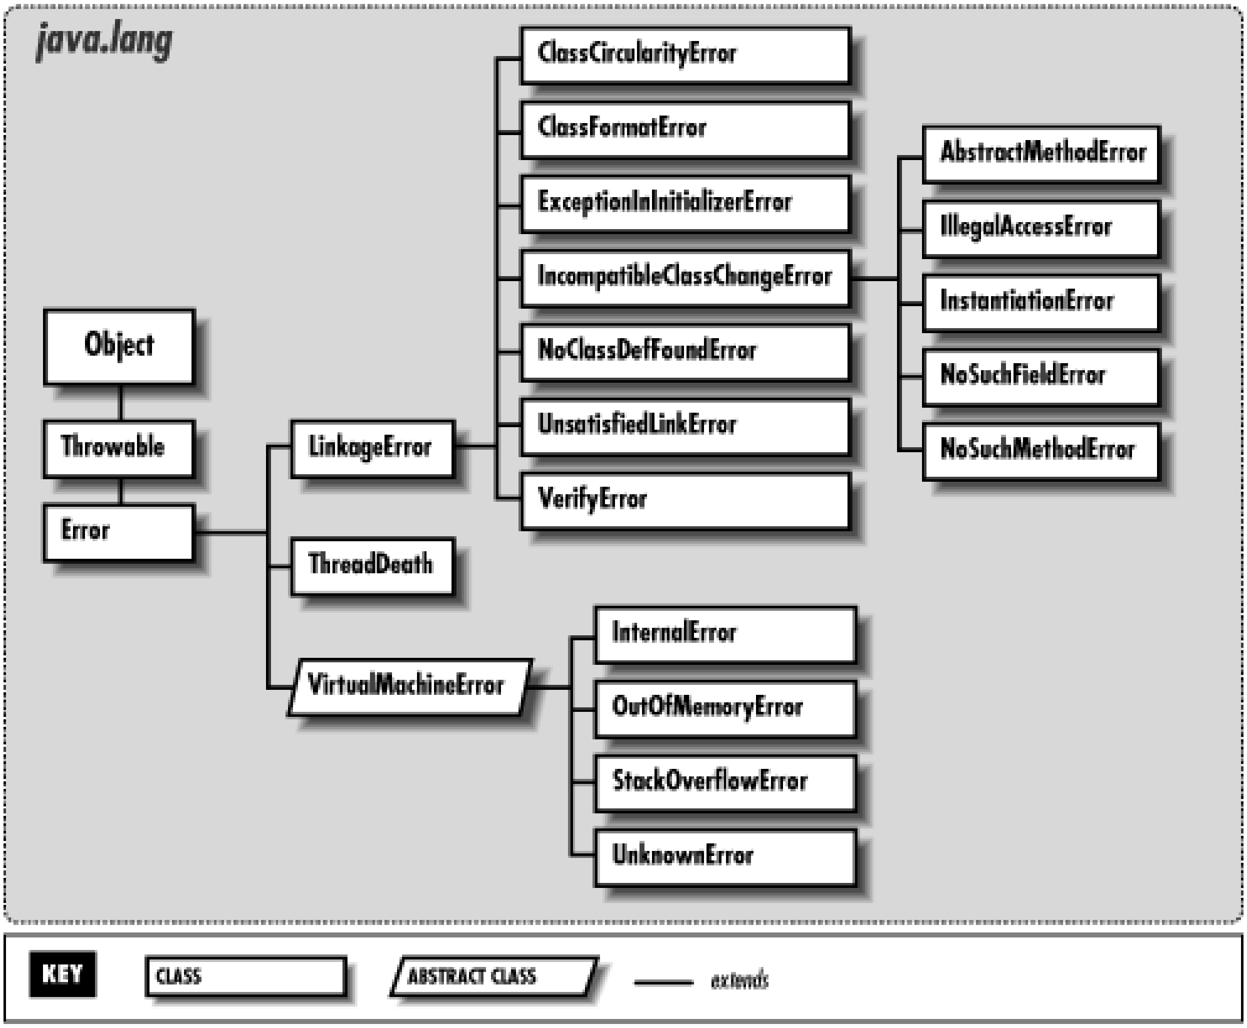

AbstractMethodError

Name

AbstractMethodError

Synopsis

Class Name:

`java.lang.AbstractMethodError`

Superclass:

`java.lang.IncompatibleClassChangeError`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

An `AbstractMethodError` is thrown when there is an attempt to invoke an `abstract` method.

Class Summary

```
public class java.lang.AbstractMethodError
             extends java.lang.IncompatibleClassChangeError {
  // Constructors
  public AbstractMethodError();
  public AbstractMethodError(String s);
}
```

Constructors

AbstractMethodError

public AbstractMethodError()

Description

This constructor creates an `AbstractMethodError` with no associated detail message.

public AbstractMethodError(String s)

Parameters

`s`

The detail message.

Description

This constructor creates an `AbstractMethodError` with the specified detail message.

Inherited Methods

Method	**Inherited From**	**Method**	**Inherited From**

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

13. The java.lang.reflect Package

Contents:

The package `java.lang.reflect` is new as of Java 1.1. It contains classes and interfaces that support the Reflection API. Reflection refers to the ability of a class to reflect upon itself, or look inside of itself, to see what it can do. The Reflection API makes it possible to:

- Discover the variables, methods, and constructors of any class.
- Create an instance of any class using any available constructor of that class, even if the class initiating the creation was not compiled with any information about the class to be instantiated.
- Access the variables of any object, even if the accessing class was not compiled with any information about the class to be accessed.
- Call the methods of any object, even if the calling class was not compiled with any information about the class that contains the methods.
- Create an array of objects that are instances of any class, even if the creating class was not compiled with any information about the class.

These capabilities are implemented by the `java.lang.Class` class and the classes in the `java.lang.reflect` package. Figure 13.1 shows the class hierarchy for the `java.lang.reflect` package.

Figure 13.1: The java.lang.reflect package

[Graphic: Figure 13-1]

Java 1.1 currently uses the Reflection API for two purposes:

- The JavaBeans API supports a mechanism for customizing objects that is based on being able to discover their public variables, methods, and constructors. See the forthcoming *Developing Java Beans* from O'Reilly & Associates for more information about the JavaBeans API.
- The object serialization functionality in `java.io` is built on top of the Reflection API. Object serialization allows arbitrary objects to be written to a stream of bytes and then read back later as objects.

Array

Name

Array

Synopsis

Class Name:

`java.lang.reflect.Array`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

New as of JDK 1.1

Description

The `Array` class provides static methods to manipulate arbitrary arrays in Java. There are methods to set and retrieve elements in an array, determine the size of an array, and create a new instance of an array.

The `Array` class is used to create array objects and manipulate their elements. The `Array` class is not used to represent array types. Because arrays in Java are objects, array types are represented by `Class` objects.

Class Summary

```
public final class java.lang.reflect.Array extends java.lang.Object {
  // Class Methods
  public static native Object get(Object array, int index);
  public static native boolean getBoolean(Object array, int index);
  public static native byte getByte(Object array, int index);
  public static native char getChar(Object array, int index);
  public static native double getDouble(Object array, int index);
  public static native float getFloat(Object array, int index);
  public static native int getInt(Object array, int index);
  public static native int getLength(Object array);
  public static native long getLong(Object array, int index);
  public static native short getShort(Object array, int index);
  public static Object newInstance(Class componentType, int length);
  public static Object newInstance(Class componentType, int[] dimensions);
  public static native void set(Object array, int index, Object value);
  public static native void setBoolean(Object array, int index, boolean z);
  public static native void setByte(Object array, int index, byte b);
  public static native void setChar(Object array, int index, char c);
  public static native void setDouble(Object array, int index, double d);
  public static native void setFloat(Object array, int index, float f);
  public static native void setInt(Object array, int index, int i);
  public static native void setLong(Object array, int index, long l);
  public static native void setShort(Object array, int index, short s);
}
```

Class Methods

get

public static native Object get(Object array, int index) throws IllegalArgumentException, ArrayIndexOutOfBoundsException

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The object at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array. If the array contains values of a primitive type, the value at the given index is wrapped in an appropriate object, and the object is returned.

getBoolean

public static native boolean getBoolean(Object array, int index) throws IllegalArgumentException, ArrayIndexOutOfBoundsException

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `boolean` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `boolean`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `boolean` value.

getByte

```
public static native byte getByte(Object array, int index) throws
IllegalArgumentException, ArrayIndexOutOfBoundsException
```

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `byte` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `byte`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `byte` value.

getChar

```
 public static native char getChar(Object array, int index) throws
IllegalArgumentException, ArrayIndexOutOfBoundsException
```

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `char` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `char`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `char` value.

getDouble

`public static native double getDouble(Object array, int index) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `double` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `double`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `double` value.

getFloat

`public static native float getFloat(Object array, int index) throws`

IllegalArgumentException, ArrayIndexOutOfBoundsException

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `float` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `float`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `float` value.

getInt

public static native int getInt(Object array, int index) throws IllegalArgumentException, ArrayIndexOutOfBoundsException

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `int` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `int`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `int` value.

getLength

`public static native int getLength(Object array) throws IllegalArgumentException`

Parameters

`array`

An array object.

Returns

The length of the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array.

Description

This method returns the length of the array.

getLong

`public static native long getLong(Object array, long index) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `long` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `long`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `long` value.

getShort

`public static native short getShort(Object array, short index) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

Returns

The `short` value at the given index in the specified array.

Throws

`IllegalArgumentException`

If the given object is not an array, or the object at the given index cannot be converted to a `short`.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method returns the object at the given index in the array as a `short` value.

newInstance

`public static Object newInstance(Class componentType, int length) throws NegativeArraySizeException`

Parameters

`componentType`

The type of each element in the array.

`length`

The length of the array.

Returns

An array object that contains elements of the given component type and has the specified length.

Throws

`NegativeArraySizeException`

If `length` is negative.

`NullPointerException`

If `componentType` is `null`.

Description

This method creates a single-dimension array with the given length and component type.

`public static Object newInstance(Class componentType, int[] dimensions) throws IllegalArgumentException, NegativeArraySizeException`

Parameters

`componentType`

The type of each element in the array.

`dimensions`

An array that specifies the dimensions of the array to be created.

Returns

An array object that contains elements of the given component type and has the specified number of dimensions.

Throws

`IllegalArgumentException`

If `dimensions` has zero dimensions itself, or if it has too many dimensions (typically 255 array dimensions are supported).

`NegativeArraySizeException`

If `length` is negative.

`NullPointerException`

If `componentType` is `null`.

Description

This method creates a multidimensional array with the given dimensions and component type.

set

`public static native void set(Object array, int index, Object value) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

`value`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if it represents an array of primitive values, and the given value cannot be unwrapped and converted to that primitive type.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the object at the given index in the array to the specified value. If the array contains values of a primitive type, the given value is automatically unwrapped before it is put in the array.

setBoolean

`public static native void setBoolean(Object array, int index, boolean z) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

`z`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `boolean` value.

setByte

```
public static native void setByte(Object array, int index, byte b) throws
IllegalArgumentException, ArrayIndexOutOfBoundsException
```

Parameters

`array`

An array object.

`index`

An index into the array.

`b`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `byte` value.

setChar

`public static native void setChar(Object array, int index, char c) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

`c`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `char` value.

setDouble

`public static native void setDouble(Object array, int index, double d) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

`d`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `double` value.

setFloat

```
 public static native void setFloat(Object array, int index, float f) throws
IllegalArgumentException, ArrayIndexOutOfBoundsException
```

Parameters

`array`

An array object.

`index`

An index into the array.

`f`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `float` value.

setInt

public static native void setInt(Object array, int index, int i) throws IllegalArgumentException, ArrayIndexOutOfBoundsException

Parameters

`array`

An array object.

`index`

An index into the array.

`i`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `int` value.

setLong

public static native void setLong(Object array, int index, long l) throws IllegalArgumentException, ArrayIndexOutOfBoundsException

Parameters

`array`

An array object.

`index`

An index into the array.

`l`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `long` value.

setShort

`public static native void setShort(Object array, int index, short s) throws IllegalArgumentException, ArrayIndexOutOfBoundsException`

Parameters

`array`

An array object.

`index`

An index into the array.

`s`

The new value.

Throws

`IllegalArgumentException`

If the given object is not an array, or if the given value cannot be converted to the component type of the array.

`ArrayIndexOutOfBoundsException`

If the given index is invalid.

`NullPointerException`

If `array` is `null`.

Description

This method sets the element at the given index in the array to the given `short` value.

14. The java.math Package

Contents:

The package `java.math` is new as of Java 1.1. It contains two classes that support arithmetic on arbitrarily large integers and floating-point numbers. Figure 14.1 shows the class hierarchy for the `java.math` package.

Figure 14.1: The java.math package

[Graphic: Figure 14-1]

BigDecimal

Name

BigDecimal

Synopsis

Class Name:

```
java.math.BigDecimal
```

Superclass:

```
java.lang.Number
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

The `BigDecimal` class represents arbitrary-precision rational numbers. A `BigDecimal` object provides a good way to represent a real number that exceeds the range or precision that can be represented by a `double` value or the rounding that is done on a `double` value is unacceptable.

The representation for a `BigDecimal` consists of an unlimited precision integer value and an integer scale factor. The scale factor indicates a power of 10 that the integer value is implicitly divided by. For example, a `BigDecimal` would represent the value 123.456 with an integer value of 123456 and the scale factor of 3. Note that the scale factor cannot be negative and a `BigDecimal` cannot overflow.

Most of the methods in `BigDecimal` perform mathematical operations or make comparisons with other `BigDecimal` objects. Operations that result in some loss of precision, such as division, require a rounding method to be specified. The `BigDecimal` class defines constants to represent the different rounding methods. The rounding method determines if the digit before a discarded fraction is rounded up or left unchanged.

Class Summary

```
public class java.math.BigDecimal extends java.lang.Number {
  // Constants
  public static final int ROUND_CEILING;
  public static final int ROUND_DOWN;
  public static final int ROUND_FLOOR;
  public static final int ROUND_HALF_DOWN;
  public static final int ROUND_HALF_EVEN;
  public static final int ROUND_HALF_UP;
  public static final int ROUND_UNNECESSARY;
  public static final int ROUND_UP;
  // Constructors
  public BigDecimal(double val);
  public BigDecimal(String val);
  public BigDecimal(BigInteger val);
  public BigDecimal(BigInteger val, int scale);
  // Class Methods
  public static BigDecimal valueOf(long val);
  public static BigDecimal valueOf(long val, int scale);
  // Instance Methods
  public BigDecimal abs();
  public BigDecimal add(BigDecimal val);
  public int compareTo(BigDecimal val);
  public BigDecimal divide(BigDecimal val, int roundingMode);
  public BigDecimal divide(BigDecimal val, int scale, int roundingMode);
  public double doubleValue();
  public boolean equals(Object x);
  public float floatValue();
  public int hashCode();
  public int intValue();
  public long longValue();
  public BigDecimal max(BigDecimal val);
  public BigDecimal min(BigDecimal val);
  public BigDecimal movePointLeft(int n);
  public BigDecimal movePointRight(int n);
  public BigDecimal multiply(BigDecimal val);
  public BigDecimal negate();
  public int scale();
  public BigDecimal setScale(int scale);
  public BigDecimal setScale(int scale, int roundingMode);
  public int signum();
  public BigDecimal subtract(BigDecimal val);
  public BigInteger toBigInteger();
  public String toString();
}
```

Constants

ROUND_CEILING

public static final int ROUND_CEILING

Description

> A rounding method that rounds towards positive infinity. Under this method, the value is rounded to the least integer greater than or equal to its value. For example, 2.5 rounds to 3 and -2.5 rounds to -2.

ROUND_DOWN

public static final int ROUND_DOWN

Description

> A rounding method that rounds towards zero by truncating. For example, 2.5 rounds to 2 and -2.5 rounds to -2.

ROUND_FLOOR

public static final int ROUND_FLOOR

Description

A rounding method that rounds towards negative infinity. Under this method, the value is rounded to the greatest integer less than or equal to its value. For example, 2.5 rounds to 2 and -2.5 rounds to -3.

ROUND_HALF_DOWN

public static final int ROUND_HALF_DOWN

Description

A rounding method that increments the digit prior to a discarded fraction if the fraction is greater than 0.5; otherwise, the digit is left unchanged. For example, 2.5 rounds to 2, 2.51 rounds to 3, -2.5 rounds to -2, and -2.51 rounds to -3.

ROUND_HALF_EVEN

public static final int ROUND_HALF_EVEN

Description

A rounding method that behaves like `ROUND_HALF_UP` if the digit prior to the discarded fraction is odd; otherwise it behaves like `ROUND_HALF_DOWN`. For example, 2.5 rounds to 2, 3.5 rounds to 4, -2.5 rounds to -2, and -3.5 rounds to -4.

ROUND_HALF_UP

public static final int ROUND_HALF_UP

Description

A rounding method that increments the digit prior to a discarded fraction if the fraction is greater than or equal to 0.5; otherwise, the digit is left unchanged. For example, 2.5 rounds to 3, 2.49 rounds to 2, -2.5 rounds to -3, and -2.49 rounds to -2.

ROUND_UNNECESSARY

public static final int ROUND_UNNECESSARY

Description

A constant that specifies that rounding is not necessary. If the result really does require rounding, an `ArithmeticException` is thrown.

ROUND_UP

public static final int ROUND_UP

Description

A rounding method that rounds away from zero by truncating. For example, 2.5 rounds to 3 and -2.5 rounds to -3.

Constructors

BigDecimal

public BigDecimal(double val) throws NumberFormatException

Parameters

`val`

The initial value.

Throws

`NumberFormatException`

If the `double` has any of the special values: `Double.NEGATIVE_INFINITY`, `Double.POSITIVE_INFINITY`, or `Double.NaN`.

Description

This constructor creates a `BigDecimal` with the given initial value. The scale of the `BigDecimal` that is created is the smallest value such that (`10^scale x val`) is an integer.

public BigDecimal(String val) throws NumberFormatException

Parameters

`val`

The initial value.

Throws

`NumberFormatException`

If the string cannot be parsed into a valid `BigDecimal`.

Description

This constructor creates a `BigDecimal` with the initial value specified by the `String`. The string can contain an optional minus sign, followed by zero or more decimal digits, followed by an optional fraction. The fraction must contain a decimal point and zero or more decimal digits. The string must contain as least one digit in the integer or fractional part. The scale of the `BigDecimal` that is created is equal to the number of digits to the right of the decimal point or 0 if there is no decimal point. The mapping from characters to digits is provided by the `Character.digit()` method.

public BigDecimal(BigInteger val)

Parameters

`val`

The initial value.

Description

This constructor creates a `BigDecimal` whose initial value comes from the given `BigInteger`. The scale of the `BigDecimal` that is created is 0.

`public BigDecimal(BigInteger val, int scale) throws NumberFormatException`

Parameters

`val`

The initial value.

`scale`

The initial scale.

Throws

`NumberFormatException`

If `scale` is negative.

Description

This constructor creates a `BigDecimal` from the given parameters. The `scale` parameter specifies how many digits of the supplied `BigInteger` fall to the right of the decimal point.

Class Methods

valueOf

public static BigDecimal valueOf(long val)

Parameters

`val`

The initial value.

Returns

A `BigDecimal` that represents the given value.

Description

This method creates a `BigDecimal` from the given `long` value. The scale of the `BigDecimal` that is created is 0.

`public static BigDecimal valueOf(long val, int scale) throws NumberFormatException`

Parameters

`val`

The initial value.

`scale`

The initial scale.

Returns

A `BigDecimal` that represents the given value and scale.

Throws

`NumberFormatException`

If `scale` is negative.

Description

This method creates a `BigDecimal` from the given parameters. The `scale` parameter specifies how many digits of the supplied `long` fall to the right of the decimal point.

Instance Methods

abs

public BigDecimal abs()

Returns

A `BigDecimal` that contains the absolute value of this number.

Description

This method returns the absolute value of this `BigDecimal`. If this `BigDecimal` is nonnegative, it is returned. Otherwise, a new `BigDecimal` that contains the absolute value of this `BigDecimal` is returned. The scale of the new `BigDecimal` is the same as that of this `BigDecimal`.

add

public BigDecimal add(BigDecimal val)

Parameters

`val`

The number to be added.

Returns

A new `BigDecimal` that contains the sum of this number and the given value.

Description

This method returns the sum of this `BigDecimal` and the given `BigDecimal` as a new `BigDecimal`. The value of the new `BigDecimal` is the sum of the values of the two `BigDecimal` objects being added; the scale is the maximum of their two scales.

compareTo

public int compareTo(BigDecimal val)

Parameters

`val`

The number to be compared.

Returns

`-1` if this number is less than `val`, `0` if this number is equal to `val`, or `1` if this number is greater than `val`.

Description

This method compares this `BigDecimal` to the given `BigDecimal` and returns a value that indicates the result of the comparison. The method considers two `BigDecimal` objects that have the same values but different scales to be equal. This method can be used to implement all six of the standard boolean comparison operators: `==`, `!=`, `<=`, `<`, `>=`, and `>`.

divide

public BigDecimal divide(BigDecimal val, int roundingMode) throws ArithmeticException, IllegalArgumentException

Parameters

`val`

The divisor.

`roundingMode`

The rounding mode.

Returns

A new `BigDecimal` that contains the result (quotient) of dividing this number by the supplied value.

Throws

`ArithmeticException`

If `val` is `0`, or if `ROUND_UNNECESSARY` is specified for the rounding mode but rounding is necessary.

`IllegalArgumentException`

If `roundingMode` is not a valid value.

Description

This method returns the quotient that results from dividing this `BigDecimal` by the given `BigDecimal` and applying the specified rounding mode. The quotient is returned as a new `BigDecimal` that has the same scale as the scale of this `BigDecimal` scale. One of the rounding constants must be specified for the rounding mode.

public BigDecimal divide(BigDecimal val, int scale, int roundingMode) throws ArithmeticException, IllegalArgumentException

Parameters

`val`

The divisor.

`scale`

The scale for the result.

`roundingMode`

The rounding mode.

Returns

A new `BigDecimal` that contains the result (quotient) of dividing this number by the supplied value.

Throws

`ArithmeticException`

If `val` is `0`, if `scale` is less than zero, or if `ROUND_UNNECESSARY` is specified for the rounding mode but rounding is necessary.

`IllegalArgumentException`

If `roundingMode` is not a valid value.

Description

This method returns the quotient that results from dividing dividing this `BigDecimal` by the given `BigDecimal` and applying the specified rounding mode. The quotient is returned as a new `BigDecimal` that has the given scale. One of the rounding constants must be specified for the rounding mode.

doubleValue

public double doubleValue()

Returns

The value of this `BigDecimal` as a `double`.

Overrides

`Number.doubleValue()`

Description

This method returns the value of this `BigDecimal` as a `double`. If the value exceeds the limits of a `double`, `Double.POSITIVE_INFINITY` or `Double.NEGATIVE_INFINITY` is returned.

equals

public boolean equals(Object x)

Parameters

`x`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `x` is an instance of `BigDecimal`, and it represents the same value as this `BigDecimal`. In order to be considered equal using this method, two `BigDecimal` objects must have the same values and scales.

floatValue

public float floatValue()

Returns

The value of this `BigDecimal` as a `float`.

Overrides

`Number.floatValue()`

Description

This method returns the value of this `BigDecimal` as a `float`. If the value exceeds the limits of a `float`, `Float.POSITIVE_INFINITY` or `Float.NEGATIVE_INFINITY` is returned.

hashCode

public int hashCode()

Returns

A hashcode for this object.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this `BigDecimal`.

intValue

public int intValue()

Returns

The value of this `BigDecimal` as an `int`.

Overrides

`Number.intValue()`

Description

This method returns the value of this `BigDecimal` as an `int`. If the value exceeds the limits of an `int`, the excessive high-order bits are discarded. Any fractional part of this `BigDecimal` is truncated.

longValue

public long longValue()

Returns

The value of this `BigDecimal` as a `long`.

Overrides

`Number.longValue()`

Description

This method returns the value of this `BigDecimal` as a `long`. If the value exceeds the limits of a `long`, the excessive high-order bits are discarded. Any fractional part of this `BigDecimal` is also truncated.

max

public BigDecimal max(BigDecimal val)

Parameters

`val`

The number to be compared.

Returns

The `BigDecimal` that represents the greater of this number and the given value.

Description

This method returns the greater of this `BigDecimal` and the given `BigDecimal`.

min

public BigDecimal min(BigDecimal val)

Parameters

`val`

The number to be compared.

Returns

The `BigDecimal` that represents the lesser of this number and the given value.

Description

This method returns the lesser of this `BigDecimal` and the given `BigDecimal`.

movePointLeft

public BigDecimal movePointLeft(int n)

Parameters

`n`

The number of digits to move the decimal point to the left.

Returns

A new `BigDecimal` that contains the adjusted number.

Description

This method returns a `BigDecimal` that is computed by shifting the decimal point of this `BigDecimal` left by the given number of digits. If `n` is nonnegative, the value of the new `BigDecimal` is the same as the current value, and the scale is increased by `n`. If `n` is negative, the method call is equivalent to `movePointRight(-n)`.

movePointRight

public BigDecimal movePointRight(int n)

Parameters

`n`

The number of digits to move the decimal point to the right.

Returns

A new `BigDecimal` that contains the adjusted number.

Description

This method returns a `BigDecimal` that is computed by shifting the decimal point of this `BigDecimal` right by the given number of digits. If `n` is nonnegative, the value of the new `BigDecimal` is the same as the current value, and the scale is decreased by `n`. If `n` is negative, the method call is equivalent to `movePointLeft(-n)`.

multiply

public BigDecimal multiply(BigDecimal val)

Parameters

`val`

The number to be multiplied.

Returns

A new `BigDecimal` that contains the product of this number and the given value.

Description

This method multiplies this `BigDecimal` and the given `BigDecimal`, and returns the result as a new `BigDecimal`. The value of the new `BigDecimal` is the product of the values of the two `BigDecimal` objects being added; the scale is the sum of their two scales.

negate

public BigDecimal negate()

Returns

A new `BigDecimal` that contains the negative of this number.

Description

This method returns a new `BigDecimal` that is identical to this `BigDecimal` except that its sign is reversed. The scale of the new `BigDecimal` is the same as the scale of this `BigDecimal`.

scale

public int scale()

Returns

The scale of this number.

Description

This method returns the scale of this `BigDecimal`.

setScale

`public BigDecimal setScale(int scale) throws ArithmeticException, IllegalArgumentException`

Parameters

`scale`

a The new scale.

Returns

A new `BigDecimal` that is identical to this number, except that is has the given scale.

Throws

`ArithmeticException`

If the new number cannot be calculated without rounding.

`IllegalArgumentException`

This exception is never thrown.

Description

This method creates a new `BigDecimal` that has the given scale and a value that is calculated by multiplying or dividing the value of this `BigDecimal` by the appropriate power of 10 to maintain the overall value. The method is typically used to increase the scale of a number, not decrease it. It can decrease the scale, however, if there are enough zeros in the fractional part of the value to allow for rescaling without loss of precision.

Calling this method is equivalent to calling `setScale(scale, BigDecimal.ROUND_UNNECESSARY)`.

`public BigDecimal setScale(int scale, int roundingMode) throws ArithmeticException, IllegalArgumentException`

Parameters

`scale`

The new scale.

`roundingMode`

The rounding mode.

Returns

A new `BigDecimal` that contains this number adjusted to the given scale.

Throws

`ArithmeticException`

If `scale` is less than zero, or if `ROUND_UNNECESSARY` is specified for the rounding mode but rounding is necessary.

`IllegalArgumentException`

If `roundingMode` is not a valid value.

Description

This method creates a new `BigDecimal` that has the given scale and a value that is calculated by multiplying or dividing the value of this `BigDecimal` by the appropriate power of 10 to maintain the overall value. When the scale is reduced, the value must be divided, so precision may be lost. In this case, the specified rounding mode is used.

signum

public int signum()

Returns

`-1` if this number is negative, `0` if this number is zero, or `1` if this number is positive.

Description

This method returns a value that indicates the sign of this `BigDecimal`.

subtract

public BigDecimal subtract(BigDecimal val)

Parameters

`val`

The number to be subtracted.

Returns

A new `BigDecimal` that contains the result of subtracting the given number from this number.

Description

This method subtracts the given `BigDecimal` from this `BigDecimal` and returns the result as a new `BigDecimal`. The value of the new `BigDecimal` is the result of subtracting the value of the given `BigDecimal` from this `BigDecimal`; the scale is the maximum of their two scales.

toBigInteger

public BigInteger toBigInteger()

Returns

The value of this `BigDecimal` as a `BigInteger`.

Description

This method returns the value of this `BigDecimal` as a `BigInteger`. The fractional part of this number is truncated.

toString

public String toString()

Returns

A string representation of this object.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `BigDecimal`. A minus sign represents the sign, and a decimal point is used to represent the scale. The mapping from digits to characters is provided by the `Character.forDigit()` method.

Inherited Methods

15. The java.net Package

Contents:

The package `java.net` contains classes and interfaces that provide a powerful infrastructure for networking in Java. These include:

- The `URL` class for basic access to Uniform Resource Locators (URLs).

- The URLConnection class, which supports more complex operations on URLs.

- The Socket class for connecting to particular ports on specific Internet hosts and reading and writing data using streams.

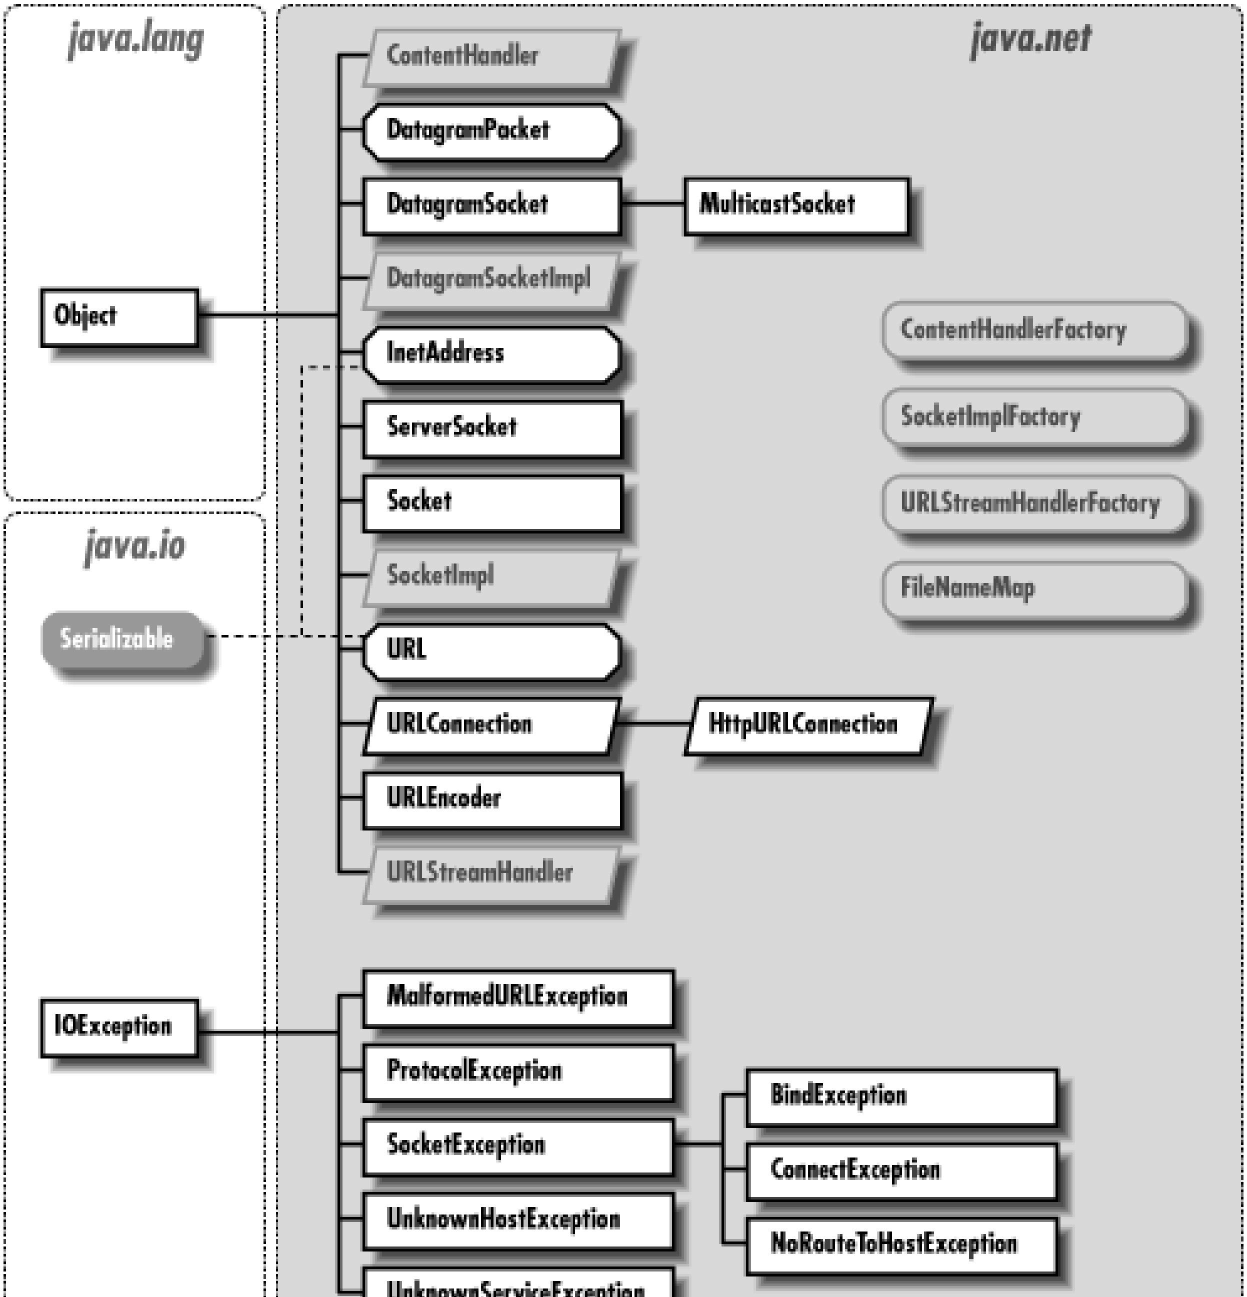
- The ServerSocket class for implementing servers that accept connections from clients.

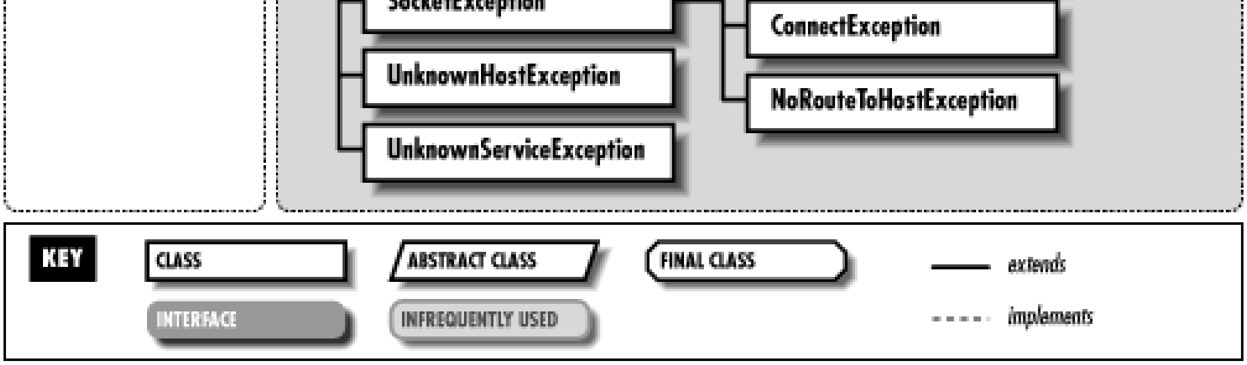
- The DatagramSocket, MulticastSocket, and DatagramPacket classes for implementing low-level networking.

- The InetAddress class, which represents Internet addresses.

Figure 15.1 shows the class hierarchy for the java.net package.

Figure 15.1: The java.net package





BindException

Name

BindException

Synopsis

Class Name:

```
java.net.BindException
```

Superclass:

```
java.net.SocketException
```

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

New as of JDK 1.1

Description

A `BindException` is thrown when a socket cannot be bound to a local address and port, which can occur if the port is already in use or the address is unavailable.

Class Summary

```
public class java.net.BindException extends java.net.SocketException {
  // Constructors
  public BindException();
  public BindException(String msg);
}
```

Constructors

BindException

public BindException()

Description

> This constructor `create`s a `BindException` with no associated detail message.

public BindException(String msg)

Parameters

> `msg`
>
> > The detail message.

Description

> This constructor creates a `BindException` with the specified detail message.

Inherited Methods

Method	Inherited From	Method	Inherited From

16. The java.text Package

Contents:

The package `java.text` is new as of Java 1.1. It contains classes that support the internationalization of Java programs. The internationalization classes can be grouped as follows:

- Classes for formatting string representations of dates, times, numbers, and messages based on the conventions of a locale.
- Classes that collate strings according to the rules of a locale.

- Classes for finding boundaries in text according to the rules of a locale.

Many of the classes in `java.text` rely upon a `java.util.Locale` object to provide information about the locale that is in use.

The `Format` class is the superclass of all of the classes that generate and parse string representations of various types of data. The `DateFormat` class formats and parses dates and times according to the customs and language of a particular locale. Similarly, the `NumberFormat` class formats and parses numbers, including currency values, in a locale-dependent manner.

The `MessageFormat` class can create a textual message from a pattern string, while `ChoiceFormat` maps numerical ranges to strings. By themselves, these classes do not provide different results for different locales. However, they can be used in conjunction with `java.util.ResourceBundle` objects that generate locale-specific pattern strings.

The `Collator` class handles collating strings according to the rules of a particular locale. Different languages have different characters and different rules for sorting those characters; `Collator` and its subclass, `RuleBasedCollator`, are designed to take those differences into account when collating strings. In addition, the `CollationKey` class can be used to optimize the sorting of a large collection of strings.

The `BreakIterator` class finds various boundaries, such as word boundaries and line boundaries, in textual data. Again, `BreakIterator` locates these boundaries according to the rules of a particular locale.

Figure 16.1 shows the class hierarchy for the `java.text` package.

Figure 16.1: The java.text package

[Graphic: Figure 16-1]

BreakIterator

Name

BreakIterator

Synopsis

Class Name:

```
java.text.BreakIterator
```

Superclass:

java.lang.Object

Immediate Subclasses:

None

Interfaces Implemented:

java.lang.Cloneable, java.io.Serializable

Availability:

New as of JDK 1.1

Description

The BreakIterator class is an abstract class that defines methods that find the locations of boundaries in text, such as word boundaries and sentence boundaries. A BreakIterator operates on the object passed to its setText() method; that object must implement the CharacterIterator interface or be a String object. When a String is passed to setText(), the BreakIterator creates an internal StringCharacterIterator to iterate over the String.

When you use a BreakIterator, you call first() to get the location of the first boundary and then repeatedly call next() to iterate through the subsequent boundaries.

The BreakIterator class defines four static factory methods that return instances of BreakIterator that locate various kinds of boundaries. Each of these factory methods selects a concrete subclass of BreakIterator based either on the default locale or a specified locale. You must create a separate instance of BreakIterator to handle each kind of boundary you are trying to locate:

- getWordInstance() returns an iterator that locates word boundaries, which is useful for search-and-replace operations. A word iterator correctly handles punctuation marks.

- getSentenceInstance() returns an iterator that locates sentence boundaries, which is useful for textual selection. A sentence iterator correctly handle punctuation marks.

- getLineInstance() returns an iterator that locates line boundaries, which is useful in line wrapping. A line iterator correctly handles hyphenation and punctuation.

- `getCharacterInstance()` returns an iterator that locates boundaries between characters, which is useful for allowing the cursor to interact with characters appropriately, since some characters are stored as a base character and a diacritical mark, but only represent one display character.

Class Summary

```
public abstract class java.util.BreakIterator extends java.lang.Object
                      implements java.lang.Cloneable,
                                 java.io.Serializable {
  // Constants
  public final static int DONE;
  // Constructors
  protected BreakIterator();
  // Class Methods
  public static synchronized Locale[] getAvailableLocales();
  public static BreakIterator getCharacterInstance();
  public static BreakIterator getCharacterInstance(Locale where);
  public static BreakIterator getLineInstance();
  public static BreakIterator getLineInstance(Locale where);
  public static BreakIterator getSentenceInstance();
  public static BreakIterator getSentenceInstance(Locale where);
  public static BreakIterator getWordInstance();
  public static BreakIterator getWordInstance(Locale where);
  // Instance Methods
  public Object clone();
  public abstract int current();
  public abstract int first();
  public abstract int following(int offset);
  public abstract CharacterIterator getText();
  public abstract int last();
  public abstract int next();
  public abstract int next(int n)
  public abstract int previous();
  public abstract void setText(CharacterIterator newText);
  public void setText(String newText);
}
```

Constants

DONE

public final static int DONE

Description

> A constant that is returned by `next()` or `previous()` if there are no more breaks to be returned.

Constructors

BreakIterator

protected BreakIterator()

Description

> This constructor should be called only from constructors of subclasses.

Class Methods

getAvailableLocales

public static synchronized Locale[] getAvailableLocales()

Returns

> An array of `Locale` objects.

Description

> This method returns an array of the `Locale` objects that can be passed to `getCharacterInstance()`, `getLineInstance()`, `getSentenceInstance()`, or `getWordInstance()`.

getCharacterInstance

public static BreakIterator getCharacterInstance()

Returns

A `BreakIterator` appropriate for the default `Locale`.

Description

This method creates a `BreakIterator` that can locate character boundaries in the default `Locale`.

public static BreakIterator getCharacterInstance(Locale where)

Parameters

`where`

The `Locale` to use.

Returns

A `BreakIterator` appropriate for the given `Locale`.

Description

This method creates a `BreakIterator` that can locate character boundaries in the given `Locale`.

getLineInstance

public static BreakIterator getLineInstance()

Returns

A `BreakIterator` appropriate for the default `Locale`.

Description

This method creates a `BreakIterator` that can locate line boundaries in the default `Locale`.

public static BreakIterator getLineInstance(Locale where)

Parameters

`where`

The `Locale` to use.

Returns

A `BreakIterator` appropriate for the given `Locale`.

Description

This method creates a `BreakIterator` that can locate line boundaries in the given `Locale`.

getSentenceInstance

public static BreakIterator getSentenceInstance()

Returns

A `BreakIterator` appropriate for the default `Locale`.

Description

This method creates a `BreakIterator` that can locate sentence boundaries in the default `Locale`.

public static BreakIterator getSentenceInstance(Locale where)

Parameters

`where`

The `Locale` to use.

Returns

A `BreakIterator` appropriate for the given `Locale`.

Description

This method creates a `BreakIterator` that can locate sentence boundaries in the given `Locale`.

getWordInstance

public static BreakIterator getWordInstance()

Returns

A `BreakIterator` appropriate for the default `Locale`.

Description

This method creates a `BreakIterator` that can locate word boundaries in the default `Locale`.

public static BreakIterator getWordInstance(Locale where)

Parameters

`where`

The `Locale` to use.

Returns

A `BreakIterator` appropriate for the given `Locale`.

Description

This method creates a `BreakIterator` that can locate word boundaries in the given `Locale`.

Instance Methods

clone

public Object clone()

Returns

A copy of this `BreakIterator`.

Overrides

`Object.clone()`

Description

This method creates a copy of this `BreakIterator` and then returns it.

current

public abstract int current()

Returns

The current position of this `BreakIterator`.

Description

This method returns the current position of this `BreakIterator`. The current position is the character index of the most recently returned boundary.

first

public abstract int first()

Returns

The position of the first boundary of this `BreakIterator`.

Description

This method finds the first boundary in this `BreakIterator` and returns its character index. The current position of the iterator is set to this boundary.

following

public abstract int following(int offset)

Parameters

`offset`

An offset into this `BreakIterator`.

Returns

The position of the first boundary after the given offset of this `BreakIterator` or `DONE` if there are no more boundaries.

Throws

`IllegalArgumentException`

If `offset` is not a valid value for the `CharacterIterator` of this `BreakIterator`.

Description

This method finds the first boundary after the given offset in this `BreakIterator` and returns its character index.

getText

public abstract CharacterIterator getText()

Returns

The `CharacterIterator` that this `BreakIterator` uses.

Description

This method returns a `CharacterIterator` that represents the text this `BreakIterator` examines.

last

public abstract int last()

Returns

The position of the last boundary of this `BreakIterator`.

Description

This method finds the last boundary in this `BreakIterator` and returns its character index. The current position of the iterator is set to this boundary.

next

public abstract int next()

Returns

The position of the next boundary of this `BreakIterator` or `DONE` if there are no more boundaries.

Description

This method finds the next boundary in this `BreakIterator` after the current position and returns its character index. The current position of the iterator is set to this boundary.

public abstract int next(int n)

Parameters

`n`

The boundary to return. A positive value moves to a later boundary a negative value moves to a previous boundary; the value 0 does nothing.

Returns

The position of the requested boundary of this `BreakIterator`.

Description

This method finds the `n`th boundary in this `BreakIterator`, starting from the current position, and returns its character index. The current position of the iterator is set to this boundary.

For example, `next(-2)` finds the third previous boundary. Thus `next(1)` is equivalent to `next()`, `next(-1)` is equivalent to `previous()`, and `next(0)` does nothing.

previous

public abstract int previous()

Returns

The position of the previous boundary of this `BreakIterator`.

Description

This method finds the previous boundary in this `BreakIterator`, starting from the current position, and returns its character index. The current position of the iterator is set to this boundary.

setText

public abstract void setText(CharacterIterator newText)

Parameters

`newText`

The `CharacterIterator` that contains the text to be examined.

Description

This method tells this `BreakIterator` to examine the piece of text specified by the `CharacterIterator`. This current position of this `BreakIterator` is set to `first()`.

public void setText(String newText)

Parameters

`newText`

The `String` that contains the text to be examined.

Description

This method tells this `BreakIterator` to examine the piece of text specified by the `String`, using a `StringCharacterIterator` created from the given string. This current position of this `BreakIterator` is set to `first()`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`equals(Object)`	`Object`	`finalize()`	`Object`
`getClass()`	`Object`	`hashCode()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`

17. The java.util Package

Contents:

The package `java.util` contains a number of useful classes and interfaces. Although the name of the package might imply that these are utility classes, they are really more important than that. In fact, Java depends directly on several of the classes in this package, and many programs will find these classes indispensable. The classes and interfaces in `java.util` include:

- The `Hashtable` class for implementing hashtables, or associative arrays.
- The `Vector` class, which supports variable-length arrays.
- The `Enumeration` interface for iterating through a collection of elements.
- The `StringTokenizer` class for parsing strings into distinct tokens separated by delimiter characters.
- The `EventObject` class and the `EventListener` interface, which form the basis of the new AWT event model in Java 1.1.
- The `Locale` class in Java 1.1, which represents a particular locale for internationalization purposes.
- The `Calendar` and `TimeZone` classes in Java. These classes interpret the value of a `Date` object in the context of a particular calendar system.
- The `ResourceBundle` class and its subclasses, `ListResourceBundle` and `PropertyResourceBundle`, which represent sets of localized data in Java 1.1.

Figure 17.1 shows the class hierarchy for the `java.util` package.

Figure 17.1: The java.util package

[Graphic: Figure 17-1]

BitSet

Name

Synopsis

Class Name:

`java.util.BitSet`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.lang.Cloneable`, `java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `BitSet` class implements a set of bits. The set grows in size as needed. Each element of a `BitSet` has a boolean value. When a `BitSet` object is created, all of the bits are set to `false` by default. The bits in a `BitSet` are indexed by nonnegative integers, starting at 0. The size of a `BitSet` is the number of bits that it currently contains. The `BitSet` class provides methods to set, clear, and retrieve the values of the individual bits in a `BitSet`. There are also methods to perform logical AND, OR, and XOR operations.

Class Summary

```
public final class java.util.BitSet extends java.lang.Object
                   implements java.lang.Cloneable, java.io.Serializable {
  // Constructors
  public BitSet();
  public BitSet(int nbits);
  // Instance Methods
  public void and(BitSet set);
  public void clear(int bit);
  public Object clone();
  public boolean equals(Object obj);
  public boolean get(int bit);
  public int hashCode();
  public void or(BitSet set);
  public void set(int bit);
  public int size();
  public String toString();
  public void xor(BitSet set);
}
```

Constructors

BitSet

public BitSet()

Description

> This constructor creates `a BitSet` with a default size of 64 bits. All of the bits in the `BitSet` are initially set to `false`.

public BitSet(int nbits)

Parameters

> `nbits`
>
> > The initial number of bits.

Description

> This constructor creates a `BitSet` with a size of `nbits`. All of the bits in the `BitSet` are initially set to `false`.

Instance Methods

and

public void and(BitSet set)

Parameters

set

The BitSet to AND with this BitSet.

Description

This method computes the logical AND of this BitSet and the specified BitSet and stores the result in this BitSet. In other words, for each bit in this BitSet, the value is set to only true if the bit is already true in this BitSet and the corresponding bit in set is true.

If the size of set is greater than the size of this BitSet, the extra bits in set are ignored. If the size of set is less than the size of this BitSet, the extra bits in this BitSet are set to false.

clear

public void clear(int bit)

Parameters

bit

The index of the bit to clear.

Description

This method sets the bit at the given index to false. If bit is greater than or equal to the number of bits in the BitSet, the size of the BitSet is increased so that it contains bit values. All of the additional bits are set to false.

clone

public Object clone()

Returns

A copy of this BitSet.

Overrides

`Object.clone()`

Description

This method creates a copy of this `BitSet` and returns it. In other words, the returned `BitSet` has the same size as this `BitSet`, and it has the same bits set to `true`.

equals

public boolean equals(Object obj)

Parameters

`obj`

The object to be compared with this object.

Returns

`true` if the objects are equal; `false` if they are not.

Overrides

`Object.equals()`

Description

This method returns `true` if `obj` is an instance of `BitSet` and it contains the same bit values as the object this method is associated with. In other words, this method compares each bit of this `BitSet` with the corresponding bit of `obj`. If any bits do not match, the method returns `false`. If the size of this `BitSet` is different than `obj`, the extra bits in either this `BitSet` or in `obj` must be `false` for this method to return `true`.

get

public boolean get(int bit)

Parameters

`bit`

The index of the bit to retrieve.

Returns

The `boolean` value of the bit at the given index.

Description

This method returns the value of the given bit. If `bit` is greater than or equal to the number of bits in the `BitSet`, the method returns `false`.

hashCode

public int hashCode()

Returns

The hashcode for this `BitSet`.

Overrides

`Object.hashCode()`

Description

This method returns a hashcode for this object.

or

public void or(BitSet set)

Parameters

`set`

The `BitSet` to OR with this `BitSet`.

Description

This method computes the logical OR of this `BitSet` and the specified `BitSet`, and stores the result in this `BitSet`. In other words, for each bit in this `BitSet`, the value is set to `true` if the bit is already `true` in this `BitSet` or the corresponding bit in `set` is `true`.

If the size of `set` is greater than the size of this `BitSet`, this `BitSet` is first increased in size to accommodate the additional bits. All of the additional bits are initially set to `false`.

set

public void set(int bit)

Parameters

`bit`

The index of the bit to set.

Description

This method sets the bit at the given index to `true`. If `bit` is greater than or equal to the number of bits in the `BitSet`, the size of the `BitSet` is increased so that it contains `bit` values. All of the additional bits except the last one are set to `false`.

size

public int size()

Returns

The size of this `BitSet`.

Description

This method returns the size of this `BitSet`, which is the number of bits currently in the set.

toString

public String toString()

Returns

A string representation of this `BitSet`.

Overrides

`Object.toString()`

Description

This method returns a string representation of this `BitSet`. The string lists the indexes of all the bits in the `BitSet` that are `true`.

xor

public void xor(BitSet set)

Parameters

`set`

The `BitSet` to XOR with this `BitSet`.

Description

This method computes the logical XOR (exclusive OR) of this `BitSet` and the specified `BitSet` and stores the result in this `BitSet`. In other words, for each bit in this `BitSet`, the value is set to `true` only if the bit is already `true` in this `BitSet`, and the corresponding bit in `set` is `false`, or if the bit is `false` in this `BitSet` and the corresponding bit in `set` is `true`.

If the size of `set` is greater than the size of this `BitSet`, this `BitSet` is first increased in size to accommodate the additional bits. All of the additional bits are initially set to `false`.

Inherited Methods

Method	Inherited From	Method	Inherited From
`finalize()`	`Object`	`getClass()`	`Object`
`notify()`	`Object`	`notifyAll()`	`Object`

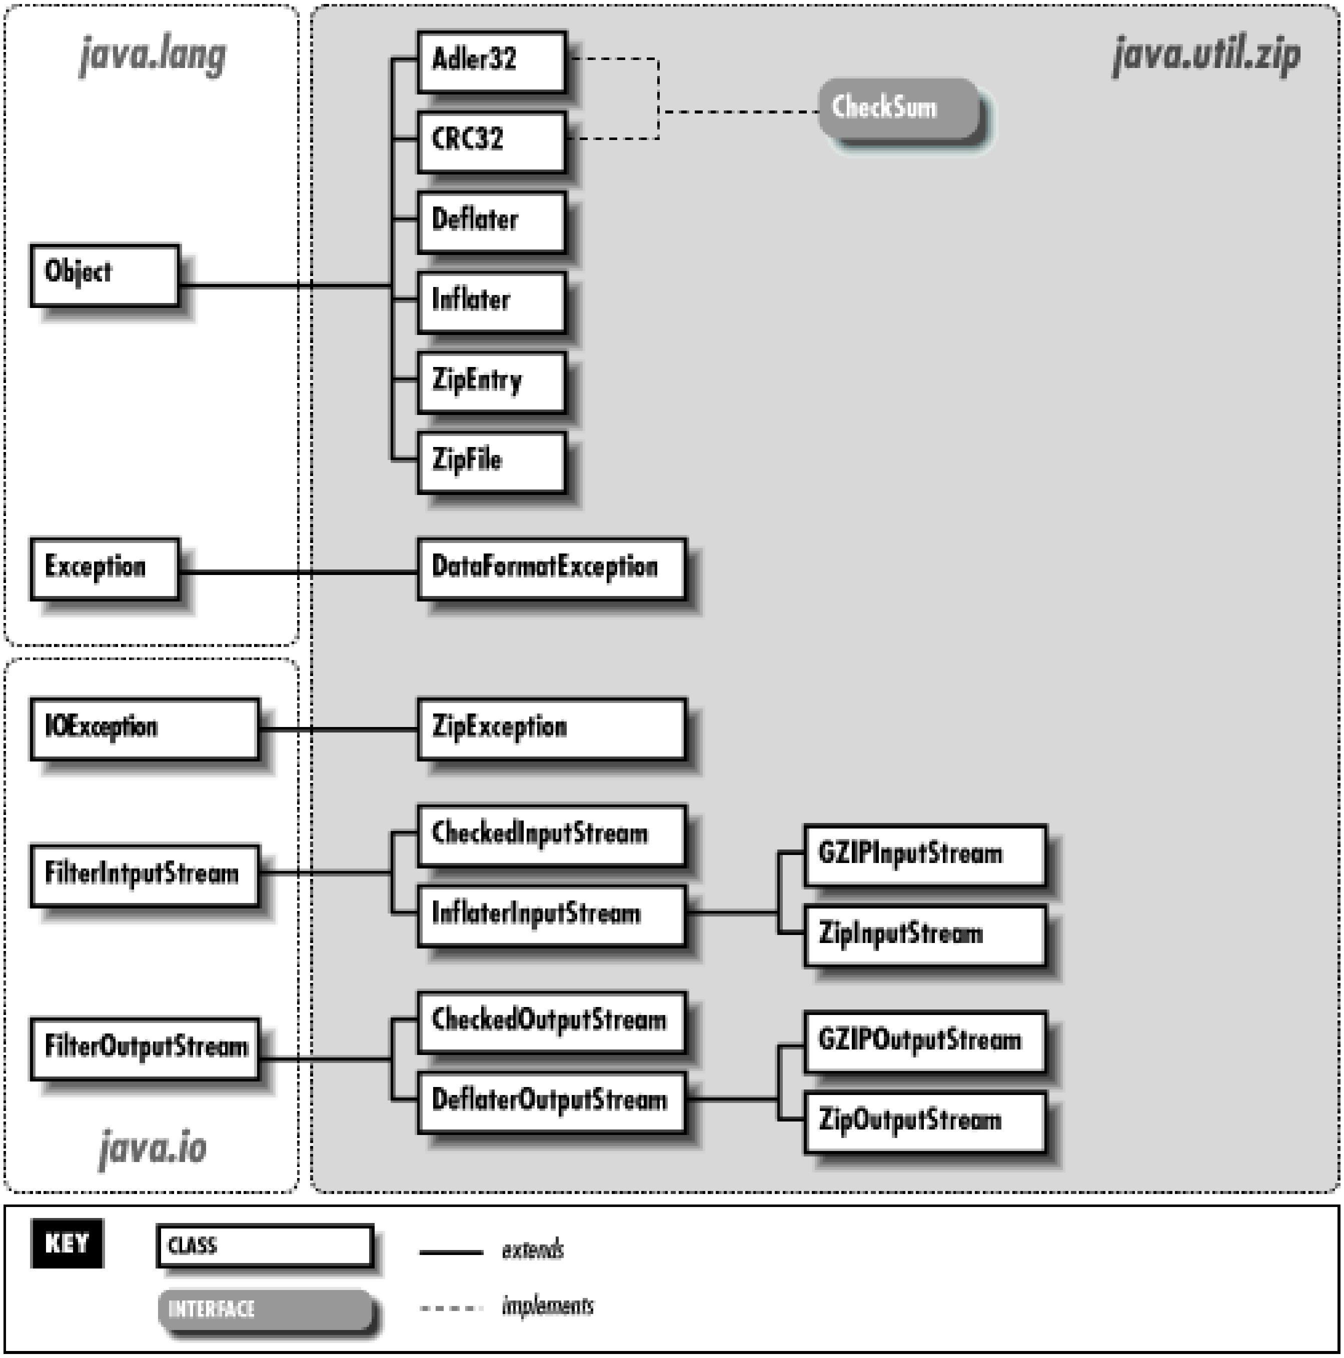
JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

18. The java.util.zip Package

Contents:

The package `java.util.zip` is new as of Java 1.1. It contains classes that provide support for general-purpose data compression and decompression using the ZLIB compression algorithms. The important classes in `java.util.zip` are those that provide the means to read and write data that is compatible with the popular GZIP and ZIP formats: `GZIPInputStream`, `GZIPOutputStream`, `ZipInputStream`, and `ZipOutputStream`. Figure 18.1 shows the class hierarchy for the `java.util.zip` package.

Figure 18.1: The java.text package



It is easy to use the GZIP and ZIP classes because they subclass `java.io.FilterInputStream` and `java.io.FilterOutputStream`. For example, to decompress GZIP data, you simply create a `GZIPInputStream` around the input stream that represents the compressed data. As with any `InputStream`, you could be reading from a file, a socket, or some other data source. You can then read decompressed data by calling the `read()` methods of the `GZIPInputStream`. The following code fragment creates a `GZIPInputStream` that reads data from the file *sample.gz* :

```
FileInputStream inFile;
try {
    inFile = new FileInputStream("sample.gz");
} catch (IOException e) {
    System.out.println("Couldn't open file.");
    return;
}
GZIPInputStream in = new GZIPInputStream(inFile);
// Now use in.read() to get decompressed data.
```

Similarly, you can compress data using the GZIP format by creating a `GZIPOutputStream` around an output stream and using the `write()` methods of `GZIPOutputStream`. The following code fragment creates a `GZIPOutputStream` that writes data to the file *sample.gz* :

```
FileOutputStream outFile;
try {
    outFile = new FileOutputStream("sample.gz");
} catch (IOException e) {
    System.out.println("Couldn't open file.");
    return;
}
GZIPOutputStream out = new GZIPOutputStream(outFile);
// Now use out.write() to write compressed data.
```

A ZIP file, or archive, is not quite as easy to use because it may contain more than one compressed file. A `ZipEntry` object represents each compressed file in the archive. When you are reading from a `ZipInputStream`, you must first call `getNextEntry()` to access an entry, and then you can read decompressed data from the stream, just like with a `GZIPInputStream`. When you are writing data to a `ZipOutputStream`, use `putNextEntry()` before you start writing each entry in the archive. The `ZipFile` class is provided as a convenience for reading an archive; it allows nonsequential access to the entries in a ZIP file.

The remainder of the classes in `java.util.zip` exist to support the GZIP and ZIP classes. The generic `Deflater` and `Inflater` classes implement the ZLIB algorithms; they are used by `DeflaterOutputStream` and `InflaterInputStream` to decompress and compress data. The `Checksum` interface and the classes that implement it, `Adler32` and `CRC32`, define algorithms that generate checksums from stream data. These checksums are used by the `CheckedInputStream` and `CheckedOutputStream` classes.

Adler32

Name

Adler32

Synopsis

Class Name:

`java.util.zip.Adler32`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.util.zip.Checksum`

Availability:

New as of JDK 1.1

Description

The `Adler32` class implements the `Checksum` interface using the Adler-32 algorithm. This algorithm is significantly faster than CRC-32 and almost as reliable.

Class Summary

```
public class java.util.zip.Adler32 extends java.lang.Object
             implements java.util.zip.Checksum {
  // Constructors
  public Adler32();

  // Instance Methods
  public long getValue();
  public void reset();
  public void update(int b);
  public void update(byte[] b);
  public native void update(byte[] b, int off, int len);
}
```

Constructors

Adler32

public Adler32()

Description

> This constructor creates an `Adler32` object.

Instance Methods

getValue

public long getValue()

Returns

> The current checksum value.

Implements

> `Checksum.getValue()`

Description

> This method returns the current value of this checksum.

reset

public void reset()

Implements

> `Checksum.reset()`

Description

This method resets the checksum to its initial value, making it appear as though it has not been updated by any data.

update

public void update(int b)

Parameters

`b`

The value to be added to the data stream for the checksum calculation.

Implements

`Checksum.update(int)`

Description

This method adds the specified value to the data stream and updates the checksum value. The method uses only the lowest eight bits of the given `int`.

public void update(byte[] b)

Parameters

`b`

An array of bytes to be added to the data stream for the checksum calculation.

Description

This method adds the bytes from the specified array to the data stream and updates the checksum value.

public native void update(byte[] b, int off, int len)

Parameters

`b`

An array of bytes to be added to the data stream for the checksum calculation.

`off`

An offset into the byte array.

`len`

The number of bytes to use.

Implements

`Checksum.update(byte[], int, int)`

Description

This method adds `len` bytes from the specified array, starting at `off`, to the data stream and updates the checksum value.

Inherited Methods

Method	Inherited From	Method	Inherited From
`clone()`	`Object`	`equals(Object)`	`Object`
`finalize()`	`Object`	`getClass()`	`Object`
`hashCode()`	`Object`	`notify()`	`Object`
`notifyAll()`	`Object`	`toString()`	`Object`
`wait()`	`Object`	`wait(long)`	`Object`
`wait(long, int)`	`Object`

Preface

Contents:

The Abstract Window Tookit (AWT) provides the user interface for Java programs. Unless you want to construct your own GUI or use a crude text-only interface, the AWT provides the tools you will use to communicate with the user. Although we are beginning to see some other APIs for building user interfaces, like Netscape's IFC (Internet Foundation Classes), those alternative APIs will not be in widespread use for some time, and some will be platform specific. Likewise, we are beginning to see automated tools for building GUIs in Java; Sun's JavaBeans effort promises to make such tools much more widespread. (In fact, the biggest changes in Java 1.1 prepare the way for using the various AWT components as JavaBeans.) However, even with automated tools and JavaBeans in the future, an in-depth knowledge of AWT is essential for the practicing Java programmer.

The major problem facing Java developers these days is that AWT is a moving target. Java 1.0.2 is being replaced by Java 1.1, with many significant new features. Java 1.1 was released on February 18, 1997, but it isn't clear how long it will take for 1.1 to be accepted in the market. The problem facing developers is not just learning about the new features and changes in Java 1.1, but also knowing when they can afford to use these new features in their code. In practice, this boils down to one question: when will Netscape Navigator support Java 1.1? Rumor has it that the answer is "as soon as possible"--and we all hope this rumor is correct. But given the realities of maintaining a very complex piece of software, and the fact that Netscape is currently in the beta process for Navigator 4.0, there's a possibility that "as soon as possible" and "soon" aren't the same thing. In other words, you should expect Java 1.0.2 to stick around for a while, especially since Web users won't all replace their browsers as soon as Navigator has 1.1 support.

This state of affairs raises obvious problems for my book. Nothing would have made me happier than to write a book that covered AWT 1.1 only. It would be significantly shorter, for one thing, and I wouldn't have to spend so much effort pointing out which features are present in which release. But that's not the current reality. For the time being, programmers still need to know about 1.0.2. Therefore, this book covers both releases thoroughly. There are many examples using 1.0.2; many more examples that require 1.1; and more examples showing you how to update 1.0.2 code to use 1.1's features.

Sun has done a good job of maintaining compatibility between versions: 1.0 code runs under Java 1.1, with very few exceptions. All of the 1.0 examples in this book have been tested under Java 1.1. However, Java 1.1--and particularly, AWT 1.1--offer many advantages over older releases. If nothing else, I hope this book convinces you that you should be looking forward to the day when you can forget about writing code for Java 1.0.2.

New Features of AWT in Java 1.1

Having spent all this time talking about 1.0.2 and 1.1 and the transitional state we're currently in and having alluded briefly to the advantages of Java 1.1, you deserve a brief summary of what has changed. Of course, you'll find the details in the book.

Improved event handling

> Java 1.1 provides a completely new event model. Instead of propagating events to all objects that might possibly have an interest, objects in Java 1.1 register their interest in particular kinds of events and get only the events they're interested in hearing. The old event model is still supported, but the new model is much more efficient.
>
> The new event model is also important in the context of JavaBeans. The old events were pretty much specific to AWT. The new model has been designed as a general purpose feature for communication between software components. Unfortunately, how to use events in this more general sense is beyond the scope of this book, but you should be aware that it's possible.

New components and containers

> Java 1.1 provides one new component, the `PopupMenu`, and one new container, the `ScrollPane`. Pop-up menus are a staple of modern user interfaces; providing them fixes a serious omission. `ScrollPane` makes it trivial to implement scrolling; in Java 1.0, you had to do scrolling "by hand." In Java 1.1, you also get menu shortcuts (i.e., the ability to select menu items using the keyboard), another standard feature of modern user interfaces.

Java 1.1 also introduces a `LightweightPeer`, which means that it is possible to create "lightweight components." To do so, you subclass `Component` or `Container` directly; this wasn't possible in earlier releases. For simple operations, lightweight components are much more efficient than full-fledged components.

Clipboards

Java 1.1 lets you read from and write to the system clipboard and create private clipboards for use by your programs. The clipboard facility is a down payment on a larger data transfer facility, which will support drag and drop. (No promises about when drag and drop will appear.)

Printing

Java 1.1 gives components the ability to print.

The rest

There are many other new features, including more flexible use of cursors; the ability to use system color schemes, and thus make your program look like other software in the run-time environment; more image filters to play with; and the ability to prescale an image.

Deprecated Methods and JavaBeans

One of the biggest changes in Java 1.1 doesn't concern the feature set at all. This was the addition of many new methods that differ from a method of Java 1.0 in name only. There are hundreds of these, particularly in AWT. The new method names show an important future direction for the AWT package (in fact, all of Java). The new names obey the naming conventions used by JavaBeans, which means that all AWT classes are potentially Beans. These conventions make it possible for an application builder to analyze what a component does based on its public methods. For example, the method `setFont()` changes the value of the component's `Font` property. In turn, this means that you will eventually be able to build user interfaces and, in some cases, entire applications, inside some other tool, without writing any Java code at all. An application builder will be able to find out what it needs to know about any component by looking at the component itself, and letting you customize the component and its interactions with others.

Comments in the JDK source code indicate that the older method names have been "deprecated," which means that you should consider the old names obsolete and avoid using them; they could disappear in a future release.

Reworking AWT to comply with JavaBeans is both necessary and inevitable. Furthermore, it's a good idea to get into the habit of following the same conventions for your own code; the advantages of

JavaBeans are much greater than the inconvenience of changing your coding style.

Other Changes in Java

Other new features are scattered throughout the rest of the Java classes, most notably, improvements in the networking and I/O packages and support for internationalization. Some new features were added to the language itself, of which the most important is "inner classes." For the most part, I don't discuss these changes; in fact, I stay away from them and base non-AWT code on the 1.0.2. release. Though these changes are important, covering the new material in AWT is enough for one book. If I used a new feature at this point, I would feel that I owed you an explanation, and this book is already long enough. A future edition will update the code so that it doesn't rely on any older features.

1. Abstract Window Toolkit Overview

Contents:

For years, programmers have had to go through the hassles of porting software from BSD-based UNIX to System V Release 4-based UNIX, from OpenWindows to Motif, from PC to UNIX to Macintosh (or some combination thereof), and between various other alternatives, too numerous to mention. Getting an application to work was only part of the problem; you also had to port it to all the platforms you supported, which often took more time than the development effort itself. In the UNIX world, standards like POSIX and X made it easier to move applications between different UNIX platforms. But they only solved part of the problem and didn't provide any help with the PC world. Portability became even more important as the Internet grew. The goal was clear: wouldn't it be great if you could just move applications between different operating environments without worrying about the software breaking because of a different operating system, windowing environment, or internal data representation?

In the spring of 1995, Sun Microsystems announced Java, which claimed to solve this dilemma. What started out as a dancing penguin (or Star Trek communicator) named Duke on remote controls for interactive television has become a new paradigm for programming on the Internet. With Java, you can create a program on one platform and deliver the compilation output (byte-codes/class files) to every other supported environment without recompiling or worrying about the local windowing environment, word size, or byte order. The first generation of Java programs consisted mostly of fancy animation applets that ran in a web browser like Netscape Navigator, Internet Explorer, or HotJava. We're beginning to see the next generation now: powerful distributed applications in areas ranging from commerce to medical imaging to network management. All of these applications require extreme portability: Joe's Online Bait Shop doesn't have the time or energy to port its "Online Bait Buyer" program to every platform on the Internet but doesn't want to limit its market to a specific platform. Java neatly solves their problem.

Windowing systems present the biggest challenges for portability. When you move an application from Windows to the Macintosh, you may be able to salvage most of the computational guts, but you'll have to rewrite the window interface code completely. In Java, this part of the portability challenge is addressed by a package called AWT, which stands for Abstract Window Toolkit (although people have come up with many other expansions). AWT provides the magic of maintaining the local look and feel of the user's environment. Because of AWT, the same application program can look appropriate in any environment. For example, if your program uses a pull-down list, that list will look like a Windows list when you run the program under Windows; a Macintosh list when you run the program on a Mac; and a Motif list when you run the program on a UNIX system under Motif. The same code works on all platforms. In addition to providing a common set of user interface components, AWT provides facilities for manipulating images and generating graphics.

This book is a complete programmer's guide and reference to the `java.awt` package (including `java.awt.image`, `java.awt.event`, `java.awt.datatransfer`, and `java.awt.peer`). It assumes that you're already familiar with the Java language and class libraries. If you aren't, *Exploring Java*, by Pat Niemeyer and Josh Peck, provides a general introduction, and other books in the O'Reilly Java series provide detailed references and tutorials on specific topics. This chapter provides a quick overview of AWT: it introduces you to the various GUI elements contained within the `java.awt` package and gives you pointers to the chapters that provide more specific information about each component. If you're interested in some of the more advanced image manipulation capabilities, head right to Chapter 12, *Image Processing*. The book ends with a reference section that summarizes what you need to know about every class in AWT.

In using this book, you should be aware that it covers two versions of AWT: 1.0.2 and 1.1. The Java 1.1 JDK (Java Developer's Kit) occurred in December 1996. This release includes many improvements and additions to AWT and is a major step forward in Java's overall functionality. It would be nice if I could say, "Forget about 1.0.2, it's obsolete--use this book to learn 1.1." However, I can't; at this point, since browsers (Netscape Navigator in particular) still incorporate 1.0.2, and we have no idea when they will incorporate the new release. As of publication, Navigator 4.0 is in beta test and incorporates 1.0.2. Therefore, Java release 1.0.2 will continue to be important, at least for the foreseeable future.

In this summary, we'll point out new features of Java 1.1 as they come up. However, one feature deserves mention and doesn't fit naturally into an overview. Many of the methods of Java 1.0.2 have been renamed in Java 1.1. The old names still work but are "deprecated." The new names adhere strictly to the design patterns discussed in the JavaBeans documentation:[1] all methods that retrieve the value of an object's property begin with "get," all methods that set the value of a property begin with "set," and all methods that test the value of some property begin with "is." For example, the `size()` method is now called `getSize()`. The Java 1.1 compiler issues warnings whenever you used a deprecated method name.

1.1 Components

Modern user interfaces are built around the idea of "components": reusable gadgets that implement a specific part of the interface. They don't need much introduction: if you have used a computer since 1985 or so, you're already familiar with buttons, menus, windows, checkboxes, scrollbars, and many other similar items. AWT comes with a repertoire of basic user interface components, along with the machinery for creating your own components (often combinations of the basic components) and for communicating between components and the rest of the program.

The next few sections summarize the components that are part of AWT. If you're new to AWT, you may find it helpful to familiarize yourself with what's available before jumping into the more detailed discussions later in this book.

Static Text

The `Label` class provides a means to display a single line of text on the screen. That's about it. They provide visual aids to the user: for example, you might use a label to describe an input field. You have control over the size, font, and color of the text. Labels are discussed in Labels. Figure 1.1 displays several labels with different attributes.

Figure 1.1: Multiple Label instances

[Graphic: Figure 1-1]

User Input

Java provides several different ways for a user to provide input to an application. The user can type the information or select it from a preset list of available choices. The choice depends primarily on the desired functionality of the program, the user-base, and the amount of back-end processing that you want to do.

The TextField and TextArea classes

Two components are available for entering keyboard input: `TextField` for single line input and `TextArea` for multi-line input. They provide the means to do things from character-level data validation to complex text editing. These are discussed in much more detail in Chapter 8, *Input Fields*. Figure 1.2 shows a screen that contains various `TextField` and `TextArea` components.

Figure 1.2: TextField and TextArea elements

[Graphic: Figure 1-2]

The Checkbox and CheckboxGroup classes

The remaining input-oriented components provide mechanisms for letting the user select from a list of choices. The first such mechanism is `Checkbox`, which lets you select or deselect an option. The left side of the applet in Figure 1.3 shows a checkbox for a Dialog option. Clicking on the box selects the option and makes the box change appearance. A second click deselects the option.

The `CheckboxGroup` class is not a component; it provides a means for grouping checkboxes into a mutual exclusion set, often called a set of radio buttons. Selecting any button in the group automatically deselects the other buttons. This behavior is useful for a set of mutually exclusive choices. For example, the right side of the applet in Figure 1.3 shows a set of checkboxes for selecting a font. It makes sense to select only one font at a time, so these checkboxes have been put in a `CheckboxGroup`.

Figure 1.3: Examples of Checkbox and CheckboxGroup

[Graphic: Figure 1-3]

The appearance of a checkbox varies from platform to platform. On the left, Figure 1.3 shows Windows; the right shows Motif. On most platforms, the appearance also changes when a checkbox is put into a `CheckboxGroup`.

The Choice class

`Checkbox` and `CheckboxGroup` present a problem when the list of choices becomes long. Every element of a `CheckboxGroup` uses precious screen real estate, which limits the amount of space available for other components. The `Choice` class was designed to use screen space more efficiently. When a `Choice` element is displayed on the screen, it takes up the space of a single item in the list, along with some extra space for decorations. This leaves more space for other components. When the user selects a `Choice` component, it displays the available options next to or below the `Choice`. Once the user makes a selection, the choices are removed from the screen, and the `Choice` displays the selection. At any time, only one item in a `Choice` may be selected, so selecting an item implicitly deselects everything else. Choice explores the details of the `Choice` class. Figure 1.4 shows examples of open (on the right of the screens) and closed (on the left) `Choice` items in Windows 95 and Motif.

Figure 1.4: Open and closed Choice items

[Graphic: Figure 1-4]

The List class

Somewhere between `Choice` and `CheckboxGroup` in the screen real estate business is a component called `List`. With a `List`, the user is still able to select any item. However, the programmer recommends how many items to display on the screen at once. All additional choices are still available, but the user moves an attached scrollbar to access them. Unlike a `Choice`, a `List` allows the user to select multiple items. Section 9.2 covers the `List` component. Figure 1.5 shows `List` components in different states.

Figure 1.5: List components in different states

[Graphic: Figure 1-5]

Menus

Most modern user interfaces use menus heavily; therefore, it's no surprise that Java supports menus. As you'd expect, Java menus look like the menus in the windowing environment under which the program runs. Currently, menus can only appear within a `Frame`, although this will probably change in the future. A `Menu` is a fairly complex object, with lots of moving parts: menu bars, menu items, etc. Java 1.1 adds hot keys to menus, allowing users to navigate a menu interface using keyboard shortcuts. The details of `Menu` are explored in Chapter 10, *Would You Like to Choose from the Menu?* Figure 1.6 shows frames with open menus for both Windows and Motif. Since tear-off menus are available on Motif systems, its menus look and act a little differently. Figure 1.6 also includes a tear-off menu. The shortcuts (Ctrl+F8) are newly supported in Java 1.1.

Figure 1.6: Examples of menus

[Graphic: Figure 1-6]

The PopupMenu class

The `PopupMenu` class is new to Java 1.1. Pop-up menus can be used for context-sensitive, component-level menus. Associated with each `Component` can be its own pop-up menu. The details of creating and working with the `PopupMenu` class and the fun time you have catching their events are covered in Chapter 10, *Would You Like to Choose from the Menu?*, *Would You Like to Choose from the Menu?* Figure 1.7 shows an example of a pop-up menu.

Figure 1.7: A Pop-up menu

[Graphic: Figure 1-7]

Event Triggers

Java provides two components whose sole purpose is to trigger actions on the screen: `Button` and `Scrollbar`. They provide the means for users to signal that they are ready to perform an operation. (Note that all components except labels generate events; I'm singling out buttons and scrollbars because their only purpose is to generate events.)

The Scrollbar class

Most people are familiar with scrollbars. In a word processor or a web browser, when an image or document is too large to fit on the screen, the scrollbar allows the user to move to another area. With Java, the `Scrollbar` performs similarly. Selecting or moving the scrollbar triggers an event that allows the program to process the scrollbar movement and respond accordingly. The details of the `Scrollbar` are covered in Scrollbar. Figure 1.8 shows horizontal and vertical scrollbars.

Figure 1.8: Horizontal and vertical scrollbars

[Graphic: Figure 1-8]

Note that a scrollbar is just that. It generates events when the user adjusts it, but the program using the scrollbar is responsible for figuring out what to do with the events, such as displaying a different part of an image or the text, etc. Several of the components we've discussed, like `TextArea` and `List`, have built-in scrollbars, saving you the trouble of writing your own code to do the actual scrolling. Java 1.1 has a new container called a `ScrollPane` that has scrolling built in. By using a scroll pane, you should be able to avoid using scroll bars as a positioning mechanism. An example of `ScrollPane` appears later in this chapter.

The Button class

A button is little more than a label that you can click on. Selecting a button triggers an event telling the program to go to work. Buttons explores the `Button` component. Figure 1.9 shows `Button` examples.

Figure 1.9: Various buttons

[Graphic: Figure 1-9]

The Java Management API includes a fancier button (`ImageButton`) with pictures rather than labels. For the time being, this is a standard extension of Java and not in the Core API. If you don't want to use these extensions, you'll have to implement an image button yourself.

Expansion

The Canvas class

The `Canvas` class is just a blank area; it doesn't have any predefined appearance. You can use `Canvas` for drawing images, building new kinds of components, or creating super-components that are aggregates of other components. For example, you can build a picture button by drawing a picture on a `Canvas` and detecting mouse click events within the area of the `Canvas`. `Canvas` is discussed in Canvas.

2. Simple Graphics

Contents:

This chapter digs into the meat of the AWT classes. After completing this chapter, you will be able to draw strings, images, and shapes via the `Graphics` class in your Java programs. We discuss geometry-related classes--`Polygon`, `Rectangle`, `Point`, and `Dimension`, and the `Shape` interface--you will see these throughout the remaining AWT objects. You will also learn several ways to do smooth animation by using double buffering and the `MediaTracker`.

After reading this chapter, you should be able to do simple animation and image manipulation with AWT. For most applications, this should be sufficient. If you want to look at AWT's more advanced graphics capabilities, be sure to take a look at Chapter 12, *Image Processing*.

2.1 Graphics

The `Graphics` class is an abstract class that provides the means to access different graphics devices. It is the class that lets you draw on the screen, display images, and so forth. `Graphics` is an abstract class because working with graphics requires detailed knowledge of the platform on which the program runs. The actual work is done by concrete classes that are closely tied to a particular platform. Your Java Virtual Machine vendor provides the necessary concrete classes for your environment. You never need to worry about the platform-specific classes; once you have a `Graphics` object, you can call all the methods of the `Graphics` class, confident that the platform-specific classes will work correctly wherever your program runs.

You rarely need to create a `Graphics` object yourself; its constructor is protected and is only called by the subclasses that extend `Graphics`. How then do you get a `Graphics` object to work with? The sole parameter of the `Component.paint()` and `Component.update()` methods is the current graphics context. Therefore, a `Graphics` object is always available when you override a component's `paint()` and `update()` methods. You can ask for the graphics context of a `Component` by calling `Component.getGraphics()`. However, many components do not have a drawable graphics context. `Canvas` and `Container` objects return a valid `Graphics` object; whether or not any other component has a drawable graphics context depends on the run-time environment. (The latest versions of Netscape Navigator provide a drawable graphics context for any component, but you shouldn't get used to writing platform-specific code.) This restriction isn't as harsh as it sounds. For most components, a drawable graphics context doesn't make much sense; for example, why would you want to draw on a `List`? If you want to draw on a component, you probably can't. The notable exception is `Button`, and that may be fixed in future versions of AWT.

Graphics Methods

Constructors

protected Graphics ()

> Because `Graphics` is an abstract class, it doesn't have a visible constructor. The way to get a `Graphics` object is to ask for one by calling `getGraphics()` or to use the one given to you by the `Component.paint()` or `Component.update()` method.

The abstract methods of the `Graphics` class are implemented by some windowing system-specific class. You rarely need to know which subclass of `Graphics` you are using, but the classes you actually get (if you are using the JDK) are `sun.awt.win32.Win32Graphics` (JDK1.0), `sun.awt.window.WGraphics` (JDK1.1), `sun.awt.motif.X11Graphics`, or `sun.awt.macos.MacGraphics`. Pseudo-constructors

In addition to using the graphics contexts given to you by `getGraphics()` or in `Component.paint()`, you can get a `Graphics` object by creating a copy of another `Graphics` object. Creating new graphics contexts has resource implications. Certain platforms have a limited number of graphics contexts that can be active. For instance, on Windows 95 you cannot have more than four in use at one time. Therefore, it's a good idea to call `dispose()` as soon as you are done with a `Graphics` object. Do not rely on the garbage collector to clean up for you.

public abstract Graphics create ()

> This method creates a second reference to the graphics context. It is useful for clipping (reducing the drawable area).

public Graphics create (int x, int y, int width, int height)

> This method creates a second reference to a subset of the drawing area of the graphics context. The new `Graphics` object covers the rectangle from (`x`, `y`) through (`x+width-1`, `y+height-1`) in the original object. The coordinate space of the new `Graphics` context is translated so that the upper left corner is (0, 0) and the lower right corner is (`width`, `height`). Shifting the coordinate system of the new object

makes it easier to work within a portion of the drawing area without using offsets.

Drawing strings

These methods let you draw text strings on the screen. The coordinates refer to the left end of the text's baseline.

public abstract void drawString (String text, int x, int y)

The `drawString()` method draws `text` on the screen in the current font and color, starting at position (`x`, `y`). The starting coordinates specify the left end of the `String`'s baseline.

public void drawChars (char text[], int offset, int length, int x, int y)

The `drawChars()` method creates a `String` from the char array `text` starting at `text[offset]` and continuing for `length` characters. The newly created `String` is then drawn on the screen in the current font and color, starting at position (`x`, `y`). The starting coordinates specify the left end of the `String`'s baseline.

public void drawBytes (byte text[], int offset, int length, int x, int y)

The `drawBytes()` method creates a `String` from the byte array `text` starting at `text[offset]` and continuing for `length` characters. This `String` is then drawn on the screen in the current font and color, starting at position (`x`, `y`). The starting coordinates specify the left end of the `String`'s baseline.

public abstract Font getFont ()

The `getFont()` method returns the current `Font` of the graphics context. See Chapter 3, *Fonts and Colors*, for more on what you can do with fonts. You cannot get meaningful results with `getFont()` until the applet or application is displayed on the screen (generally, not in `init()` of an applet or `main()` of an application).

public abstract void setFont (Font font)

The `setFont()` method changes the current `Font` to `font`. If `font` is not available on the current platform, the system chooses a default. To change the current font to 12 point bold TimesRoman:

```
setFont (new Font ("TimesRoman", Font.BOLD, 12));
```

public FontMetrics getFontMetrics ()

The `getFontMetrics()` method returns the current `FontMetrics` object of the graphics context. You use `FontMetrics` to reveal sizing properties of the current `Font`--for example, how wide the "Hello World" string will be in pixels when displayed on the screen.

public abstract FontMetrics getFontMetrics (Font font)

This version of `getFontMetrics()` returns the `FontMetrics` for the `Font` font instead of the current font. You might use this method to see how much space a new font requires to draw text.

For more information about `Font` and `FontMetrics`, see Chapter 3, *Fonts and Colors*. Painting

public abstract Color getColor ()

The `getColor()` method returns the current foreground `Color` of the `Graphics` object. All future drawing operations will use this color. Chapter 3, *Fonts and Colors* describes the `Color` class.

public abstract void setColor (Color color)

The `setColor()` method changes the current drawing color to `color`. As you will see in the next chapter, the `Color` class defines some common colors for you. If you can't use one of the predefined colors, you can create a color from its RGB values. To change the current color to red, use any of the following:

```
setColor (Color.red);
setColor (new Color (255, 0, 0));
setColor (new Color (0xff0000));
```

public abstract void clearRect (int x, int y, int width, int height)

The `clearRect()` method sets the rectangular drawing area from (`x`, `y`) to (`x+width-1`, `y+height-1`) to the current background color. Keep in mind that the second pair of parameters is not the opposite corner of the rectangle, but the width and height of the area to clear.

public abstract void clipRect (int x, int y, int width, int height)

The `clipRect()` method reduces the drawing area to the intersection of the current drawing area and the rectangular area from (`x`, `y`) to (`x+width-1`, `y+height-1`). Any future drawing operations outside this clipped area will have no effect. Once you clip a drawing area, you cannot increase its size with `clipRect()`; the drawing area can only get smaller. (However, if the `clipRect()` call is in `paint()`, the size of the drawing area will be reset to its original size on subsequent calls to `paint()`.) If you want the ability to draw to the entire area, you must create a second `Graphics` object that contains a copy of the drawing area before calling `clipRect()` or use `setClip()`. The following code is a simple applet that demonstrates clipping; Figure 2.1 shows the result.

```
import java.awt.*;
public class clipping extends java.applet.Applet {
    public void paint (Graphics g) {
        g.setColor (Color.red);
        Graphics clippedGraphics = g.create();
        clippedGraphics.drawRect (0,0,100,100);
        clippedGraphics.clipRect (25, 25, 50, 50);
        clippedGraphics.drawLine (0,0,100,100);
        clippedGraphics.dispose();
        clippedGraphics=null;
        g.drawLine (0,100,100,0);
      }
    }
```

Figure 2.1: Clipping restricts the drawing area

[Graphic: Figure 2-1]

The `paint()` method for this applet starts by setting the foreground color to red. It then creates a copy of the `Graphics` context for clipping, saving the original object so it can draw on the entire screen later. The applet then draws a rectangle, sets the clipping area to a smaller region, and draws a diagonal line across the rectangle from upper left to lower right. Because clipping is in effect, only part of the line is displayed. The applet then discards the clipped `Graphics` object and draws an unclipped line from lower left to upper right using the original object `g`.

public abstract void setClip(int x, int y, int width, int height) ★

> This `setClip()` method allows you to change the current clipping area based on the parameters provided. `setClip()` is similar to `clipRect()`, except that it is not limited to shrinking the clipping area. The current drawing area becomes the rectangular area from (`x`, `y`) to (`x+width-1`, `y+height-1`); this area may be larger than the previous drawing area.

public abstract void setClip(Shape clip) ★

> This `setClip()` method allows you to change the current clipping area based on the `clip` parameter, which may be any object that implements the `Shape` interface. Unfortunately, practice is not as good as theory, and in practice, `clip` must be a `Rectangle`; if you pass `setClip()` a `Polygon`, it throws an `IllegalArgumentException`.[1] (The `Shape` interface is discussed later in this chapter.)

[1] It should be simple for Sun to fix this bug; one would expect clipping to a `Polygon` to be the same as clipping to the `Polygon`'s bounding rectangle.

public abstract Rectangle getClipBounds () ★
public abstract Rectangle getClipRect () ☆

The `getClipBounds()` methods returns a `Rectangle` that describes the clipping area of a `Graphics` object. The `Rectangle` gives you the (`x`, `y`) coordinates of the top left corner of the clipping area along with its width and height. (`Rectangle` objects are discussed later in this chapter.)

`getClipRect()` is the Java 1.0 name for this method.

public abstract Shape getClip () ★

The `getClip()` method returns a `Shape` that describes the clipping area of a `Graphics` object. That is, it returns the same thing as `getClipBounds()` but as a `Shape`, instead of as a `Rectangle`. By calling `Shape.getBounds()`, you can get the (`x`, `y`) coordinates of the top left corner of the clipping area along with its width and height. In the near future, it is hard to imagine the actual object that `getClip()` returns being anything other than a `Rectangle`.

public abstract void copyArea (int x, int y, int width, int height, int delta_x, int delta_y)

The `copyArea()` method copies the rectangular area from (`x`, `y`) to (`x+width`, `y+height`) to the area with an upper left corner of (`x+delta_x`, `y+delta_y`). The `delta_x` and `delta_y` parameters are not the coordinates of the second point but an offset from the first coordinate pair (`x`, `y`). The area copied may fall outside of the clipping region. This method is often used to tile an area of the graphics context. `copyArea()` does not save the contents of the area copied.

Painting mode

There are two painting or drawing modes for the `Graphics` class: paint (the default) and XOR mode. In paint mode, anything you draw replaces whatever is already on the screen. If you draw a red square, you get a red square, no matter what was underneath; this is what most programmers have learned to expect.

The behavior of XOR mode is rather strange, at least to people accustomed to modern programming environments. XOR mode is short for eXclusive-OR mode. The idea behind XOR mode is that drawing the same object twice returns the screen to its original state. This technique was commonly used for simple animations prior to the development of more sophisticated methods and cheaper hardware.

The side effect of XOR mode is that painting operations don't necessarily get the color you request. Instead of replacing the original pixel with the new value, XOR mode merges the original color, the painting color, and an XOR color (usually the background color) to form a new color. The new color is chosen so that if you repaint the pixel with the same color, you get the original pixel back. For example, if you paint a red square in XOR mode, you get a square of some other color on the screen. Painting the same red square again returns the screen to its original state.

public abstract void setXORMode (Color xorColor)

The `setXORMode()` method changes the drawing mode to XOR mode. In XOR mode, the system uses the `xorColor` color to determine an alternate color for anything drawn such that drawing the same item twice restores the screen to its original condition. The `xorColor` is usually the current background color but can be any color. For each pixel, the new color is determined by an exclusive-or of the old pixel color, the painting color, and the `xorColor`.

For example, if the old pixel is red, the XOR color is blue, and the drawing color is green, the end result would be white. To see why, it is necessary to look at the RGB values of the three colors. Red is (255, 0, 0). Blue is (0, 0, 255). Green is (0, 255, 0). The exclusive-or of these three values is (255, 255, 255), which is white. Drawing another green pixel with a blue XOR color yields red, the pixel's original color, since (255, 255, 255) ^ (0, 0, 255) ^ (0, 255, 0) yields (255, 0, 0).[2] The following code generates the display shown in Figure 2.2.

[2] ^ is the Java XOR operator.

```
import java.awt.*;
public class xor extends java.applet.Applet {
    public void init () {
        setBackground (Color.red);
    }
    public void paint (Graphics g) {
        g.setColor (Color.green);
        g.setXORMode (Color.blue);
        g.fillRect (10, 10, 100, 100);
        g.fillRect (10, 60, 100, 100);
    }
}
```

Figure 2.2: Drawing in XOR mode

[Graphic: Figure 2-2]

Although it's hard to visualize what color XOR mode will pick, there is one important special case. Let's say that there are only two colors: a background color (the XOR color) and a foreground color (the painting color). Each pixel must be in one color or the other. Painting "flips" each pixel to the other color. Foreground pixels become background, and vice versa.

public abstract void setPaintMode ()

> The `setPaintMode()` method puts the system into paint mode. When in paint mode, any drawing operation replaces whatever is underneath it. Call `setPaintMode()` to return to normal painting when finished with XOR mode.

Drawing shapes

Most of the drawing methods require you to specify a bounding rectangle for the object you want to draw: the location of the object's upper left corner, plus its width and height. The two exceptions are lines and polygons. For lines, you supply two endpoints; for polygons, you provide a set of points.

Versions 1.0.2 and 1.1 of AWT always draw solid lines that are one pixel wide; there is no support for line width or fill patterns. A future version should support lines with variable widths and patterns.

public abstract void drawLine (int x1, int y1, int x2, int y2)

> The `drawLine()` method draws a line on the graphics context in the current color from (`x1`, `y1`) to (`x2`, `y2`). If (`x1`, `y1`) and (`x2`, `y2`) are the same point, you will draw a point. There is no method specific to drawing a point. The following code generates the display shown in Figure 2.3.

```
g.drawLine (5, 5, 50, 75);    // line
g.drawLine (5, 75, 5, 75);    // point
g.drawLine (50, 5, 50, 5);    // point
```

Figure 2.3: Drawing lines and points with drawLine()

public void drawRect (int x, int y, int width, int height)

The `drawRect()` method draws a rectangle on the drawing area in the current color from (`x`, `y`) to (`x+width`, `y+height`). If `width` or `height` is negative, nothing is drawn.

public abstract void fillRect (int x, int y, int width, int height)

The `fillRect()` method draws a filled rectangle on the drawing area in the current color from (`x`, `y`) to (`x+width-1`, `y+height-1`). Notice that the filled rectangle is one pixel smaller to the right and bottom than requested. If `width` or `height` is negative, nothing is drawn.

public abstract void drawRoundRect (int x, int y, int width, int height, int arcWidth, int arcHeight)

The `drawRoundRect()` method draws a rectangle on the drawing area in the current color from (`x`, `y`) to (`x+width`, `y+height`). However, instead of perpendicular corners, the corners are rounded with a horizontal diameter of `arcWidth` and a vertical diameter of `arcHeight`. If `width` or `height` is a negative number, nothing is drawn. If `width`, `height`, `arcWidth`, and `arcHeight` are all equal, you get a circle.

To help you visualize the `arcWidth` and `arcHeight` of a rounded rectangle, Figure 2.4 shows one corner of a rectangle drawn with an `arcWidth` of 20 and a `arcHeight` of 40.

Figure 2.4: Drawing rounded corners

[Graphic: Figure 2-4]

public abstract void fillRoundRect (int x, int y, int width, int height, int arcWidth, int arcHeight)

The `fillRoundRect()` method draws a filled rectangle on the drawing area in the current color from (`x`, `y`) to (`x+width-1`, `y+height-1`). However, instead of having perpendicular corners, the corners are rounded with a horizontal diameter of `arcWidth` and a vertical diameter of `arcHeight` for the four corners. Notice that the filled rectangle is one pixel smaller to the right and bottom than requested. If `width` or `height` is a negative number, nothing is filled. If `width`, `height`, `arcWidth`, and `arcHeight` are all equal, you get a filled circle.

Figure 2.4 shows how AWT generates rounded corners. Figure 2.5 shows the collection of rectangles created by the following code. The rectangles in Figure 2.5 are filled and unfilled, with rounded and square corners.

```
g.drawRect (25, 10, 50, 75);
g.fillRect (25, 110, 50, 75);
g.drawRoundRect (100, 10, 50, 75, 60, 50);
g.fillRoundRect (100, 110, 50, 75, 60, 50);
```

Figure 2.5: Varieties of rectangles

[Graphic: Figure 2-5]

public void draw3DRect (int x, int y, int width, int height, boolean raised)

The `draw3DRect()` method draws a rectangle in the current color from (`x`, `y`) to (`x+width`, `y+height`); a shadow effect makes the rectangle appear to float slightly above or below the screen. The `raised` parameter has an effect only if the current color is not black. If `raised` is `true`, the rectangle looks like a button waiting to be pushed. If `raised` is `false`, the rectangle looks like a depressed button. If `width` or `height` is negative, the shadow appears from another direction.

public void fill3DRect (int x, int y, int width, int height, boolean raised)

The `fill3DRect()` method draws a filled rectangle in the current color from (`x`, `y`) to (`x+width`, `y+height`); a shadow effect makes the rectangle appear to float slightly above or below the screen. The `raised` parameter has an effect only if the current color is not black. If `raised` is `true`, the rectangle looks like a button waiting to be pushed. If `raised` is `false`, the rectangle looks like a depressed button. To enhance the shadow effect, the depressed area is given a slightly deeper shade of the drawing color. If `width` or `height` is negative, the shadow appears from another direction, and the rectangle isn't filled. (Different platforms could deal with this differently. Try to ensure the parameters have positive values.)

Figure 2.6 shows the collection of three-dimensional rectangles created by the following code. The rectangles in the figure are raised and depressed, filled and unfilled.

```
g.setColor (Color.gray);
g.draw3DRect (25, 10, 50, 75, true);
g.draw3DRect (25, 110, 50, 75, false);
g.fill3DRect (100, 10, 50, 75, true);
g.fill3DRect (100, 110, 50, 75, false);
```

Figure 2.6: Filled and unfilled 3D rectangles

[Graphic: Figure 2-6]

public abstract void drawOval (int x, int y, int width, int height)

The `drawOval()` method draws an oval in the current color within an invisible bounding rectangle from (`x`, `y`) to (`x+width`, `y+height`). You cannot specify the oval's center point and radii. If `width` and `height` are equal, you get a circle. If `width` or `height` is negative, nothing is drawn.

public abstract void fillOval (int x, int y, int width, int height)

The `fillOval()` method draws a filled oval in the current color within an invisible bounding rectangle from (`x`, `y`) to (`x+width-1`, `y+height-1`). You cannot specify the oval's center point and radii. Notice that the filled oval is one pixel smaller to the right and bottom than requested. If `width` or `height` is negative, nothing is drawn.

Figure 2.7 shows the collection of ovals, filled and unfilled, that were generated by the following code:

```
g.drawOval (25, 10, 50, 75);
g.fillOval (25, 110, 50, 75);
g.drawOval (100, 10, 50, 50);
g.fillOval (100, 110, 50, 50);
```

Figure 2.7: Filled and unfilled ovals

[Graphic: Figure 2-7]

public abstract void drawArc (int x, int y, int width, int height, int startAngle, int arcAngle)

The `drawArc()` method draws an arc in the current color within an invisible bounding rectangle from (`x`, `y`) to (`x+width`, `y+height`). The arc starts at `startAngle` degrees and goes to `startAngle` + `arcAngle` degrees. An angle of 0 degrees is at the 3 o'clock position; angles increase counter-clockwise. If `arcAngle` is negative, drawing is in a clockwise direction. If `width` and `height` are equal and `arcAngle` is 360 degrees, `drawArc()` draws a circle. If `width` or `height` is negative, nothing is drawn.

public abstract void fillArc (int x, int y, int width, int height, int startAngle, int arcAngle)

The `fillArc()` method draws a filled arc in the current color within an invisible bounding rectangle from (`x`, `y`) to (`x+width-1`, `y+height-1`). The arc starts at `startAngle` degrees and goes to `startAngle` + `arcAngle` degrees. An angle of 0 degrees is at the 3 o'clock position; angles increase counter-clockwise. If `arcAngle` is negative, drawing is in a clockwise direction. The arc fills like a pie (to the origin), not from arc endpoint to arc endpoint. This makes creating pie charts easier. If `width` and `height` are equal and `arcAngle` is 360 degrees, `fillArc()` draws a filled circle. If `width` or `height` is negative, nothing is drawn.

Figure 2.8 shows a collection of filled and unfilled arcs that were generated by the following code:

```
g.drawArc (25, 10, 50, 75, 0, 360);
g.fillArc (25, 110, 50, 75, 0, 360);
g.drawArc (100, 10, 50, 75, 45, 215);
g.fillArc (100, 110, 50, 75, 45, 215);
```

Figure 2.8: Filled and unfilled arcs

[Graphic: Figure 2-8]

public void drawPolygon (Polygon p)

The `drawPolygon()` method draws a path for the points in polygon `p` in the current color. Polygon discusses the `Polygon` class in detail.

The behavior of `drawPolygon()` changes slightly between Java 1.0.2 and 1.1. With version 1.0.2, if the first and last points of a `Polygon` are not the same, a call to `drawPolygon()` results in an open polygon, since the endpoints are not connected for you. Starting with version 1.1, if the first and last points are not the same, the endpoints are connected for you.

public abstract void drawPolygon (int xPoints[], int yPoints[], int numPoints)

The `drawPolygon()` method draws a path of `numPoints` nodes by plucking one element at a time out of `xPoints` and `yPoints` to make each point. The path is drawn in the current color. If either `xPoints` or `yPoints` does not have `numPoints` elements, `drawPolygon()` throws a run-time exception. In 1.0.2, this exception is an `IllegalArgumentException`; in 1.1, it is an `ArrayIndexOutOfBoundsException`. This change shouldn't break older programs, since you are not required to catch run-time exceptions.

public abstract void drawPolyline (int xPoints[], int yPoints[], int numPoints) ★

The `drawPolyline()` method functions like the 1.0 version of `drawPolygon()`. It plays connect the dots with the points in the `xPoints` and `yPoints` arrays and does not connect the endpoints. If either `xPoints` or `yPoints` does not have `numPoints` elements, `drawPolygon()` throws the run-time exception, `ArrayIndexOutOfBoundsException`.

Filling polygons is a complex topic. It is not as easy as filling rectangles or ovals because a polygon may not be closed and its edges may cross. AWT uses an even-odd rule to fill polygons. This algorithm works by counting the number of times each scan line crosses an edge of the polygon. If the total number of crossings to the left of the current point is odd, the point is colored. If it is even, the point is left alone. Figure 2.9 demonstrates this algorithm for a single scan line that intersects the polygon at x values of 25, 75, 125, 175, 225, and 275.

Figure 2.9: Polygon fill algorithm

[Graphic: Figure 2-9]

The scan line starts at the left edge of the screen; at this point there haven't been any crossings, so the pixels are left untouched. The scan line reaches the first crossing when x equals 25. Here, the total number of crossings to the left is one, so the scan line is inside the polygon, and the pixels are colored. At 75, the scan line crosses again; the total number of crossings is two, so coloring stops.

public void fillPolygon (Polygon p)

> The `fillPolygon()` method draws a filled polygon for the points in `Polygon p` in the current color. If the polygon is not closed, `fillPolygon()` adds a segment connecting the endpoints. Polygon discusses the `Polygon` class in detail.

public abstract void fillPolygon (int xPoints[], int yPoints[], int nPoints)

> The `fillPolygon()` method draws a polygon of `numPoints` nodes by plucking one element at a time out of `xPoints` and `yPoints` to make each point. The polygon is drawn in the current color. If either `xPoints` or `yPoints` does not have `numPoints` elements, `fillPolygon()` throws the run-time exception `IllegalArgumentException`. If the polygon is not closed, `fillPolygon()` adds a segment connecting the endpoints.[3]
>
> > [3] In Java 1.1, this method throws `ArrayIndexOutOfBoundsException`, not `IllegalArgumentException`.

Figure 2.10 shows several polygons created by the following code, containing different versions of `drawPolygon()` and `fillPolygon()`:

```
int[] xPoints[] = {{50, 25, 25, 75, 75},
                   {50, 25, 25, 75, 75},
                   {100, 100, 150, 100, 150, 150, 125, 100, 150},
                   {100, 100, 150, 100, 150, 150, 125, 100, 150}};
int[] yPoints[] = {{10, 35, 85, 85, 35, 10},
                   {110, 135, 185, 185, 135},
                   {85, 35, 35, 85, 85, 35, 10, 35, 85},
                   {185, 135, 135, 185, 185, 135, 110, 135, 185}};
int   nPoints[] = {5, 5, 9, 9};
g.drawPolygon (xPoints[0], yPoints[0], nPoints[0]);
g.fillPolygon (xPoints[1], yPoints[1], nPoints[1]);
g.drawPolygon (new Polygon(xPoints[2], yPoints[2], nPoints[2]));
g.fillPolygon (new Polygon(xPoints[3], yPoints[3], nPoints[3]));
```

Figure 2.10: Filled and unfilled polygons

[Graphic: Figure 2-10]

Drawing images

An `Image` is a displayable object maintained in memory. To get an image on the screen, you must draw it onto a graphics context, using the `drawImage()` method of the `Graphics` class. For example, within a `paint()` method, you would call `g.drawImage(image, ... , this)` to display some image on the screen. In other situations, you might use the `createImage()` method to generate an offscreen `Graphics` object, then use `drawImage()` to draw an image onto this object, for display later.

This begs the question: where do images come from? We will have more to say about the `Image` class later in this chapter. For now, it's enough to say that you can call `getImage()` to load an image from disk or across the Net. There are versions of `getImage()` in the `Applet` and `Toolkit` classes; the latter is for use in applications. You can also call `createImage()`, a method of the `Component` class, to generate an image in memory.

What about the last argument to `drawImage()`? What is `this` for? The last argument of `drawImage()` is always an image observer--that is, an object that implements the `ImageObserver` interface. This interface is discussed in detail in Chapter 12, *Image Processing*. For the time being, it's enough to say that the call to `drawImage()` starts a new thread that loads the requested image. An image observer monitors the process of loading an image; the thread that is loading the image notifies the image observer whenever new data has arrived.

The `Component` class implements the `ImageObserver` interface; when you're writing a `paint()` method, you're almost certainly overriding some component's `paint()` method; therefore, it's safe to use `this` as the image observer in a call to `drawImage()`. More simply, we could say that any component can serve as an image observer for images that are drawn on it.

public abstract boolean drawImage (Image image, int x, int y, ImageObserver observer)

> The `drawImage()` method draws `image` onto the screen with its upper left corner at (`x`, `y`), using `observer` as its `ImageObserver`. Returns `true` if the object is fully drawn, `false` otherwise.

public abstract boolean drawImage (Image image, int x, int y, int width, int height, ImageObserver observer)

> The `drawImage()` method draws `image` onto the screen with its upper left corner at (`x`, `y`), using `observer` as its `ImageObserver`. The system scales `image` to fit into a `width` x `height` area. The scaling may take time. This method returns `true` if the object is fully drawn, `false` otherwise.
>
> With Java 1.1, you don't need to use `drawImage()` for scaling; you can prescale the image with the `Image.getScaledInstance()` method, then use the previous version of `drawImage()`.

public abstract boolean drawImage (Image image, int x, int y, Color backgroundColor, ImageObserver observer)

> The `drawImage()` method draws `image` onto the screen with its upper left corner at (`x`, `y`), using `observer` as its `ImageObserver`. `backgroundColor` is the color of the background seen through the transparent parts of the image. If no part of the image is transparent, you will not see `backgroundColor`. Returns `true` if the object is fully drawn, `false` otherwise.

public abstract boolean drawImage (Image image, int x, int y, int width, int height, Color backgroundColor, ImageObserver observer)

> The `drawImage()` method draws `image` onto the screen with its upper left corner at (`x`, `y`), using `observer` as its `ImageObserver`. `backgroundColor` is the color of the background seen through the transparent parts of the image. The system scales `image` to fit into a `width` x `height` area. The scaling may take time. This method returns `true` if the image is fully drawn, `false` otherwise.
>
> With Java 1.1, you can prescale the image with the `AreaAveragingScaleFilter` or `ReplicateScaleFilter` described in Chapter 12, *Image Processing*, then use the previous version of `drawImage()` to display it.

The following code generated the images in Figure 2.11. The images on the left come from a standard JPEG file. The images on the right come from a file in GIF89a format, in which the white pixel is "transparent." Therefore, the gray background shows through this pair of images.

```
import java.awt.*;
import java.applet.*;
public class drawingImages extends Applet {
    Image i, j;
    public void init () {
        i = getImage (getDocumentBase(), "rosey.jpg");
        j = getImage (getDocumentBase(), "rosey.gif");
    }
    public void paint (Graphics g) {
        g.drawImage (i, 10, 10, this);
        g.drawImage (i, 10, 85, 150, 200, this);
        g.drawImage (j, 270, 10, Color.lightGray, this);
        g.drawImage (j, 270, 85, 150, 200, Color.lightGray, this);
    }
}
```

Figure 2.11: Scaled and unscaled images

[Graphic: Figure 2-11]

public abstract boolean drawImage(Image img, int dx1, int dy1, int dx2, int dy2, int sx1, int sy1, int sx2, int sy2, ImageObserver observer) ★

> The `drawImage()` method draws a portion of `image` onto the screen. It takes the part of the image with corners at (`sx1`, `sy1`) and (`sx2`, `sy2`); it places this rectangular snippet on the screen with one corner at (`dx1`, `dy1`) and another at (`dx2`, `dy2`), using `observer` as its `ImageObserver`. (Think of `d` for destination location and `s` for source image.) This method returns `true` if the object is fully drawn, `false` otherwise.
>
> `drawImage()` flips the image if source and destination endpoints are not the same corners, crops the image if the destination is smaller than the original size, and scales the image if the destination is larger than the original size. It does not do rotations, only flips (i.e., it can produce a mirror image or an image rotated 180 degrees but not an image rotated 90 or 270 degrees).

public abstract boolean drawImage(Image img, int dx1, int dy1, int dx2, int dy2, int sx1, int sy1, int sx2, int sy2, Color backgroundColor, ImageObserver observer) ★

The drawImage() method draws a portion of image onto the screen. It takes the part of the image with corners at (sx1, sy1) and (sx2, sy2); it places this rectangular snippet on the screen with one corner at (dx1, dy1) and another at (dx2, dy2), using observer as its ImageObserver. (Think of d for destination location and s for source image.) backgroundColor is the color of the background seen through the transparent parts of the image. If no part of the image is transparent, you will not see backgroundColor. This method returns true if the object is fully drawn, false otherwise.

Like the previous version of drawImage(), this method flips the image if source and destination endpoints are not the same corners, crops the image if the destination is smaller than the original size, and scales the image if the destination is larger than the original size. It does not do rotations, only flips (i.e., it can produce a mirror image or an image rotated 180 degrees but not an image rotated 90 or 270 degrees).

The following code demonstrates the new drawImage() methods in Java 1.1. They allow you to scale, flip, and crop images without the use of image filters. The results are shown in Figure 2.12.

```
// Java 1.1 only
import java.awt.*;
import java.applet.*;
public class drawingImages11 extends Applet {
    Image i, j;
    public void init () {
        i = getImage (getDocumentBase(), "rosey.gif");
    }
    public void paint (Graphics g) {
        g.drawImage (i, 10, 10, this);
        g.drawImage (i, 10, 85,
                     i.getWidth(this)+10, i.getHeight(this)+85,
                     i.getWidth(this), i.getHeight(this), 0, 0, this);
        g.drawImage (i, 270, 10,
                     i.getWidth(this)+270, i.getHeight(this)*2+10, 0, 0,
                     i.getWidth(this), i.getHeight(this), Color.gray, this);
        g.drawImage (i, 10, 170,
                     i.getWidth(this)*2+10, i.getHeight(this)+170, 0,
                     i.getHeight(this)/2, i.getWidth(this)/2, 0, this);
    }
}
```

Figure 2.12: Flipped, mirrored, and cropped images

[Graphic: Figure 2-12]

Miscellaneous methods

public abstract void translate (int x, int y)

The `translate()` method sets how the system translates the coordinate space for you. The point at the (`x`, `y`) coordinates becomes the origin of this graphics context. Any future drawing will be relative to this location. Multiple translations are cumulative. The following code leaves the coordinate system translated by (100, 50).

```
translate (100, 0);
translate (0, 50);
```

Note that each call to `paint()` provides an entirely new `Graphics` context with its origin in the upper left corner. Therefore, don't expect translations to persist from one call to `paint()` to the next.

public abstract void dispose ()

The `dispose()` method frees any system resources used by the `Graphics` context. It's a good idea to call `dispose()` whenever you are finished with a `Graphics` object, rather than waiting for the garbage collector to call it automatically (through `finalize()`). Disposing of the `Graphics` object yourself will help your programs on systems with limited resources. However, you should not dispose the `Graphics` parameter to `Component.paint()` or `Component.update()`.

public void finalize ()

The garbage collector calls `finalize()` when it determines that the `Graphics` object is no longer needed. `finalize()` calls `dispose()`, which frees any resources that the `Graphics` object has used.

public String toString ()

The `toString()` method of `Graphics` returns a string showing the current font and color. However, `Graphics` is an abstract class, and classes that extend `Graphics` usually override `toString()`. For example, on a Windows 95 machine, `sun.awt.win32.Win32Graphics` is the concrete class that extends `Graphics`. The class's `toString()` method displays the current origin of the `Graphics` object, relative to the original coordinate system:

```
sun.awt.win32.Win32Graphics[0,0]
```

3. Fonts and Colors

Contents:

This chapter introduces the `java.awt` classes that are used to work with different fonts and colors. First, we discuss the `Font` class, which determines the font used to display text strings, whether they are drawn directly on the screen (with `drawString()`) or displayed within a component like a text field. The `FontMetrics` class gives you detailed information about a font, which you can use to position text strings intelligently. Next, the `Color` class is used to represent colors and can be used to specify the background color of any object, as well as the foreground color used to display a text string or a shape. Finally, the `SystemColor` class (which is new to Java 1.1) provides access to the desktop color scheme.

3.1 Fonts

An instance of the `Font` class represents a specific font to the system. Within AWT, a font is specified by its name, style, and point size. Each platform that supports Java provides a basic set of fonts; to find the fonts supported on any platform, call `Toolkit.getDefaultToolkit().getFontList()`. This method returns a `String` array of the fonts available. Under Java 1.0, on any platform, the available fonts were: TimesRoman, Helvetica, Courier, Dialog, DialogInput, and ZapfDingbats. For copyright reasons, the list is substantially different in Java 1.1: the available font names are TimesRoman ☆, Serif, Helvetica ☆, SansSerif, Courier ☆, Monospaced, Dialog, and DialogInput. The actual fonts available aren't changing; the deprecated font names are being replaced by non-copyrighted equivalents. Thus, TimesRoman is now Serif, Helvetica is now SansSerif, and Courier is Monospaced. The ZapfDingbats font name has been dropped completely because the characters in this font have official Unicode mappings in the range \u2700 to \u27ff.

NOTE:

If you desire non-Latin font support with Java 1.1, use the Unicode mappings for the characters. The actual font used is specified in a set of *font.properties* files in the *lib* subdirectory under *java.home*. These localized font files allow you to remap the "Serif", "SansSerif", and "Monospaced" names to different fonts.

The font's `style` is passed with the help of the class variables `Font.PLAIN`, `Font.BOLD`, and `Font.ITALIC`. The combination `Font.BOLD | Font.ITALIC` specifies bold italics.

A font's `size` is represented as an integer. This integer is commonly thought of as a point size; although that's not strictly correct, this book follows common usage and talks about font sizes in points.

It is possible to add additional font names to the system by setting properties. For example, putting the line below in the properties file or a resource file (resource files are new to Java 1.1) defines the name "AvantGarde" as an alias for the font SansSerif:

```
awt.font.avantgarde=SansSerif
```

With this line in the properties file, a Java program can use "AvantGarde" as a font name; when this font is selected, AWT uses the font SansSerif for display. The property name must be all lowercase. Note that we haven't actually added a new font to the system; we've only created a new name for an old font. See the discussion of `getFont()` and `decode()` for more on font properties.

The Font Class

Constants

There are four styles for displaying fonts in Java: plain, bold, italic, and bold italic. Three class constants are used to represent font styles:

public static final int BOLD

> The `BOLD` constant represents a boldface font.

public static final int ITALIC

> The `ITALIC` constant represents an italic font.

public static final int PLAIN

> The `PLAIN` constant represents a plain or normal font.

The combination `BOLD | ITALIC` represents a bold italic font. `PLAIN` combined with either `BOLD` or

ITALIC represents bold or italic, respectively.

There is no style for underlined text. If you want underlining, you have to do it manually, with the help of FontMetrics.

NOTE:

If you are using Microsoft's SDK, the com.ms.awt.FontX class includes direct support for underlined, strike through (line through middle), and outline fonts.

Variables

Three protected variables access the font setting. They are initially set through the Font constructor. To read these variables, use the Font class's "get" methods.

protected String name

The name of the font.

protected int size

The size of the font.

protected int style

The style of the font. The style is some logical combination of the constants listed previously.

Constructors

public Font (String name, int style, int size)

There is a single constructor for Font. It requires a name, style, and size. name represents the name of the font to create, case insensitive.

```
setFont (new Font ("TimesRoman", Font.BOLD | Font.ITALIC, 20));
```

Characteristics

public String getName ()

The getName() method returns the font's logical name. This is the name passed to the constructor for the specific instance of the Font. Remember that system properties can be used to alias font names, so the name used in the constructor isn't necessarily the actual name of a font on the system.

public String getFamily ()

The `getFamily()` method returns the actual name of the font that is being used to display characters. If the font has been aliased to another font, the `getFamily()` method returns the name of the platform-specific font, not the alias. For example, if the constructor was `new Font ("AvantGarde", Font.PLAIN, 10)` and the `awt.font.avantgarde=Helvetica` property is set, then `getName()` returns AvantGarde, and `getFamily()` returns Helvetica. If nobody set the property, both methods return AvantGarde, and the system uses the default font (since AvantGarde is a nonstandard font).

public int getStyle ()

The `getStyle()` method returns the current style of the font as an integer. Compare this value with the constants `Font.BOLD`, `Font.PLAIN`, and `Font.ITALIC` to see which style is meant. It is easier to use the `isPlain()`, `isBold()`, and `isItalic()` methods to find out the current style. `getStyle()` is more useful if you want to copy the style of some font when creating another.

public int getSize ()

The `getSize()` method retrieves the point size of the font, as set by the size parameter in the constructor. The actual displayed size may be different.

public FontPeer getPeer () ★

The `getPeer()` method retrieves the platform-specific peer object. The object `FontPeer` is a platform-specific subclass of `sun.awt.PlatformFont`. For example, on a Windows 95 platform, this would be an instance of `sun.awt.windows.WFontPeer`.

Styles

public boolean isPlain ()

The `isPlain()` method returns `true` if the current font is neither bold nor italic. Otherwise, it returns `false`.

public boolean isBold ()

The `isBold()` method returns `true` if the current font is either bold or bold and italic. Otherwise, it returns `false`.

public boolean isItalic ()

The `isItalic()` method returns `true` if the current font is either italic or bold and italic. Otherwise, it returns `false`.

Font properties

Earlier, you saw how to use system properties to add aliases for fonts. In addition to adding aliases, you can use system properties to specify which fonts your program will use when it runs. This allows your users to customize their environments to their liking; your program reads the font settings at run-time, rather than using hard-coded settings. The format of the settings in a properties file is:

```
propname=fontname--style--size
```

where `propname` is the name of the property being set, `fontname` is any valid font name (including aliases), `style` is `plain`, `bold`, `italic`, or `bolditalic`, and `size` represents the desired size for the font. `style` and `size` default to `plain` and 12 points. Order is important; the font's style must always precede its size.

For example, let's say you have three areas on your screen: one for menus, one for labels, and one for input. In the system properties, you allow users to set three properties: `myPackage.myClass.menuFont`, `myPackage.myClass.labelFont`, and `myPackage.myClass.inputFont`. One user sets two:

```
myPackage.myClass.menuFont=TimesRoman-italic-24
myPackage.myClass.inputFont=Helvetica
```

The user has specified a Times font for menus and Helvetica for other input. The property names are up to the developer. The program uses `getFont()` to read the properties and set the fonts accordingly.

NOTE:

The location of the system properties file depends on the run-time environment and version you are using. Normally, the file goes into a subdirectory of the installation directory, or for environments where users have home directories, in a subdirectory for the user. Sun's HotJava, JDK, and *appletviewer* tools use the *properties* file in the *.hotjava* directory.

Most browsers do not permit modifying properties, so there is no file.

Java 1.1 adds the idea of "resource files," which are syntactically similar to properties files. Resource files are then placed on the server or within a directory found in the `CLASSPATH`. Updating the properties file is no longer recommended.

public static Font getFont (String name)

The getFont() method gets the font specified by the system property name. If name is not a valid system property, null is returned. This method is implemented by a call to the next version of getFont(), with the defaultFont parameter set to null.

Assuming the properties defined in the previous example, if you call the getFont() method with name set to myPackage.myClass.menuFont, the return value is a 24-point, italic, TimesRoman Font object. If called with name set to myPackage.myClass.inputFont, getFont() returns a 12-point, plain Helvetica Font object. If called with myPackage.myClass.labelFont as name, getFont() returns null because this user did not set the property myPackage.myClass.labelFont.

public static Font getFont (String name, Font defaultFont)

The getFont() method gets the font specified by the system property name. If name is not a valid system property, this version of getFont() returns the Font specified by defaultFont. This version allows you to provide defaults in the event the user does not wish to provide his own font settings.

public static Font decode (String name) ★

The decode() method provides an explicit means to decipher font property settings, regardless of where the setting comes from. (The getFont() method can decipher settings, but only if they're in the system properties file.) In particular, you can use decode() to look up font settings in a resource file. The format of name is the same as that used by getFont(). If the contents of name are invalid, a 12-point plain font is returned. To perform the equivalent of getFont(`myPackage.myClass.menuFont`) without using system properties, see the following example. For a more extensive example using resource files, see Appendix A.

```
// Java 1.1 only
InputStream is = instance.getClass().getResourceAsStream("propfile");
Properties p = new Properties();
try {
    p.load (is);
    Font f = Font.decode(p.getProperty("myPackage.myClass.menuFont"));
} catch (IOException e) {
    System.out.println ("error loading props...");
}
```

Miscellaneous methods

public int hashCode ()

The hashCode() method returns a hash code for the font. This hash code is used whenever a Font object is used as the key in a `Hashtable`.

public boolean equals (Object o)

The `equals()` method overrides the `equals()` method of `Object` to define equality for `Font` objects. Two `Font` objects are equal if their size, style, and name are equal. The following example demonstrates why this is necessary.

```
Font a = new Font ("TimesRoman", Font.PLAIN, 10);
Font b = new Font ("TimesRoman", Font.PLAIN, 10);
// displays false since the objects are different objects
System.out.println (a == b);
// displays true since the objects have equivalent settings
System.out.println (a.equals (b));
```

public String toString ()

The `toString()` method of `Font` returns a string showing the current family, name, style, and size settings. For example:

```
java.awt.Font[family=TimesRoman,name=TimesRoman,style=bolditalic,size=20]
```

4. Events

Contents:

This chapter covers Java's event-driven programming model. Unlike procedural programs, windows-based programs require an event-driven model in which the underlying environment tells your program when something happens. For example, when the user clicks on the mouse, the environment generates an event that it sends to the program. The program must then figure out what the mouse click means and act accordingly.

This chapter covers two different event models, or ways of handling events. In Java 1.0.2 and earlier, events were passed to all components that could possibly have an interest in them. Events themselves were encapsulated in a single `Event` class. Java 1.1 implements a "delegation" model, in which events are distributed only to objects that have been registered to receive the event. While this is somewhat more complex, it is much more efficient and also more flexible, because it allows any object to receive the events generated by a component. In turn, this means that you can separate the user interface itself from the event-handling code.

In the Java 1.1 event model, all event functionality is contained in a new package, `java.awt.event`. Within this package, subclasses of the abstract class `AWTEvent` represent different kinds of events. The package also includes a number of `EventListener` interfaces that are implemented by classes that want to receive different kinds of events; they define the methods that are called when events of the appropriate type occur. A number of adapter classes are also included; they correspond to the `EventListener` interfaces and provide null implementations of the methods in the corresponding listener. The adapter classes aren't essential but provide a convenient shortcut for developers; rather than declaring that your class implements a particular `EventListener` interface, you can declare that your class extends the appropriate adapter.

The old and new event models are incompatible. Although Java 1.1 supports both, you should not use both models in the same program.

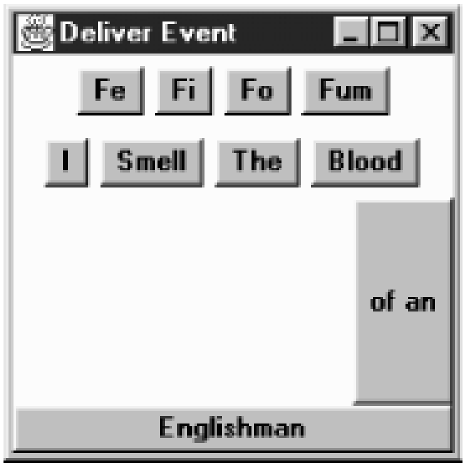
4.1 Java 1.0 Event Model

The event model used in versions 1.0 through 1.0.2 of Java is fairly simple. Upon receiving a user-initiated event, like a mouse click, the system generates an instance of the Event class and passes it along to the program. The program identifies the event's target (i.e., the component in which the event occurred) and asks that component to handle the event. If the target can't handle this event, an attempt is made to find a component that can, and the process repeats. That is all there is to it. Most of the work takes place behind the scenes; you don't have to worry about identifying potential targets or delivering events, except in a few special circumstances. Most Java programs only need to provide methods that deal with the specific events they care about.

Identifying the Target

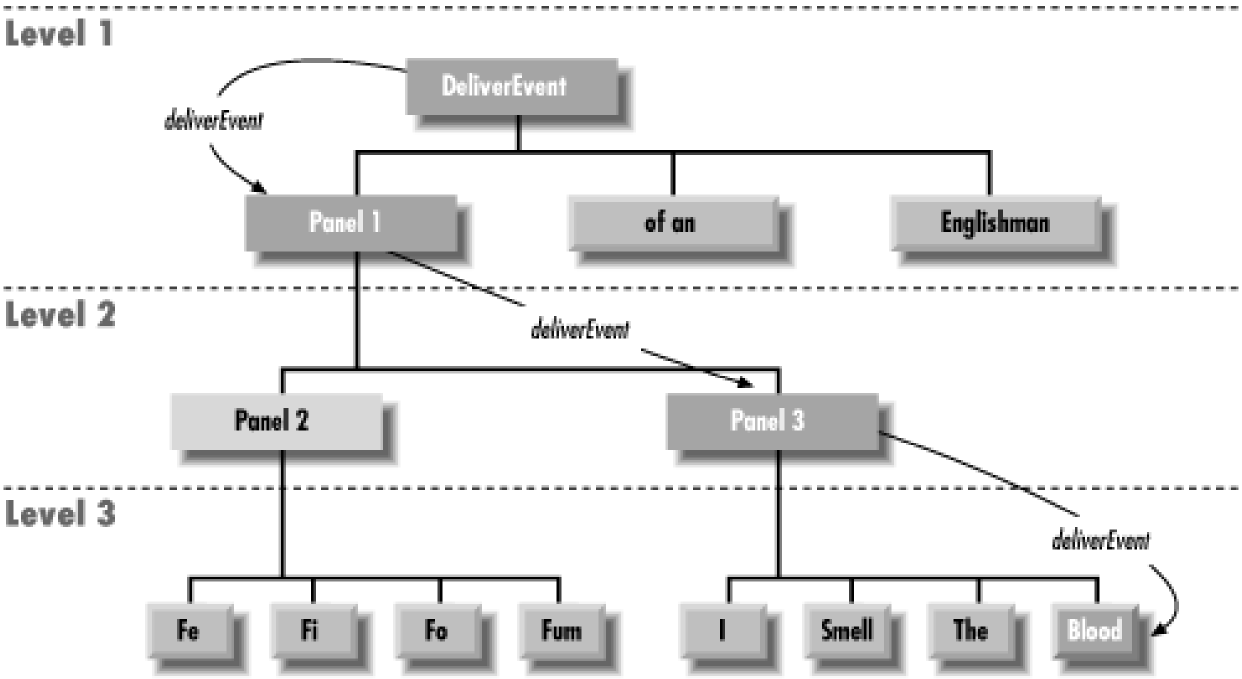
All events occur within a Java Component. The program decides which component gets the event by starting at the outermost level and working in. In Figure 4.1, assume that the user clicks at the location (156, 70) within the enclosing Frame's coordinate space. This action results in a call to the Frame's deliverEvent() method, which determines which component within the frame should receive the event and calls that component's deliverEvent() method. In this case, the process continues until it reaches the Button labeled Blood, which occupies the rectangular space from (135, 60) to (181, 80). Blood doesn't contain any internal components, so it must be the component for which the event is intended. Therefore, an action event is delivered to Blood, with its coordinates translated to fit within the button's coordinate space--that is, the button receives an action event with the coordinates (21, 10). If the user clicked at the location (47, 96) within the Frame's coordinate space, the Frame itself would be the target of the event because there is no other component at this location.

Figure 4.1: deliverEvent



To reach Blood, the event follows the component/container hierarchy shown in Figure 4.2.

Figure 4.2: deliverEvent screen model



Dealing With Events

Once `deliverEvent()` identifies a target, it calls that target's `handleEvent()` method (in this case, the `handleEvent()` method of Blood) to deliver the event for processing. If Blood has not overridden `handleEvent()`, its default implementation would call Blood's `action()` method. If Blood has not overridden `action()`, its default implementation (which is inherited from `Component`) is executed and does nothing. For your program to respond to the event, you would have to provide your own implementation of `action()` or `handleEvent()`.

`handleEvent()` plays a particularly important role in the overall scheme. It is really a dispatcher, which looks at the type of event and calls an appropriate method to do the actual work: `action()` for action events, `mouseUp()` for mouse up events, and so on. Table 4.1 shows the event-handler methods you would have to override when using the default `handleEvent()` implementation. If you create your own `handleEvent()`, either to handle an event without a default handler or to process events differently, it is best to leave these naming conventions in place. Whenever you override an event-handler method, it is a good idea to call the overridden method to ensure that you don't lose any functionality. All of the event handler methods return a boolean, which determines whether there is any further event processing; this is described in the next section, "Passing the Buck."

Table 4.1: Event Types and Event Handlers

Event Type	**Event Handler**
`MOUSE_ENTER`	`mouseEnter()`
`MOUSE_EXIT`	`mouseExit()`
`MOUSE_MOVE`	`mouseMove()`
`MOUSE_DRAG`	`mouseDrag()`
`MOUSE_DOWN`	`mouseDown()`

MOUSE_UP	mouseUp()
KEY_PRESS	keyDown()
KEY_ACTION	keyDown()
KEY_RELEASE	keyUp()
KEY_ACTION_RELEASE	keyUp()
GOT_FOCUS	gotFocus()
LOST_FOCUS	lostFocus()
ACTION_EVENT	action()

Passing the Buck

In actuality, `deliverEvent()` does not call `handleEvent()` directly. It calls the `postEvent()` method of the target component. In turn, `postEvent()` manages the calls to `handleEvent()`. `postEvent()` provides this additional level of indirection to monitor the return value of `handleEvent()`. If the event handler returns `true`, the handler has dealt with the event completely. All processing has been completed, and the system can move on to the next event. If the event handler returns `false`, the handler has not completely processed the event, and `postEvent()` will contact the component's `Container` to finish processing the event. Using the screen in Figure 4.1 as the basis, Example 4.1 traces the calls through `deliverEvent()`, `postEvent()`, and `handleEvent()`. The action starts when the user clicks on the Blood button at coordinates (156, 70). In short, Java dives into the depths of the screen's component hierarchy to find the target of the event (by way of the method `deliverEvent()`). Once it locates the target, it tries to find something to deal with the event by working its way back out (by way of `postEvent()`, `handleEvent()`, and the convenience methods). As you can see, there's a lot of overhead, even in this relatively simple example. When we discuss the Java 1.1 event model, you will see that it has much less overhead, primarily because it doesn't need to go looking for a component to process each event.

Example 4.1: The deliverEvent, postEvent, and handleEvent Methods

```
DeliverEvent.deliverEvent (Event e) called
    DeliverEvent.locate (e.x, e.y)
    Finds Panel1
    Translate Event Coordinates for Panel1
    Panel1.deliverEvent (Event e)
        Panel1.locate (e.x, e.y)
        Finds Panel3
        Translate Event Coordinates for Panel3
        Panel3.deliverEvent (Event e)
            Panel3.locate (e.x, e.y)
            Finds Blood
            Translate Event Coordinates for Blood
            Blood.deliverEvent (Event e)
                Blood.postEvent (Event e)
                    Blood.handleEvent (Event e)
```

```
                        Blood.mouseDown   (Event e, e.x, e.y)
                            returns false
                        return false
                    Get parent Container Panel3
                    Translate Event Coordinates for Panel3
                    Panel3.postEvent (Event e)
                        Panel3.handleEvent (Event e)
                            Component.mouseDown (Event e, e.x, e.y)
                                returns false
                            return false
                        Get parent Container Panel1
                        Translate Event Coordinates for Panel1
                        Panel1.postEvent (Event e)
                            Panel1.handleEvent (Event e)
                                Component.action (Event e, e.x, e.y)
                                    return false
                                return false
                            Get parent Container DeliverEvent
                            Translate Event Coordinates for DeliverEvent
                            DeliverEvent.postEvent (Event e)
                                DeliverEvent.handleEvent
                                    DeliverEvent.action (Event e, e.x, e.y)
                                        return true
                                    return true
                                return true
                            return true
                        return true
                    return true
                return true
            return true
        return true
    return true
```

Overriding handleEvent()

In many programs, you only need to override convenience methods like `action()` and `mouseUp()`; you usually don't need to override `handleEvent()`, which is the high level event handler that calls the convenience methods. However, convenience methods don't exist for all event types. To act upon an event that doesn't have a convenience method (for example, `LIST_SELECT`), you need to override `handleEvent()` itself. Unfortunately, this presents a problem. Unlike the convenience methods, for which the default versions don't take any action, `handleEvent()` does quite a lot: as we've seen, it's the dispatcher that calls the convenience methods. Therefore, when you override `handleEvent()`, either you should reimplement all the features of the method you are overriding (a very bad idea), or you must make sure that the original `handleEvent()`is still executed to ensure that the remaining events get handled properly. The simplest way for you to do this is for your new `handleEvent()` method to act on any events that it is interested in and return `true` if it has handled those events completely. If the incoming event is not an event that your handleEvent() is interested in, you should call super.handleEvent() and return its return value. The following code shows how you might override handleEvent() to deal with a LIST_SELECT event:

```
public boolean handleEvent (Event e) {
    if (e.id == Event.LIST_SELECT) {   // take care of LIST_SELECT
        System.out.println ("Selected item: " + e.arg);
        return true;    // LIST_SELECT handled completely; no further action
    } else {   // make sure we call the overridden method to ensure
                // that other events are handled correctly
        return super.handleEvent (e);
    }
}
```

Basic Event Handlers

The convenience event handlers like mouseDown(), keyUp(), and lostFocus() are all implemented by the Component class. The default versions of these methods do nothing and return false. Because these methods do nothing by default, when overriding them you do not have to ensure that the overridden method gets called. This simplifies the programming task, since your method only needs to return false if it has not completely processed the event. However, if you start to subclass nonstandard components (for example, if someone has created a fancy AudioButton, and you're subclassing that, rather than the standard Button), you probably should explicitly call the overridden method. For example, if you are overriding mouseDown(), you should include a call to super.mouseDown(), just as we called super.handleEvent() in the previous example. This call is "good housekeeping"; most of the time, your program will work without it. However, your program will break as soon as someone changes the behavior of the AudioButton and adds some feature to its mouseDown() method. Calling the super class's event handler helps you write "bulletproof " code.

The code below overrides the mouseDown() method. I'm assuming that we're extending a standard component, rather than extending some custom component, and can therefore dispense with the call to super.mouseDown().

```
public boolean mouseDown (Event e, int x, int y) {
    System.out.println ("Coordinates: " + x + "-" + y);
    if ((x > 100) || (y < 100))
        return false;    // we're not interested in this event; pass it on
    else                 // we're interested;
        ...              // this is where event-specific processing goes
        return true;     // no further event processing
}
```

Here's a debugging hint: when overriding an event handler, make sure that the parameter types are correct--remember that each convenience method has different parameters. If your overriding method has parameters that don't match the original method, the program will still compile correctly. However, it won't work. Because the parameters don't match, your new method simply overloads the original, rather than overriding it. As a result, your method will never be called.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5. Components

Contents:

This chapter introduces the generic graphical widget used within the AWT package, `Component`, along with a trio of specific components: `Label`, `Button`, and `Canvas`. It also covers the `Cursor` class, new to Java 1.1. (Cursor support was previously part of the `Frame` class.) Although many objects within AWT don't subclass `Component`, and though you will never create an instance of `Component`, anything that provides screen-based user interaction and relies on the system for its layout will be a child of `Component`. As a subclass of `Component`, each child inherits a common set of methods and an API for dealing with the different events (i.e., mouse click, keyboard input) that occur within your Java programs.

After discussing the methods in `Component` classes, this chapter goes into detail about two specific components, `Label` and `Button`. A `Label` is a widget that contains descriptive text, usually next to an input field. A `Button` is a basic mechanism that lets the user signal the desire to perform an action. You will learn about the `Canvas` object and how to use a `Canvas` to create your own component. Finally, we cover the `Cursor` class, which lets you change the cursor over a `Component`.

Before going into the mechanics of the `Component` class, it's necessary to say a little about the relationship between components and containers. A `Container` is also a component with the ability to contain other components. There are several different kinds of containers; they are discussed in Chapter 6, *Containers*. To display a component, you have to put it in a container by calling the container's `add()` method. We often call the container that holds a component the component's *parent* ; likewise, we call the components a container holds its *children*. Certain operations are legal only if a component has a parent--that is, the component is in a container. Of course, since containers are components, containers can contain other containers, *ad infinitum*.

NOTE:

If you think some component is missing a method that should obviously be there, check the methods it inherits. For example, the `Label` class appears to lack a `setFont()` method. Obviously, labels ought to be able to change their fonts. The `setFont()` method really is there; it is inherited from the `Component` class, and therefore, not documented as part of the `Label` class. Even if you're familiar with object-oriented techniques, the need to work up a class hierarchy to find all of the class's methods can lead to confusion and frustration. While all Java objects inherit methods from other classes, the potential for confusion is worst with components, which inherit over a hundred methods from `Component` and may only have a few methods of their own.

5.1 Component

Every GUI-based program consists of a screen with a set of objects. With Java, these objects are called components. Some of the more frequently used components are buttons, text fields, and containers.

A container is a special component that allows you to group different components together within it. You will learn more about containers in the next chapter, but they are in fact just another kind of component. Also, some of the parameters and return types for the methods of `Component` have not been explained yet and have their own sections in future chapters.

Component Methods

Constants

Prior to Java 1.1, you could not subclass `Component` or `Container`. With the introduction of the `LightweightPeer`, you can now subclass either `Component` or `Container`. However, since you no longer have a native peer, you must rely on your container to provide a display area and other services that are normally provided by a full-fledged peer. Because you cannot rely on your peer to determine your alignment, the `Component` class now has five constants to indicate six possible alignment settings (one constant is used twice). The alignment constants designate where to position a lightweight component; their values range from 0.0 to 1.0. The lower the number, the closer the component will be placed to the origin (top left corner) of the space allotted to it.[1]

[1] As of Beta 3, these constants appear to be seldom used. The `getAlignmentX()` and `getAlignmentY()` methods return these values, but there are no `setAlignment` methods.

public static final float BOTTOM_ALIGNMENT ★

> The `BOTTOM_ALIGNMENT` constant indicates that the component should align itself to the bottom of its available space. It is a return value from the method `getAlignmentY()`.

public static final float CENTER_ALIGNMENT ★

> The `CENTER_ALIGNMENT` constant indicates that the component should align itself to the middle of its available space. It is a return value from either the `getAlignmentX()` or `getAlignmentY()` method. This constant represents both the horizontal and vertical center.

public static final float LEFT_ALIGNMENT ★

> The `LEFT_ALIGNMENT` constant indicates that the component should align itself to the left side of its available space. It is a return value from `getAlignmentX()`.

public static final float RIGHT_ALIGNMENT ★

> The `RIGHT_ALIGNMENT` constant indicates that the component should align itself to the right side of its available space. It is a return value from the method `getAlignmentX()`.

public static final float TOP_ALIGNMENT ★

> The `TOP_ALIGNMENT` constant indicates that the component should align itself to the top of its available space. It is a return value from `getAlignmentY()`.

Variables

protected Locale locale ★

> The protected `locale` variable can be accessed by calling the `getLocale()` method.

Constructor

Prior to Java 1.1, there was no public or protected constructor for `Component`. Only package members were able to subclass `Component` directly. With the introduction of lightweight peers, components can exist without a native peer, so the constructor was made `protected`, allowing you to create your own `Component` subclasses.

protected Component() ★

> The constructor for `Component` creates a new component without a native peer. Since you no longer have a native peer, you must rely on your container to provide a display area. This allows you to create components that require fewer system resources than components that subclass `Canvas`. The example in the "Using an event multicaster" section of the previous chapter is of a lightweight component. Use the `SystemColor` class to help you colorize the new component appropriately or make it transparent.

Appearance

public Toolkit getToolkit ()

The `getToolkit()` method returns the current `Toolkit` of the `Component`. This returns the parent's `Toolkit` (from a `getParent()` call) when the `Component` has not been added to the screen yet or is lightweight. If there is no parent, `getToolkit()` returns the default `Toolkit`. Through the `Toolkit`, you have access to the details of the current platform (like screen resolution, screen size, and available fonts), which you can use to adjust screen real estate requirements or check on the availability of a font.

public Color getForeground ()

The `getForeground()` method returns the foreground color of the component. If no foreground color is set for the component, you get its parent's foreground color. If none of the component's parents have a foreground color set, `null` is returned.

public void setForeground (Color c)

The `setForeground()` method changes the current foreground color of the area of the screen occupied by the component to `c`. After changing the color, it is necessary for the screen to refresh before the change has any effect. To refresh the screen, call `repaint()`.

public Color getBackground ()

The `getBackground()` method returns the background color of the component. If no background color is set for the component, its parent's background color is retrieved. If none of the component's parents have a background color set, `null` is returned.

public void setBackground (Color c)

The `setBackground()` method changes the current background color of the area of the screen occupied by the component to `c`. After changing the color, it is necessary for the screen to refresh before the change has any affect. To refresh the screen, call `repaint()`.

public Font getFont ()

The `getFont()` method returns the font of the component. If no font is set for the component, its parent's font is retrieved. If none of the component's parents have a font set, `null` is returned.

public synchronized void setFont (Font f)

The `setFont()` method changes the component's font to `f`. If the font family (such as TimesRoman) provided within `f` is not available on the current platform, the system uses a default font family, along with the supplied size and style (plain, bold, italic). Depending upon the platform, it may be necessary to refresh the component/screen before seeing any changes.

Changing the font of a component could have an affect on the layout of the component.

public synchronized ColorModel getColorModel ()

The `getColorModel()` method returns the `ColorModel` used to display the current component. If the component is not displayed, the `ColorModel` from the component's `Toolkit` is used. The normal `ColorModel` for a Java program is 8 bits each for red, green, and blue.

public Graphics getGraphics ()

The `getGraphics()` method gets the component's graphics context. Most noncontainer components do not manage them correctly and therefore throw an `InternalError` exception when you call this method. The `Canvas` component is one that does since you can draw on that directly. If the component is not visible, `null` is returned.

public FontMetrics getFontMetrics (Font f)

The `getFontMetrics()` method retrieves the component's view of the `FontMetrics` for the requested font `f`. Through the `FontMetrics`, you have access to the platform-specific sizing for the appearance of a character or string.

public Locale getLocale () ★

The `getLocale()` method retrieves the current `Locale` of the component, if it has one. Using a `Locale` allows you to write programs that can adapt themselves to different languages and different regional variants. If no `Locale` has been set, `getLocale()` returns the parent's `Locale`.[2] If the component has no locale of its own and no parent (i.e., it isn't in a container), `getLocale()` throws the run-time exception `IllegalComponentStateException`.

> [2] For more on the `Locale` class, see the *Java Fundamental Classes Reference* from O'Reilly & Associates.

public void setLocale (Locale l) ★

The `setLocale()` method changes the current `Locale` of the component to `l`. In order for this change to have any effect, you must localize your components so that they have different labels or list values for different environments. Localization is part of the broad topic of internationalization and is beyond the scope of this book.

public Cursor getCursor () ★

> The `getCursor()` method retrieves the component's current `Cursor`. If one hasn't been set, the default is `Cursor.DEFAULT_CURSOR`. The `Cursor` class is described fully in [Cursor]. Prior to Java 1.1, the ability to associate cursors with components was restricted to frames.

public synchronized void setCursor (Cursor c) ★

> The `setCursor()` method changes the current `Cursor` of the component to `c`. The change takes effect as soon as the cursor is moved. Lightweight components cannot change their cursors.

Positioning/Sizing

`Component` provides a handful of methods for positioning and sizing objects. Most of these are used behind the scenes by the system. You will also need them if you create your own `LayoutManager` or need to move or size an object. All of these depend on support for the functionality from the true component's peer.

public Point getLocation () ★
public Point location () ☆

> The `getLocation()` method returns the current position of the `Component` in its parent's coordinate space. The `Point` is the top left corner of the bounding box around the `Component`.
>
> `location()`is the Java 1.0 name for this method.

public Point getLocationOnScreen () ★

> The `getLocationOnScreen()` method returns the current position of the `Component` in the screen's coordinate space. The `Point` is the top left corner of the bounding box around the `Component`. If the component is not showing, the `getLocationOnScreen()` method throws the `IllegalComponentStateException` run-time exception.

public void setLocation (int x, int y) ★
public void move (int x, int y) ☆

> The `setLocation()` method moves the `Component` to the new position (`x`, `y`). The coordinates provided are in the parent container's coordinate space. This method calls `setBounds()` to move the component. The `LayoutManager` of the container may make it impossible to change a component's location.
>
> Calling this method with a new position for the component generates a `ComponentEvent` with the ID `COMPONENT_MOVED`.

`move()`is the Java 1.0 name for this method.

public void setLocation (Point p) ★

This `setLocation()` method moves the component to the position specified by the given `Point`. It is the same as calling `setLocation(p.x, p.y)`.

Calling this method with a new position for the component generates a `ComponentEvent` with the ID `COMPONENT_MOVED`.

public Dimension getSize () ★
public Dimension size () ☆

The `getSize()` method returns the width and height of the component as a `Dimension` object.

`size()`is the Java 1.0 name for this method.

public void setSize (int width, int height) ★
public void resize (int width, int height) ☆

The `setSize()` method changes the component's width and height to the `width` and `height` provided. `width` and `height` are specified in pixels. The component is resized by a call to `setBounds()`. The `LayoutManager` of the `Container` that contains the component may make it impossible to change a component's size.

Calling this method with a new size for the component generates a `ComponentEvent` with the ID `COMPONENT_RESIZED`.

`resize()`is the Java 1.0 name for this method.

public void setSize (Dimension d) ★
public void resize (Dimension d) ☆

This `setSize()` method changes the component's width and height to the `Dimension d` provided. The `Dimension` object includes the width and height attributes in one object. The component is resized by a call to the `setBounds()` method. The `LayoutManager` of the `Container` that contains the component may make it impossible to change a component's size.

Calling this method with a new size for the component generates a `ComponentEvent` with the ID `COMPONENT_RESIZED`.

`resize()`is the Java 1.0 name for this method.

public Rectangle getBounds () ★
public Rectangle bounds () ☆

The `getBounds()` method returns the bounding rectangle of the object. The fields of the `Rectangle` that you get back contain the component's position and dimensions.

`bounds()`is the Java 1.0 name for this method.

public void setBounds (int x, int y, int width, int height) ★
public void reshape (int x, int y, int width, int height) ☆

The `setBounds()` method moves and resizes the component to the bounding rectangle with coordinates of (`x`, `y`) (top left corner) and `width` x `height`. If the size and shape have not changed, no reshaping is done. If the component is resized, it is invalidated, along with its parent container. The `LayoutManager` of the `Container` that contains the component may make it impossible to change the component's size or position. Calling `setBounds()` invalidates the container, which results in a call to the `LayoutManager` to rearrange the container's contents. In turn, the `LayoutManager` calls `setBounds()` to give the component its new size and position, which will probably be the same size and position it had originally. In short, if a layout manager is in effect, it will probably undo your attempts to change the component's size and position.

Calling this method with a new size for the component generates a `ComponentEvent` with the ID `COMPONENT_RESIZED`. Calling this method with a new position generates a `ComponentEvent` with the ID `COMPONENT_MOVED`.

`reshape()`is the Java 1.0 name for this method.

public void setBounds (Rectangle r) ★

This `setBounds()` method calls the previous method with parameters of `r.x`, `r.y`, `r.width`, and `r.height`.

Calling this method with a new size for the component generates a `ComponentEvent` with the ID `COMPONENT_RESIZED`. Calling this method with a new position generates a `ComponentEvent` with the ID `COMPONENT_MOVED`.

public Dimension getPreferredSize () ★
public Dimension preferredSize () ☆

The `getPreferredSize()` method returns the `Dimension` (width and height) for the preferred size of the component. Each component's peer knows its preferred size. Lightweight objects return `getSize()`.

`preferredSize()`is the Java 1.0 name for this method.

public Dimension getMinimumSize () ★
public Dimension minimumSize () ☆

The `getMinimumSize()` method returns the `Dimension` (width and height) for the minimum size of the component. Each component's peer knows its minimum size. Lightweight objects return `getSize()`. It is possible that the methods `getMinimumSize()` and `getPreferredSize()` will return the same dimensions.

`minimumSize()`is the Java 1.0 name for this method.

public Dimension getMaximumSize () ★

The `getMaximumSize()` method returns the `Dimension` (width and height) for the maximum size of the component. This may be used by a layout manager to prevent a component from growing beyond a predetermined size. None of the `java.awt` layout managers call this method. By default, the value returned is `Short.MAX_VALUE` for both dimensions.

public float getAlignmentX () ★

The `getAlignmentX()` method returns the alignment of the component along the x axis. The alignment could be used by a layout manager to position this component relative to others. The return value is between 0.0 and 1.0. Values nearer 0 indicate that the component should be placed closer to the left edge of the area available. Values nearer 1 indicate that the component should be placed closer to the right. The value 0.5 means the component should be centered. The default setting is `Component.CENTER_ALIGNMENT`.

public float getAlignmentY () ★

The `getAlignmentY()` method returns the alignment of the component along the y axis. The alignment could be used by a layout manager to position this component relative to others. The return value is between 0.0 and 1.0. Values nearer 0 indicate that the component should be placed closer to the top of the area available. Values nearer 1 indicate that the component should be placed closer to the bottom. The value 0.5 means the component should be centered. The default setting is `Component.CENTER_ALIGNMENT`.

public void doLayout () ★
public void layout () ☆

The `doLayout()` method of `Component` does absolutely nothing. It is called when the `Component` is validated (through the `validate()` method). The `Container` class overrides this method.

`layout()`is the Java 1.0 name for this method.

public boolean contains (int x, int y) ★
public boolean inside (int x, int y) ☆

The `contains()` method checks if the `x` and `y` coordinates are within the bounding box of the component. If the `Component` is not rectangular, the method acts as if there is a rectangle around the `Component`. `contains()` returns `true` if the `x` and `y` coordinates are within the component, `false` otherwise.

`inside()`is the Java 1.0 name for this method.

public boolean contains (Point p) ★

This `contains()` method calls the previous method with parameters of `p.x` and `p.y`.

public Component getComponentAt (int x, int y) ★
public Component locate (int x, int y) ☆

The `getComponentAt()` method uses `contains()` to see if the `x` and `y` coordinates are within the component. If they are, this method returns the `Component`. If they aren't, it returns `null`. `getComponentAt()` is overridden by `Container` to provide enhanced functionality.

`locate()`is the Java 1.0 name for this method.

public Component getComponentAt (Point p) ★

This `getComponentAt()` method calls the previous method with parameters of `p.x` and `p.y`.

Painting

The only methods in this section that you call directly are the versions of `repaint()`. The `paint()` and `update()` methods are called by the system when the display area requires refreshing, such as when a user resizes a window. When your program changes the display you should call `repaint()` to trigger a call to `update()` and `paint()`. Otherwise, the system is responsible for updating the display.

public void paint (Graphics g)

The `paint()` method is offered so the system can display whatever you want in a `Component`. In the base `Component` class, this method does absolutely nothing. Ordinarily, it would be overridden in an applet to do something other than the default, which is display a box in the current background color. `g` is the graphics context of the component being drawn on.

public void update (Graphics g)

The `update()` method is automatically called when you ask to repaint the `Component`. If the component is not lightweight, the default implementation of `update()` clears graphics context `g` by drawing a filled rectangle in the background color, resetting the color to the current foreground color, and calling `paint()`. If you do not override `update()` when you do animation, you will see some flickering because `Component` clears the screen. Animation is discussed in Chapter 2, *Simple Graphics*.

public void paintAll (Graphics g)

The `paintAll()` method validates the component and paints its peer if it is visible. `g` represents the graphics context of the component. This method is called when the `paintComponents()` method of `Container` is called.

public void repaint ()

The `repaint()` method requests the scheduler to redraw the component as soon as possible. This will result in `update()` getting called soon thereafter. There is not a one-to-one correlation between `repaint()` and `update()` calls. It is possible that multiple `repaint()` calls can result in a single `update()`.

public void repaint (long tm)

This version of `repaint()` allows for a delay of `tm` milliseconds. It says, please update this component within `tm` milliseconds, which may happen immediately.

public void repaint (int x, int y, int width, int height)

This version of `repaint()` allows you to select the region of the `Component` you desire to be updated. (`x`, `y`) are the coordinates of the upper left corner of the bounding box of the component with dimensions of `width`x`height`. This is similar to creating a clipping area and results in a quicker repaint.

public void repaint (long tm, int x, int y, int width, int height)

This final version of `repaint()` is what the other three `repaint()` methods call. `tm` is the maximum delay in milliseconds before update should be called. (`x`, `y`) are the coordinates of the upper left corner of the clipping area of the component with dimensions of `width` x `height`.

public void print (Graphics g)

The default implementation of the `print()` method calls `paint()`.

In Java 1.0, there was no way to print; in Java 1.1, if the `graphics` parameter implements `PrintGraphics`, anything drawn on `g` will be printed. Printing is covered in Chapter 17, *Printing*.

public void printAll (Graphics g)

The `printAll()` method validates the component and paints its peer if it is visible. `g` represents the graphics context of the component. This method is called when the `printComponents()` method of `Container` is called or when you call it with a `PrintGraphics` parameter.

The default implementation of `printAll()` is identical to `paintAll()`. As with `paintAll()`, `g` represents the graphics context of the component; if `g` implements `PrintGraphics`, it can be printed.

Imaging

Background information about using images is discussed in Chapter 2, *Simple Graphics* and Chapter 12, *Image Processing*. The `imageUpdate()` method of `Component` is the sole method of the `ImageObserver` interface. Since images are loaded in a separate thread, this method is called whenever additional information about the image becomes available.

public boolean imageUpdate (Image image, int infoflags, int x, int y, int width, int height)

`imageUpdate()` is the `java.awt.image.ImageObserver` method implemented by `Component`. It is an asynchronous update interface for receiving notifications about `Image` information as `image` is loaded and is automatically called when additional information becomes available. This method is necessary because image loading is done in a separate thread from the `getImage()` call. Ordinarily, `x` and `y` would be the coordinates of the upper left corner of the image loaded so far, usually (0, 0). However, the method `imageUpdate()` of the component ignores these parameters. `width` and `height` are the `image`'s dimensions, so far, in the loading process.

The `infoflags` parameter is a bit-mask of information available to you about `image`. Please see the text about `ImageObserver` in Chapter 12, *Image Processing* for a complete description of the different flags that can be set. When overriding this method, you can wait for some condition to be true by checking a flag in your program and then taking the desired action. To check for a particular flag, perform an AND (&) of `infoflags` and the constant. For example, to check if the `FRAMEBITS` flag is set:

```
if ((infoflags & ImageObserver.FRAMEBITS) == ImageObserver.FRAMEBITS)
    System.out.println ("The Flag is set");
```

The return value from a call to `imageUpdate()` is `true` if `image` has changed and `false` otherwise.

Two system properties let the user control the behavior of updates:

- `awt.image.incrementaldraw` allows the user to control whether or not partial images are displayed. Initially, the value of `incrementaldraw` is unset and defaults to `true`, which means that partial images are drawn. If `incrementaldraw` is set to `false`, the image will be drawn only when it is complete or when the screen is resized or refreshed.

- `awt.image.redrawrate` allows the user to change the delay between successive repaints. If not set, the default redraw rate is 100 milliseconds.

public Image createImage (int width, int height)

The `createImage()` method creates an empty `Image` of size `width` x `height`. The returned `Image` is an in-memory image that can be drawn on for double buffering to manipulate an image in the background. If an image of size `width` x `height` cannot be created, the call returns `null`. In order for `createImage()` to succeed, the peer of the `Component` must exist; if the component is lightweight, the peer of the component's container must exist.

public Image createImage (ImageProducer producer)

This `createImage()` method allows you to take an existing image and modify it in some way to produce a new `Image`. This can be done through `ImageFilter` and `FilteredImageSource` or a `MemoryImageSource`, which accepts an array of pixel information. You can learn more about these classes and this method in Chapter 12, *Image Processing*.

public boolean prepareImage (Image image, ImageObserver observer)

The `prepareImage()` method forces `image` to start loading, asynchronously, in another thread. `observer` is the `Component` that `image` will be rendered on and is notified (via `imageUpdate()`) as `image` is being loaded. In the case of an `Applet`, `this` would be passed as the `ImageObserver`. If `image` has already been fully loaded, `prepareImage()` returns `true`. Otherwise, `false` is returned. Since `image` is loaded asynchronously, `prepareImage()` returns immediately. Ordinarily, `prepareImage()` would be called by the system when `image` is first needed to be displayed (in `drawImage()` within `paint()`). As more information about the image gets loaded, `imageUpdate()` is called periodically.

If you do not want to go through the trouble of creating a `MediaTracker` instance to start the loading of the image objects, you can call `prepareImage()` to trigger the start of image loading prior to a call to `drawImage()`.

If `image` has already started loading when this is called or if this is an in-memory image, there is no effect.

public boolean prepareImage (Image image, int width, int height, ImageObserver observer)

This version of `prepareImage()` is identical to the previous one, with the addition of a scaling factor of `width`x`height`. As with other `width` and `height` parameters, the units for these parameters are pixels. Also, if `width` and `height` are -1, no scaling factor is assumed. This method is called by one of the internal `MediaTracker` methods.

public int checkImage (Image image, ImageObserver observer)

The `checkImage()` method returns the status of the construction of a screen representation of `image`, being watched by `observer`. If `image` has not started loading yet, this will not start it. The return value is the `ImageObserver` flags ORed together for the data that is now available. The available `ImageObserver` flags are: `WIDTH`, `HEIGHT`, `PROPERTIES`, `SOMEBITS`, `FRAMEBITS`, `ALLBITS`, `ERROR`, and `ABORT`. See Chapter 12, *Image Processing* for a complete description of `ImageObserver`.

public int checkImage (Image image, int width, int height, ImageObserver observer)

This version of `checkImage()` is identical to the previous one, with the addition of a scaling factor of `width`x`height`. If you are using the `drawImage()` version with `width` and `height` parameters, you should use this version of `checkImage()` with the same `width` and `height`.

Peers

public ComponentPeer getPeer () ☆

The `getPeer()` method returns a reference to the component's peer as a `ComponentPeer` object. For example, if you issue this method from a `Button` object, `getPeer()` returns an instance of the `ComponentPeer` subclass `ButtonPeer`.

This method is flagged as deprecated in comments but not with `@deprecated`. There is no replacement method for Java 1.1.

public void addNotify ()

The `addNotify()` method is overridden by each individual component type. When `addNotify()` is called, the peer of the component gets created, and the `Component` is invalidated. The `addNotify()` method is called by the system when it needs to create the peer. The peer needs to be created when a `Component` is first shown, or when a new `Component` is added to a `Container` and the `Container` is already being shown (in which case it already has a peer, but a new one must be created to take account of the new `Component`). If you override this method for a specific `Component`, call `super.addNotify()` first, then do what you need for the `Component`. You will then have information available about the newly created peer.

Certain tasks cannot succeed unless the peer has been created. An incomplete list includes finding the size of a component, laying out a container (because it needs the component's size), and creating an `Image` object. Peers are discussed in more depth in Chapter 15, *Toolkit and Peers*.

public synchronized void removeNotify ()

The `removeNotify()` method destroys the peer of the component and removes it from the screen. The state information about the `Component` is retained by the specific subtype. The `removeNotify()` method is called by the system when it determines the peer is no longer needed. Such times would be when the `Component` is removed from a `Container`, when its container changes, or when the `Component` is disposed. If you override this method for a specific `Component`, issue the particular commands for you need for this `Component`, then call `super.removeNotify()` last.

State Procedures

These methods determine whether the component is ready to be displayed and can be seen by the user. The first requirement is that it be *valid*--that is, whether the system knows its size, and (in the case of a container) whether the layout manager is aware of all its parts and has placed them as requested. A component becomes invalid if the size has changed since it was last displayed. If the component is a container, it becomes invalid when one of the components contained within it becomes invalid.

Next, the component must be *visible*--a possibly confusing term, because components can be considered "visible" without being seen by the user. Frames (because they have their own top-level windows) are not visible until you request that they be shown, but other components are visible as soon as you create them.

Finally, to be seen, a component must be *showing*. You show a component by adding it to its container. For something to be showing, it must be visible and be in a container that is visible and showing.

A subsidiary aspect of state is the *enabled* quality, which determines whether a component can accept input.

public boolean isValid ()

The `isValid()` method tells you whether or not the component needs to be laid out.

public void validate ()

The `validate()` method sets the component's valid state to `true`. Ordinarily, this is done for you when the `Component` is laid out by its `Container`. Since objects are invalid when they are first drawn on the screen, you should call `validate()` to tell the system you are finished adding objects so that it can validate the screen and components. One reason you can override `validate()` is to find out when the container that the component exists in has been resized. The only requirement when overriding is that the original `validate()` be called. With Java 1.1, instead of overriding, you can listen for resize events.

public void invalidate ()

The `invalidate()` method sets the component's valid state to `false` and propagates the invalidation to its parent. Ordinarily, this is done for you, or should be, whenever anything that affects the layout is changed.

public boolean isVisible ()

The `isVisible()` methods tells you if the component is currently visible. Most components are initially visible, except for top-level objects like frames. Any component that is visible will be shown on the screen when the screen is painted.

public boolean isShowing ()

The `isShowing()` method tells you if the component is currently shown on the screen. It is possible for `isVisible()` to return `true` and `isShowing()` to return `false` if the screen has not been painted yet.

Table 5.1 compares possible return values from `isVisible()` and `isShowing()`. The first two entries are for objects that have their own `Window`. These will always return the same values for `isVisible()` and `isShowing()`. The next three are for `Component` objects that exist within a `Window`, `Panel`, or `Applet`. The visible setting is always initially `true`. However, the showing setting is not true until the object is actually drawn. The last case shows another possibility. If the component exists within an invisible `Container`, the component will be visible but will not be shown.

Table 5.1: isVisible vs. isShowing

Happenings	**isVisible**	**isShowing**
`Frame` created	`false`	`false`
`Frame f = new Frame ()`		
`Frame` showing	`true`	`true`
`f.show ()`		
`Component` created	`true`	`false`
`Button b= new Button ("Help")`		

`Button` added to screen in `init()`	`true`	`false`
`add (b)`		
`Container` laid out with `Button` in it	`true`	`true`
`Button` within `Panel` that is not visible	`true`	`false`

public void show ()

The `show()` method displays a component by making it visible and showing its peer. The parent `Container` becomes invalid because the set of children to display has changed. You would call `show()` directly to display a `Frame` or `Dialog`.

In Java 1.1, you should use `setVisible()` instead.

public void hide ()

The `hide()` method hides a component by making it invisible and hiding its peer. The parent `Container` becomes invalid because the set of children to display has changed. If you call `hide()` for a `Component` that does not subclass `Window`, the component's `Container` reserves space for the hidden object.

In Java 1.1, you should use `setVisible()` instead.

public void setVisible(boolean condition) ★
public void show (boolean condition) ☆

The `setVisible()` method calls either `show()` or `hide()` based on the value of `condition`. If `condition` is `true`, `show()` is called. When `condition` is `false`, `hide()` is called.

`show()` is the Java 1.0 name for this method.

public boolean isEnabled ()

The `isEnabled()` method checks to see if the component is currently enabled. An enabled `Component` can be selected and trigger events. A disabled `Component` usually has a slightly lighter font and doesn't permit the user to select or interact with it. Initially, every `Component` is enabled.

public synchronized void enable ()

The `enable()` method allows the user to interact with the component. Components are enabled by default but can be disabled by a call to `disabled()` or `setEnabled(false)`.

In Java 1.1, you should use `setEnabled()` instead.

public synchronized void disable ()

The `disable()` method disables the component so that it is unresponsive to user interactions.

In Java 1.1, you should use `setEnabled()` instead.

public void setEnabled (boolean condition) ★
public void enable (boolean condition) ☆

The `setEnabled()` method calls either `enable()` or `disable()` based on the value of `condition`. If `condition` is `true`, `enable()` is called. When `condition` is `false`, `disable()` is called. Enabling and disabling lets you create components that can be operated only under certain conditions--for example, a `Button` that can be pressed only after the user has typed into a `TextArea`.

`enable()` is the Java 1.0 name for this method.

Focus

Although there was some support for managing input focus in version 1.0, 1.1 improved on this greatly by including support for Tab and Shift+Tab to move input focus to the next or previous component, and by being more consistent across different platforms. This support is provided by the package-private class `FocusManager`.

public boolean isFocusTraversable() ★

The `isFocusTraversable()` method is the support method that tells you whether or not a component is capable of receiving the input focus. Every component asks its peer whether or not it is traversable. If there is no peer, this method returns `false`.

If you are creating a component by subclassing `Component` or `Canvas` and you want it to be traversable, you should override this method; a `Canvas` is not traversable by default.

public void requestFocus ()

The `requestFocus()` method allows you to request that a component get the input focus. If it can't (`isFocusTraversable()` returns `false`), it won't.

public void transferFocus () ★
public void nextFocus () ☆

The `transferFocus()` method moves the focus from the current component to the next one.

`nextFocus()` is the Java 1.0 name for this method.

Miscellaneous methods

public final Object getTreeLock () ★

The `getTreeLock()` method retrieves the synchronization lock for all AWT components. Instead of using `synchronized` methods in Java 1.1, previously synchronized methods lock the tree within a `synchronized (component.getTreeLock()) {}` code block. This results in a more efficient locking mechanism to improve performance.

public String getName () ★

The `getName()` method retrieves the current name of the component. The component's name is useful for object serialization. Components are given a name by default; you can change the name by calling `setName()`.

public void setName (String name) ★

The `setName()` method changes the name of the component to `name`.

public Container getParent ()

The `getParent()` method returns the component's `Container`. The container for anything added to an applet is the applet itself, since it subclasses `Panel`. The container for the applet is the browser. In the case of Netscape Navigator versions 2.0 and 3.0, the return value would be a specific instance of the `netscape.applet.EmbeddedAppletFrame` class. If the applet is running within the *appletviewer*, the return value would be an instance of `sun.applet.AppletViewerPanel`.

public synchronized void add(PopupMenu popup) ★

The `add()` method introduced in Java 1.1 provides the ability to associate a `PopupMenu` with a `Component`. The pop-up menu can be used to provide context-sensitive menus for specific components. (On some platforms for some components, pop-up menus exist already and cannot be overridden.) Interaction with the menu is discussed in Chapter 10, *Would You Like to Choose from the Menu?*

Multiple pop-up menus can be associated with a component. To display the appropriate pop-up menu, call the pop-up menu's `show()`method.

public synchronized void remove(MenuComponent popup) ★

The `remove()` method is the `MenuContainer` interface method to disassociate the `popup` from the component. (`PopupMenu` is a subclass of `MenuComponent`.) If `popup` is not associated with the `Component`, nothing happens.

protected String paramString ()

The `paramString()` method is a protected method that helps build a `String` listing the different parameters of the `Component`. When the `toString()` method is called for a specific `Component`, `paramString()` is called for the lowest level and works its way up the inheritance hierarchy to build a complete parameter string to display. At the `Component` level, potentially seven (Java1.0) or eight (1.1) items are added. The first five items added are the component's name (if non-null and using Java 1.1), x and y coordinates (as returned by `getLocation()`), along with its width and height (as returned by `getSize()`). If the component is not valid, "invalid" is added next. If the component is not visible, "hidden" is added next. Finally, if the component is not enabled, "disabled" is added.

public String toString ()

The `toString()` method returns a `String` representation of the object's values. At the `Component` level, the class's name is placed before the results of `paramString()`. This method is called automatically by the system if you try to print an object using `System.out.println()`.

public void list ()

The `list()` method prints the contents of the `Component` (as returned by `toString()`) to `System.out`. If `c` is a type of `Component`, the two statements `System.out.println(c)` and `c.list()` are equivalent. This method is more useful at the `Container` level, because it prints all the components within the container.

public void list (PrintWriter out) ★
public void list (PrintStream out)

This version of `list()` prints the contents of the `Component` (as returned by `toString()`) to a different `PrintStream`, `out`.

public void list (PrintWriter out, int indentation) ★
public void list (PrintStream out, int indentation)

These versions of `list()` are called by the other two. They print the component's contents (as returned by `toString()`) with the given indentation. This allows you to prepare nicely formatted lists of a container's contents for debugging; you could use the indentation to reflect how deeply the component is nested within the container.

Component Events

Chapter 4, *Events* covers event handling in detail. This section summarizes what `Component` does for the different event-related methods.

With the Java 1.0 event model, many methods return `true` to indicate that the program has handled the event and `false` to indicate that the event was not handled (or only partially handled); when `false` is returned, the system passes the event up to the parent container. Thus, it is good form to return `true` only when you have fully handled the event, and no further processing is necessary.

With the Java 1.1 event model, you register a listener for a specific event type. When that type of event happens, the listener is notified. Unlike the 1.0 model, you do not need to override any methods of `Component` to handle the event. Controllers

The Java 1.0 event model controllers are `deliverEvent()`, `postEvent()`, and `handleEvent()`. With 1.1, the controller is a method named `dispatchEvent()`.

public void deliverEvent (Event e) ☆

> The `deliverEvent()` method delivers the 1.0 `Event e` to the `Component` in which an event occurred. Internally, this method calls `postEvent()`. The `deliverEvent()` method is an important enhancement to `postEvent()` for `Container` objects since they have to determine which component in the `Container` gets the event.

public boolean postEvent (Event e) ☆

> The `postEvent()` method tells the `Component` to deal with 1.0 `Event e`. It calls `handleEvent()`, which returns `true` if some other object handled `e` and `false` if no one handles it. If `handleEvent()` returns `false`, `postEvent()` posts the `Event` to the component's parent. You can use `postEvent()` to hand any events you generate yourself to some other component for processing. (Creating your own events is a useful technique that few developers take advantage of.) You can also use `postEvent()` to reflect an event from one component into another.

public boolean handleEvent (Event e) ☆

> The `handleEvent()` method determines the type of event `e` and passes it along to an appropriate method to deal with it. For example, when a mouse motion event is delivered to `postEvent()`, it is passed off to `handleEvent()`, which calls `mouseMove()`. As shown in the following listing, `handleEvent()` can be implemented as one big switch statement. Since not all event types have default event handlers, you may need to override this method. If you do, remember to call the overridden method to ensure that the default behavior still takes place. To do so, call `super.handleEvent(event)` for any event your method does not deal with.

```
public boolean handleEvent(Event event) {
    switch (event.id) {
      case Event.MOUSE_ENTER:
        return mouseEnter (event, event.x, event.y);
      case Event.MOUSE_EXIT:
        return mouseExit (event, event.x, event.y);
      case Event.MOUSE_MOVE:
        return mouseMove (event, event.x, event.y);
      case Event.MOUSE_DOWN:
        return mouseDown (event, event.x, event.y);
      case Event.MOUSE_DRAG:
        return mouseDrag (event, event.x, event.y);
      case Event.MOUSE_UP:
        return mouseUp (event, event.x, event.y);
      case Event.KEY_PRESS:
      case Event.KEY_ACTION:
        return keyDown (event, event.key);
      case Event.KEY_RELEASE:
      case Event.KEY_ACTION_RELEASE:
        return keyUp (event, event.key);
      case Event.ACTION_EVENT:
        return action (event, event.arg);
      case Event.GOT_FOCUS:
        return gotFocus (event, event.arg);
      case Event.LOST_FOCUS:
        return lostFocus (event, event.arg);
    }
    return false;
}
```

public final void dispatchEvent(AWTEvent e) ★

The `dispatchEvent()` method allows you to post new AWT events to this component's listeners. `dispatchEvent()` tells the `Component` to deal with the `AWTEvent e` by calling its `processEvent()` method. This method is similar to Java 1.0's `postEvent()` method. Events delivered in this way bypass the system's event queue. It's not clear why you would want to bypass the event queue, except possibly to deliver some kind of high priority event.

Action

public boolean action (Event e, Object o) ☆

The `action()` method is called when the user performs some action in the `Component`. `e` is the 1.0

`Event` instance for the specific event, while the content of `o` varies depending upon the specific `Component`. The particular action that triggers a call to `action()` depends on the `Component`. For example, with a `TextField`, `action()` is called when the user presses the carriage return. This method should not be called directly; to deliver any event you generate, call `postEvent()`, and let it decide how the event should propagate.

The default implementation of the `action()` method does nothing and returns `false`. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.action(e, o)` to ensure that the event propagates to the component's container or component's superclass, respectively.

Keyboard

public boolean keyDown (Event e, int key) ★

The `keyDown()` method is called whenever the user presses a key. `e` is the 1.0 `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) could be either `Event.KEY_PRESS` for a regular key or `Event.KEY_ACTION` for an action-oriented key (e.g., arrow or function key). The default `keyDown()` method does nothing and returns `false`. If you are doing input validation, return `true` if the character is invalid; this keeps the event from propagating to a higher component. If you wish to alter the input (i.e., convert to uppercase), return `false`, but change `e.key` to the new character.

public boolean keyUp (Event e, int key)

The `keyUp()` method is called whenever the user releases a key. `e` is the `Event` instance for the specific event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) could be either `Event.KEY_RELEASE` for a regular key or `Event.KEY_ACTION_RELEASE` for an action-oriented key (e.g., arrow or function key). `keyUp()` may be used to determine how long `key` has been pressed. The default `keyUp()` method does nothing and returns `false`.

Mouse

NOTE:

Early releases of Java (1.0.2 and earlier) propagated only mouse events from `Canvas` and `Container` objects. However, Netscape Navigator seems to have jumped the gun and corrected the situation with their 3.0 release, which is based on Java release 1.0.2.1. Until other Java releases catch up, use these events with care. For more information on platform dependencies, see Appendix C, *Platform-Specific Event Handling*.

public boolean mouseDown (Event e, int x, int y) ☆

The `mouseDown()` method is called when the user presses a mouse button over the `Component`. `e` is the `Event` instance for the specific event, while `x` and `y` are the coordinates where the cursor was located when the event was initiated. It is necessary to examine the modifiers field of `e` to determine which mouse button the user pressed. The default `mouseDown()` method does nothing and returns `false`. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.mouseDown(e, x, y)` to ensure that the event propagates to the component's container or component's superclass, respectively.

public boolean mouseDrag (Event e, int x, int y) ☆

The `mouseDrag()` method is called when the user is pressing a mouse button and moves the mouse. `e` is the `Event` instance for the specific event, while `x` and `y` are the coordinates where the cursor was located when the event was initiated. `mouseDrag()` could be called multiple times as the mouse is moved. The default `mouseDrag()` method does nothing and returns `false`. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.mouseDrag(e, x, y)` to ensure that the event propagates to the component's container or component's superclass, respectively.

public boolean mouseEnter (Event e, int x, int y) ☆

The `mouseEnter()` method is called when the mouse enters the `Component`. `e` is the `Event` instance for the specific event, while `x` and `y` are the coordinates where the cursor was located when the event was initiated. The default `mouseEnter()` method does nothing and returns `false`. `mouseEnter()` can be used for implementing balloon help. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.mouseEnter(e, x, y)` to ensure that the event propagates to the component's container or component's superclass, respectively.

public boolean mouseExit (Event e, int x, int y) ☆

The `mouseExit()` method is called when the mouse exits the `Component`. `e` is the `Event` instance for the specific event, while `x` and `y` are the coordinates where the cursor was located when the event was initiated. The default method `mouseExit()` does nothing and returns `false`. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.mouseExit(e, x, y)` to ensure that the event propagates to the component's container or component's superclass, respectively.

public boolean mouseMove (Event e, int x, int y) ☆

The `mouseMove()` method is called when the user moves the mouse without pressing a mouse button. `e` is the `Event` instance for the specific event, while `x` and `y` are the coordinates where the cursor was located when the event was initiated. `mouseMove()` will be called numerous times as the mouse is moved. The default `mouseMove()` method does nothing and returns `false`. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.mouseMove(e, x, y)` to ensure that the event propagates to the component's container or component's superclass, respectively.

public boolean mouseUp (Event e, int x, int y) ☆

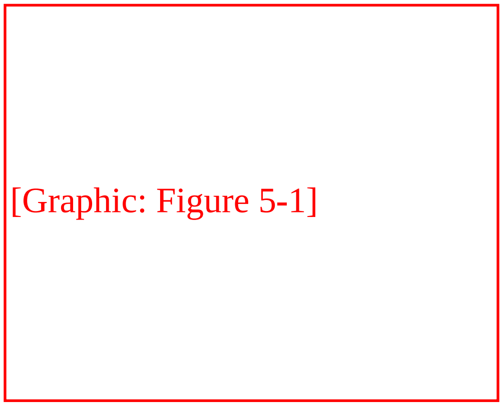
The `mouseUp()` method is called when the user releases a mouse button over the `Component`. `e` is the `Event` instance for the specific event, while `x` and `y` are the coordinates where the cursor was located when the event was initiated. The default `mouseUp()` method does nothing and returns `false`. When you override this method, return `true` only if you fully handle the event. Your method should always have a default case that returns `false` or calls `super.mouseUp(e, x, y)` to ensure that the event propagates to the component's container or component's superclass, respectively.

Focus

Focus events indicate whether a component can get keyboard input. Not all components can get focus (e.g., `Label` cannot). Precisely which components can get the focus is platform specific.

Ordinarily, the item with the focus has a light gray rectangle around it, though the actual display depends on the platform and the component. Figure 5.1 displays the effect of focus for buttons in Windows 95.

Figure 5.1: Focused and UnFocused buttons



NOTE:

Early releases of Java (1.0.2 and earlier) do not propagate all focus events on all platforms. Java 1.1 seems to propagate them properly. For more information on platform dependencies, see Appendix C, *Platform-Specific Event Handling*.

public boolean gotFocus (Event e, Object o) ☆

The `gotFocus()` method is triggered when the `Component` gets the input focus. `e` is the 1.0 `Event` instance for the specific event, while the content of `o` varies depending upon the specific

`Component`. The default `gotFocus()` method does nothing and returns `false`. For a `TextField`, when the cursor becomes active, it has the focus. When you override this method, return `true` to indicate that you have handled the event completely or `false` if you want the event to propagate to the component's container.

public boolean lostFocus (Event e, Object o) ☆

The `lostFocus()` method is triggered when the input focus leaves the `Component`. `e` is the `Event` instance for the specific event, while the content of `o` varies depending upon the specific `Component`. The default `lostFocus()` method does nothing and returns `false`. When you override this method, return `true` to indicate that you have handled the event completely or `false` if you want the event to propagate to the component's container.

Listeners and 1.1 Event Handling

With the 1.1 event model, you receive events by registering event listeners, which are told when the event happens. Components don't have to receive and handle their own events; you can cleanly separate the event-handling code from the user interface itself. This section covers the methods used to add and remove event listeners, which are part of the `Component` class. There is a pair of methods to add and remove listeners for each event type that is appropriate for a `Component`: `ComponentEvent`, `FocusEvent`, `KeyEvent`, `MouseEvent`, and `MouseMotionEvent`. Subclasses of `Component` may have additional event types and therefore will have additional methods for adding and removing listeners. For example, `Button`, `List`, `MenuItem`, and `TextField` each generate action events and therefore have methods to add and remove action listeners. These additional listeners are covered with their respective components.

public void addComponentListener(ComponentListener listener) ★

The `addComponentListener()` method registers `listener` as an object interested in being notified when a `ComponentEvent` passes through the `EventQueue` with this `Component` as its target. When such an event occurs, a method in the `ComponentListener` interface is called. Multiple listeners can be registered.

public void removeComponentListener(ComponentListener listener) ★

The `removeComponentListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

public void addFocusListener(FocusListener listener) ★

The `addFocusListener()` method registers `listener` as an object interested in being notified when a `FocusEvent` passes through the `EventQueue` with this `Component` as its target. When such an event occurs, a method in the `FocusListener` interface is called. Multiple listeners can be registered.

public void removeFocusListener(FocusListener listener) ★

The `removeFocusListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

public void addKeyListener(KeyListener listener) ★

The `addKeyListener()` method registers `listener` as an object interested in being notified when a `KeyEvent` passes through the `EventQueue` with this `Component` as its target. When such an event occurs, a method in the `KeyListener` interface is called. Multiple listeners can be registered.

public void removeKeyListener(KeyListener listener) ★

The `removeKeyListener()` method removes `listener` as a interested listener. If listener is not registered, nothing happens.

public void addMouseListener(MouseListener listener) ★

The `addMouseListener()` method registers `listener` as an object interested in being notified when a nonmotion-oriented `MouseEvent` passes through the `EventQueue` with this `Component` as its target. When such an event occurs, a method in the `MouseListener` interface is called. Multiple listeners can be registered.

public void removeMouseListener(MouseListener listener) ★

The `removeMouseListener()` method removes `listener` as a interested listener. If listener is not registered, nothing happens.

public void addMouseMotionListener(MouseMotionListener listener) ★

The `addMouseMotionListener()` method registers `listener` as an object interested in being notified when a motion-oriented `MouseEvent` passes through the `EventQueue` with this `Component` as its target. When such an event occurs, a method in the `MouseMotionListener` interface is called. Multiple listeners can be registered.

The mouse motion-oriented events are separate from the other mouse events because of their frequency of generation. If they do not have to propagate around, resources can be saved.

public void removeMouseMotionListener(MouseMotionListener listener) ★

> The `removeMouseMotionListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

Handling your own events

Under the 1.1 event model, it is still possible for components to receive their own events, simulating the old event mechanism. If you want to write components that process their own events but are also compatible with the new model, you can override `processEvent()` or one of its related methods. `processEvent()` is logically similar to `handleEvent()` in the old model; it receives all the component's events and sees that they are forwarded to the appropriate listeners. Therefore, by overriding `processEvent()`, you get access to every event the component generates. If you want only a specific type of event, you can override `processComponentEvent()`, `processKeyEvent()`, or one of the other event-specific methods.

However, there is one problem. In Java 1.1, events aren't normally generated if there are no listeners. Therefore, if you want to receive your own events without registering a listener, you should first enable event processing (by a call to `enableEvent()`) to make sure that the events you are interested in are generated.

protected final void enableEvents(long eventsToEnable) ★

> The `enableEvents()` method allows you to configure a component to listen for events without having any active listeners. Under normal circumstances (i.e., if you are not subclassing a component), it is not necessary to call this method.
>
> The `eventsToEnable` parameter contains a mask specifying which event types you want to enable. The `AWTEvent` class (covered in [Chapter 4, *Events*]) contains constants for the following types of events:
>
> *COMPONENT_EVENT_MASK*
> *CONTAINER_EVENT_MASK*
> *FOCUS_EVENT_MASK*
> *KEY_EVENT_MASK*
> *MOUSE_EVENT_MASK*
> *MOUSE_MOTION_EVENT_MASK*
> *WINDOW_EVENT_MASK*
> *ACTION_EVENT_MASK*
> *ADJUSTMENT_EVENT_MASK*
> *ITEM_EVENT_MASK*
> *TEXT_EVENT_MASK*
>
> OR the masks for the events you want; for example, call `enableEvents(MOUSE_EVENT_MASK | MOUSE_MOTION_EVENT_MASK)` to enable all mouse events. Any previous event mask settings are retained.

protected final void disableEvents(long eventsToDisable) ★

The `disableEvents()` method allows you to stop the delivery of events when they are no longer needed. `eventsToDisable` is similar to the `eventsToEnable` parameter but instead contains a mask specifying which event types to stop. A disabled event would still be delivered if someone were listening.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent` with this `Component` as its target. `processEvent()` then passes them along to one of the event-specific processing methods (e.g., `processKeyEvent()`). When you subclass `Component`, overriding `processEvent()` allows you to process all events without providing listeners. Remember to call `super.processEvent(e)` last to ensure that normal event processing still occurs; if you don't, events won't get distributed to any registered listeners. Overriding `processEvent()` is like overriding the `handleEvent()` method using the 1.0 event model.

protected void processComponentEvent(ComponentEvent e) ★

The `processComponentEvent()` method receives `ComponentEvent` with this `Component` as its target. If any listeners are registered, they are then notified. When you subclass `Component`, overriding `processComponentEvent()` allows you to process component events without providing listeners. Remember to call `super.processComponentEvent(e)` last to ensure that normal event processing still occurs; if you don't, events won't get distributed to any registered listeners. Overriding `processComponentEvent()` is roughly similar to overriding `resize()`, `move()`, `show()`, and `hide()` to add additional functionality when those methods are called.

protected void processFocusEvent(FocusEvent e) ★

The `processFocusEvent()` method receives `FocusEvent` with this `Component` as its target. If any listeners are registered, they are then notified. When you subclass `Component`, overriding `processFocusEvent()` allows you to process the focus event without providing listeners. Remember to call `super.processFocusEvent(e)` last to ensure that normal event processing still occurs; if you don't, events won't get distributed to any registered listeners. Overriding `processFocusEvent()` is like overriding the methods `gotFocus()` and `lostFocus()` using the 1.0 event model.

protected void processKeyEvent(KeyEvent e) ★

The `processKeyEvent()` method receives `KeyEvent` with this `Component` as its target. If any listeners are registered, they are then notified. When you subclass `Component`, overriding `processKeyEvent()` allows you to process key events without providing listeners. Be sure to remember to call `super.processKeyEvent(e)` last to ensure that normal event processing still occurs; if you don't, events won't get distributed to any registered listeners. Overriding `processKeyEvent()` is roughly similar to overriding `keyDown()` and `keyUp()` with one method using the 1.0 event model.

protected void processMouseEvent(MouseEvent e) ★

This `processMouseEvent()` method receives all nonmotion-oriented `MouseEvents` with this `Component` as its target. If any listeners are registered, they are then notified. When you subclass `Component`, overriding the method `processMouseEvent()` allows you to process mouse events without providing listeners. Remember to call `super.processMouseEvent(e)` last to ensure that normal event processing still occurs; if you don't, events won't get distributed to any registered listeners. Overriding the method `processMouseEvent()` is roughly similar to overriding `mouseDown()`, `mouseUp()`, `mouseEnter()`, and `mouseExit()` with one method using the 1.0 event model.

protected void processMouseMotionEvent(MouseEvent e) ★

The `processMouseMotionEvent()` method receives all motion-oriented `MouseEvents` with this `Component` as its target. If there are any listeners registered, they are then notified. When you subclass `Component`, overriding `processMouseMotionEvent()` allows you to process mouse motion events without providing listeners. Remember to call `super.processMouseMotionEvent(e)` last to ensure that normal event processing still occurs; if you don't, events won't get distributed to any registered listeners. Overriding the method `processMouseMotionEvent()` is roughly similar to overriding `mouseMove()` and `mouseDrag()` with one method using the 1.0 event model.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

6. Containers

Contents:

This chapter covers a special type of `Component` called `Container`. A `Container` is a subclass of `Component` that can contain other components, including other containers. `Container` allows you to create groupings of objects on the screen. This chapter covers the methods in the `Container` class and its subclasses: `Panel`, `Window`, `Frame`, `Dialog`, and `FileDialog`. It also covers the `Insets` class, which provides an internal border area for the `Container` classes.

Every container has a layout associated with it that controls how the container organizes the components in it. The layouts are described in Chapter 7, *Layouts*.

Java 1.1 introduces a special `Container` called `ScrollPane`. Because of the similarities between scrolling and `ScrollPane`, the new `ScrollPane` container is covered with the `Scrollbar` class in Chapter 11, *Scrolling*.

6.1 Container

`Container` is an abstract class that serves as a general purpose holder of other `Component` objects. The `Container` class holds the methods for grouping the components together, laying out the components inside it, and dealing with events occurring within it. Because `Container` is an abstract class, you never see a pure `Container` object; you only see subclasses that add specific behaviors to a generic container.

Container Methods

Constructors

The abstract `Container` class contains a single constructor to be called by its children. Prior to Java 1.1, the constructor was package private.

protected Container() ★

> The constructor for `Container` creates a new component without a native peer. Since you no longer have a native peer, you must rely on your container to provide a display area. This allows you to create containers that require fewer system resources. For example, if you are creating panels purely for layout management, you might consider creating a `LightweightPanel` class to let you assign a layout manager to a component group. Using `LightweightPanel` will speed things up since events do not have to propagate through the panel and you do not have to get a peer from the native environment. The following code creates the `LightweightPanel` class:

```
import java.awt.*;
public class LightweightPanel extends Container {
    LightweightPanel () {}
    LightweightPanel (LayoutManager lm) {
        setLayout(lm);
    }
}
```

Grouping

A `Container` holds a set of objects within itself. This set of methods describes how to examine and add components to the set.

public int getComponentCount () ★
public int countComponents () ☆

> The `getComponentCount()` method returns the number of components within the container at this level. `getComponentCount()` does not count components in any child `Container` (i.e., containers within the current container).
>
> `countComponents()` is the Java 1.0 name for this method.

public Component getComponent (int position)

The `getComponent()` method returns the component at the specific `position` within it. If `position` is invalid, this method throws the run-time exception `ArrayIndexOutOfBoundsException`.

public Component[] getComponents ()

`getComponents()` returns an array of all the components held within the container. Since these are references to the actual objects on the screen, any changes made to the components returned will be reflected on the display.

public Component add (Component component, int position)

The `add()` method adds `component` to the container at `position`. If `position` is -1, `add()` inserts `component` as the last object within the container. What the container does with `position` depends upon the `LayoutManager` of the container. If `position` is invalid, the `add()` method throws the run-time exception `IllegalArgumentException`. If you try to add `component`'s container to itself (anywhere in the containment tree), this method throws an `IllegalArgumentException`. In Java 1.1, if you try to add a `Window` to a container, `add()` throws the run-time exception `IllegalArgumentException`. If you try to add `component` to a container that already contains it, the container is removed and re-added, probably at a different position.

Assuming that nothing goes wrong, the parent of `component` is set to the container, and the container is invalidated. `add()` returns the `component` just added.

Calling this method generates a `ContainerEvent` with the id `COMPONENT_ADDED`.

public Component add (Component component)

The `add()` method adds `component` to the container as the last object within the container. This is done by calling the earlier version of `add()` with a `position` of -1. If you try to add `component`'s container to itself (anywhere in the containment tree), this method throws the run-time exception `IllegalArgumentException`. In Java 1.1, if you try to add a `Window` to a container, `add()` throws the run-time exception `IllegalArgumentException`.

Calling this method generates a `ContainerEvent` with the id `COMPONENT_ADDED`.

public void add (Component component, Object constraints) ★
public Component add (String name, Component component)

This next version of `add()` is necessary for layouts that require additional information in order to place components. The additional information is provided by the `constraints` parameter. This version of the `add()` method calls the `addLayoutComponent()` method of the `LayoutManager`. What the container does with `constraints` depends upon the actual `LayoutManager`. It can be used for naming containers within a `CardLayout`, specifying a screen area for `BorderLayout`, or providing a set of `GridBagConstraints` for a `GridBagLayout`. In the event that this `add()` is called and the current `LayoutManager` does not take advantage of `constraints`, `component` is added at the end with a position of -1. If you try to add `component`'s container to itself (anywhere in the containment tree), this method throws the run-time exception `IllegalArgumentException`. In Java 1.1, if you try to add a `Window` to a container, `add()` throws the run-time exception `IllegalArgumentException`.

The `add(String`, `Component)` method was changed to `add(component, object)` in Java 1.1 to accommodate the `LayoutManager2` interface (discussed in Chapter 7, *Layouts*) and to provide greater flexibility. In all cases, you can just flip the parameters to bring the code up to 1.1 specs. The string used as an identifier in Java 1.0 is just treated as a particular kind of constraint.

Calling this method generates a `ContainerEvent` with the id `COMPONENT_ADDED`.

public void add (Component component, Object constraints, int index) ★

This final version of `add()` is necessary for layouts that require an `index` and need additional information to place components. The additional information is provided by the `constraints` parameter. This version of `add()` also calls the `addLayoutComponent()` method of the `LayoutManager`. `component` is added with a position of `index`. If you try to add `component`'s container to itself (anywhere in the containment tree), this method throws the run-time exception `IllegalArgumentException`. In Java 1.1, if you try to add a `Window` to a `Container`, `add()` throws the run-time exception `IllegalArgumentException`.

Some layout managers ignore any index. For example, if you call `add(aButton, BorderLayout.NORTH, 3)` to add a `Button` to a `BorderLayout` panel, the `Button` appears in the north region of the layout, no matter what the index.

Calling this method generates a `ContainerEvent` with the id `COMPONENT_ADDED`.

protected void addImpl(Component comp, Object constraints, int index) ★

The protected `addImpl()` method is the helper method that all the others call. It deals with synchronization and enforces all the restrictions on adding components to containers.

The `addImpl()` method tracks the container's components in an internal list. The index with which each component is added determines its position in the list. The lower the component's index, the higher it appears in the stacking order. In turn, the stacking order determines how components are displayed when sufficient space isn't available to display all of them. Components that are added without indices are placed at the end of the list (i.e., at the end of the stacking order) and therefore displayed behind other components. If all components are added without indices, the first component added to the container is first in the stacking order and therefore displayed in front.

You could override `addImpl()` to track when components are added to a container. However, the proper way to find out when components are added is to register a `ContainerListener` and watch for the `COMPONENT_ADDED` and the `COMPONENT_REMOVED` events.

public void remove (int index) ★

The `remove()` method deletes the `component` at position `index` from the container. If `index` is invalid, the `remove()` method throws the run-time exception `IllegalArgumentException`. This method calls the `removeLayoutComponent()` method of the container's `LayoutManager`.

`removeAll()` generates a `ContainerEvent` with the id `COMPONENT_REMOVED`.

public void remove (Component component)

The `remove()` method deletes `component` from the container, if the container directly contains `component`. `remove()` does not look through nested containers trying to find `component`. This method calls the `removeLayoutComponent()` method of the container's `LayoutManager`.

When you call this method, it generates a `ContainerEvent` with the id `COMPONENT_REMOVED`.

public void removeAll ()

The `removeAll()` method removes all components from the container. This is done by looping through all the components, setting each component's parent to `null`, setting the container's reference to the component to `null`, and invalidating the container.

When you call this method, it generates a `ContainerEvent` with the id `COMPONENT_REMOVED` for each component removed.

public boolean isAncestorOf(Component component) ★

The `isAncestorOf()` method checks to see if `component` is a parent (or grandparent or great grandparent) of this container. It could be used as a helper method for `addImpl()` but is not. If `component` is an ancestor of the container, `isAncestorOf()` returns `true`; otherwise, it returns `false`.

Layout and sizing

Every container has a `LayoutManager`. The `LayoutManager` is responsible for positioning the components inside the container. The `Container` methods listed here are used in sizing the objects within the container and specifying a layout.

public LayoutManager getLayout ()

The `getLayout()` method returns the container's current `LayoutManager`.

public void setLayout (LayoutManager manager)

The `setLayout()` method changes the container's `LayoutManager` to `manager` and invalidates the container. This causes the components contained inside to be repositioned based upon `manager`'s rules. If `manager` is `null`, there is no layout manager, and you are responsible for controlling the size and position of all the components within the container yourself.

public Dimension getPreferredSize () ★
public Dimension preferredSize () ☆

The `getPreferredSize()` method returns the `Dimension` (`width` and `height`) for the preferred size of the components within the container. The container determines its preferred size by calling the `preferredLayoutSize()` method of the current `LayoutManager`, which says how much space the layout manager needs to arrange the components. If you override this method, you are overriding the default preferred size.

`preferredSize()` is the Java 1.0 name for this method.

public Dimension getMinimumSize () ★
public Dimension minimumSize () ☆

The `getMinimumSize()` method returns the minimum `Dimension` (`width` and `height`) for the size of the components within the container. This container determines its minimum size by calling the `minimumLayoutSize()` method of the current `LayoutManager`, which computes the minimum amount of space the layout manager needs to arrange the components. It is possible for `getMinimumSize()` and `getPreferredSize()` to return the same dimensions. There is no guarantee that you will get this amount of space for the layout.

`minimumSize()` is the Java 1.0 name for this method.

public Dimension getMaximumSize () ★

The `getMaximumSize()` method returns the maximum `Dimension` (`width` and `height`) for the size of the components within the container. This container determines its maximum size by calling the `maximumLayoutSize()` method of the current `LayoutManager2`, which computes the maximum amount of space the layout manager needs to arrange the components. If the layout manager is not an instance of `LayoutManager2`, this method calls the `getMaximumSize()` method of the `Component`, which returns `Integer.MAX_VALUE` for both dimensions. None of the `java.awt` layout managers use the concept of maximum size yet.

public float getAlignmentX () ★

The `getAlignmentX()` method returns the alignment of the components within the container along the x axis. This container determines its alignment by calling the current `LayoutManager2`'s `getLayoutAlignmentX()` method, which computes it based upon its children. The return value is between 0.0 and 1.0. Values nearer 0 indicate that the component should be placed closer to the left edge of the area available. Values nearer 1 indicate that the component should be placed closer to the right. The value 0.5 means the component should be centered. If the layout manager is not an instance of `LayoutManager2`, this method calls `Component`'s `getAlignmentX()` method, which returns the constant `Component.CENTER_ALIGNMENT`. None of the `java.awt` layout managers use the concept of alignment yet.

public float getAlignmentY () ★

The `getAlignmentY()` method returns the alignment of the components within the container along the y axis. This container determines its alignment by calling the current `LayoutManager2`'s `getLayoutAlignmentY()` method, which computes it based upon its children. The return value is between 0.0 and 1.0. Values nearer 0 indicate that the component should be placed closer to the top of the area available. Values nearer 1 indicate that the component should be placed closer to the bottom. The value 0.5 means the component should be centered. If the layout manager is not an instance of `LayoutManager2`, this method calls `Component`'s `getAlignmentY()` method, which returns the constant `Component.CENTER_ALIGNMENT`. None of the `java.awt` layout managers use the concept of alignment yet.

public void doLayout () ★
public void layout () ☆

The `doLayout()` method of `Container` instructs the `LayoutManager` to lay out the container. This is done by calling the `layoutContainer()` method of the current `LayoutManager`.

`layout()`is the Java 1.0 name for this method.

public void validate ()

The `validate()` method sets the container's valid state to `true` and recursively validates all of its children. If a child is a `Container`, its children are in turn validated. Some components are not completely initialized until they are validated. For example, you cannot ask a `Button` for its display dimensions or position until it is validated.

protected void validateTree () ★

The `validateTree()` method is a helper for `validate()` that does all the work.

public void invalidate () ★

The `invalidate()` method invalidates the container and recursively invalidates the children. If the layout manager is an instance of `LayoutManager2`, its `invalidateLayout()` method is called to invalidate any cached values.

Event delivery

The event model for Java is described in Chapter 4, *Events*. These methods help in the handling of the various system events at the container level.

public void deliverEvent (Event e) ☆

The `deliverEvent()` method is called by the system when the Java 1.0 `Event e` happens. `deliverEvent()` tries to locate a component contained in the container that should receive it. If one is found, the x and y coordinates of `e` are translated for the new target, and `Event e` is delivered to this by calling its `deliverEvent()`. If `getComponentAt()` fails to find an appropriate target, the event is just posted to the container with `postEvent()`.

public Component getComponentAt (int x, int y) ★

public Component locate (int x, int y) ☆

> The container's `getComponentAt()` method calls each component's `contains()` method to see if the `x` and `y` coordinates are within it. If they are, that component is returned. If the coordinates are not in any child component of this container, the container is returned. It is possible for `getComponentAt()` to return `null` if the `x` and `y` coordinates are not within the container. The method `getComponentAt()` can return another `Container` or a lightweight component.
>
> `locate()`is the Java 1.0 name for this method.

public Component getComponentAt (Point p) ★

> This `getComponentAt()` method is identical to the previous method, with the exception that the location is passed as a single point, rather than as separate `x` and `y` coordinates.

Listeners and 1.1 event handling

With the 1.1 event model, you register listeners, which are told when events occur. Container events occur when a component is added or removed.

public synchronized void addContainerListener(ContainerListener listener) ★

> The `addContainerListener()` method registers `listener` as an object interested in receiving notifications when an `ContainerEvent` passes through the `EventQueue` with this `Container` as its target. The `listener.componentAdded()` or `listener.componentRemoved()` method is called when these events occur. Multiple listeners can be registered. The following code demonstrates how to use a `ContainerListener` to register action listeners for all buttons added to an applet. It is similar to the `ButtonTest11` example in Button Events. The trick that makes this code work is the call to `enableEvents()` in `init()`. This method makes sure that container events are delivered in the absence of listeners. In this applet, we know there won't be any container listeners, so we must enable container events explicitly before adding any components.

```
// Java 1.1 only
import java.awt.*;
import java.applet.*;
import java.awt.event.*;
public class NewButtonTest11 extends Applet implements ActionListener {
    Button b;
    public void init () {
        enableEvents (AWTEvent.CONTAINER_EVENT_MASK);
        add (b = new Button ("One"));
        add (b = new Button ("Two"));
        add (b = new Button ("Three"));
        add (b = new Button ("Four"));
    }
    protected void processContainerEvent (ContainerEvent e) {
        if (e.getID() == ContainerEvent.COMPONENT_ADDED) {
            if (e.getChild() instanceof Button) {
                Button b = (Button)e.getChild();
                b.addActionListener (this);
            }
        }
    }
    public void actionPerformed (ActionEvent e) {
        System.out.println ("Selected: " + e.getActionCommand());
    }
}
```

public void removeContainerListener(ContainerListener listener) ★

> The `removeContainerListener()` method removes `listener` as an interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

> The `processEvent()` method receives all `AWTEvent`s with this `Container` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `Container`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. There is no equivalent under the 1.0 event model.
>
> If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processContainerEvent(ContainerEvent e) ★

> The `processContainerEvent()` method receives all `ContainerEvent`s with this `Container` as its target. `processContainerEvent()` then passes them along to any listeners for processing. When you subclass `Container`, overriding the `processContainerEvent()` method allows you to process all container events yourself,

before sending them to any listeners. There is no equivalent under the 1.0 event model.

If you override the `processContainerEvent()` method, remember to call `super.processContainerEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

Painting

The following methods are early vestiges of an approach to painting and printing. They are not responsible for anything that couldn't be done with a call to `paintAll()` or `printAll()`. However, they are available if you wish to call them.

public void paintComponents (Graphics g)

The `paintComponents()` method of `Container` paints the different components it contains. It calls each component's `paintAll()` method with a clipped graphics context `g`, which is eventually passed to `paint()`.

public void printComponents (Graphics g)

The `printComponents()` method of `Container` prints the different components it contains. It calls each component's `printAll()` method with a clipped graphics context `g`, which is passed to `print()`, and eventually works its way to `paint()`.

Since it is the container's responsibility to deal with painting lightweight peers, the `paint()` and `print()` methods are overridden in Java 1.1.

public void paint(Graphics g) ★

The `paint()` method of `Container` paints the different lightweight components it contains.

public void print(Graphics g) ★

The `print()` method of `Container` prints the different lightweight components it contains.

NOTE:

If you override `paint()` or `print()` in your containers (especially applets), call `super.paint(g)` or `super.print(g)`, respectively, to make sure that lightweight components are rendered. This is a good practice even if you don't currently use any lightweight components; you don't want your code to break mysteriously if you add a lightweight component later.

Peers

The container is responsible for creating and destroying all the peers of the components within it.

public void addNotify ()

The `addNotify()` method of `Container` creates the peer of all the components within it. After `addNotify()` is called, the `Container` is invalid. It is useful for top-level containers to call this method explicitly before calling the method `setVisible(true)` to guarantee that the container is laid out before it is displayed.

public void removeNotify ()

The `removeNotify()` method destroys the peer of all the top-level objects contained within it. This in effect destroys the peers of all the components within the container.

Miscellaneous methods

protected String paramString ()

When you call the `toString()` method of a container, the default `toString()` method of `Component` is called. This in turn calls `paramString()` which builds up the string to display. At the `Container` level, `paramString()` appends the layout manager name, like `layout=java.awt.BorderLayout`, to the output.

public Insets getInsets () ★
public Insets insets () ☆

The `getInsets()` method gets the container's current insets. An inset is the amount of space reserved for the container to use between its edge and the area actually available to hold components. For example, in a `Frame`, the inset for the top would be the space required for the title bar and menu bar. Insets exist for top, bottom, right, and left. When you override this method, you are providing an area within the container that is reserved for free space. If the container has insets, they would be the default. If not, the default values are all zeroes.

The following code shows how to override `insets()` to provide values other than the default. The top and bottom have 20 pixels of inset. The left and right have 50. Insets describes the `Insets` class in more detail.

```
public Insets insets () {            // getInsets() for Java 1.1
        return new Insets (20, 50, 20, 50);
}
```

To find out the current value, just call the method and look at the results. For instance, for a `Frame` the results could be the following in the format used by `toString()`:

```
java.awt.Insets[top=42,left=4,right=4,bottom=4]
```

The `42` is the space required for the title and menu bar, while the `4` around the edges are for the window decorations. These results are platform specific and allow you to position items based upon the user's run-time environment.

When drawing directly onto the graphics context of a container with a large inset such as `Frame`, remember to work around the insets. If you do something like `g.drawString("Hello World", 5, 5)` onto a `Frame`, the user won't see the text. It will be under the title bar and menu bar.

`insets()` is the Java 1.0 name for this method.

public void list (PrintWriter output, int indentation) ★
public void list (PrintStream output, int indentation)

The `list()` method is very helpful if you need to find out what is inside a container. It recursively calls itself for each container level of objects inside it, increasing the `indentation` at each level. The results are written to the `PrintStream` or `PrintWriter` `output`.

7. Layouts

Contents:

This chapter expands upon the idea of a layout manager, which was mentioned briefly in the previous chapter. Every container has a `LayoutManager` that is responsible for positioning the component objects within it, regardless of the platform or the screen size. Layout managers eliminate the need to compute component placement on your own, which would be a losing proposition since the size required for any component depends on the platform on which it is displayed. Even for a simple layout, the code required to discover component sizes and compute absolute positions could be hundreds of lines, particularly if you concern yourself with what happens when the user resizes a window. A layout manager takes care of this for you. It asks each component in the layout how much space it requires, then arranges the components on the screen as best it can, based on the component sizes on the platform in use and the space available, resizing the components as needed.

To find out how much space a component needs, a layout manager calls the component's `getMinimumSize()` and `getPreferredSize()` methods. (Java 1.1 also has a `getMaximumSize()` method; the existing layout managers don't take advantage of it.) These methods report the minimum space that a component requires to be displayed correctly and the optimal size at which it looks best. Thus, each component must know its space requirements; the layout manager uses these to arrange the screen; and your Java program never has to worry about platform-dependent positioning.

The `java.awt` package provides five layout managers: `FlowLayout`, `BorderLayout`, `GridLayout`, `CardLayout`, and `GridBagLayout`. Four additional layouts are provided in the `sun.awt` package: `HorizBagLayout`, `VerticalBagLayout`, `OrientableFlowLayout`, and `VariableGridLayout`. `OrientableFlowLayout` is new to Java 1.1. Of the 1.0 layouts, all are available in the JDK and Internet Explorer. The `VariableGridLayout` is also available with Netscape Navigator. This chapter discusses all of them, along with the `LayoutManager` and `LayoutManager2` interfaces; we'll pay particular attention to how each layout manager computes positions for its components. We will also discuss how to combine layouts to generate more complex screens and how to create your own `LayoutManager` for special situations.

7.1 The LayoutManager Interface

The `LayoutManager` interface defines the responsibilities of something that wants to lay out `Component`s within a `Container`. It is the `LayoutManager`'s duty to determine the position and size of each component within the `Container`. You will never directly call the methods of the `LayoutManager` interface; for the most part, layout managers do their work behind the scenes. Once you have created a `LayoutManager` object and told the container to use it (by calling `setLayout()`), you're finished with it. The system calls the appropriate methods in the layout manager when necessary.

Therefore, the `LayoutManager` interface is most important when you are writing a new layout manager; we'll discuss it here because it's the scaffolding on which all layout managers are based. Like any interface, `LayoutManager` specifies the methods a layout manager must implement but says nothing about how the `LayoutManager` does its job. Therefore, we'll make a few observations before proceeding. First, a layout manager is free to ignore some of its components; there is no requirement that a layout manager display everything. For example, a `Container` using a `BorderLayout` might include thirty or forty components. However, the `BorderLayout` will display at most five of them (the last component placed in each of its five named areas). Likewise, a `CardLayout` may manage many components but displays only one at a time.

Second, a layout manager can do anything it wants with the components' minimum and preferred sizes. It is free to ignore either. It makes sense that a layout manager can ignore a preferred size; after all, "preferred" means "give me this if it's available." However, a layout manager can also ignore a minimum size. At times, there is no reasonable alternative: the container may not have enough room to display a component at its minimum size. How to handle this situation is left to the layout manager's discretion. All layout managers currently ignore a component's maximum size, though this may change in the future.

Methods of the LayoutManager Interface

Five methods make up the `LayoutManager` interface. If you create your own class that implements `LayoutManager`, you must define all five. As you will see, many of the methods do not have to do anything, but there must still be a stub with the appropriate method signature.

public abstract void addLayoutComponent (String name, Component component)

> The `addLayoutComponent()` method is called only when the program assigns a `name` to the `component` when adding it to the layout (i.e., the program calls `add(String, Component)` rather than simply calling `add(Component)` or the Java 1.1 `add(Component, Object)`). It is up to the layout manager to decide what, if anything, to do with the name. For example, `BorderLayout` uses `name` to specify an area on the screen in which to display the component. Most layout managers don't require a name and will only implement a stub.

public abstract void removeLayoutComponent (Component component)

> The `removeLayoutComponent()` method's responsibility is to remove `component` from any internal storage used by the layout manager. This method will probably be stubbed out for your own layouts and do nothing. However, it may need to do something if your layout manager associates components with names.

public abstract Dimension preferredLayoutSize (Container parent)

> The `preferredLayoutSize()` method is called to determine the preferred size of the components within the `Container`. It returns a `Dimension` object that contains the required height and width. `parent` is the object whose components need to be laid out. Usually, the `LayoutManager` determines how to size `parent` by calculating the sizes of the components within it and calculating the dimensions required to display them. On other occasions, it may just return `parent.setSize()`.

public abstract Dimension minimumLayoutSize (Container parent)

> The `minimumLayoutSize()` method is called to determine the minimum size of the components within the `Container`. It returns a `Dimension` object that contains the required height and width. `parent` is the object whose components need to be laid out.

public abstract void layoutContainer (Container parent)

> The `layoutContainer()` method is where a `LayoutManager` does most of its work. The `layoutContainer()` method is responsible for the positioning of all the `Components` of `parent`. Each specific layout positions the enclosed components based upon its own rules.

The LayoutManager2 Interface

Numerous changes were introduced in Java 1.1 to make it conform to various design patterns. These patterns provide consistency in usage and make Java programming easier. The `LayoutManager2` interface was introduced for this reason. This new interface solves a problem that occurs when working with the `GridBagLayout`. While the `addLayoutComponent(String, Component)` method of `LayoutManager` works great for `BorderLayout` and `CardLayout`, you can't use it for a `GridBagLayout`. The position of a component in a `GridBagLayout` is controlled by a number of constraints, which are encapsulated in a `GridBagConstraints` object. To associate constraints with a component, you needed to call a `setConstraints()` method. Although this works, it is not consistent with the way you add components to other layouts. Furthermore, as more and more people create their own layout managers, the number of ways to associate positioning information with a component could grow endlessly. `LayoutManager2` defines a version of `addLayoutComponent()` that can be used by all constraint-based layout managers, including older managers like `BorderLayout` and `CardLayout`. This method lets you pass an arbitrary object to the layout manager to provide positioning information. Layout managers that need additional information (like the `GridBagConstraints` object) now implement `LayoutManager2` instead of `LayoutManager`.

In addition to swapping the parameters to the `addLayoutComponent(Component, Object)`, the new `LayoutManager2` interface also defines several methods that aren't really needed now but will facilitate the introduction of "peerless components" in a later release. Methods of the LayoutManager2 interface

public abstract void addLayoutComponent(Component comp, Object constraints) ★

The `addLayoutComponent()` method is called when a program assigns `constraints` to the component `comp` when adding it to the layout. In practice, this means that the program added the component by calling the new method `add(Component component, Object constraints)` rather than the older methods `add(Component component)` or `add(String name, Component component)`). It is up to the layout manager to decide what, if anything, to do with the `constraints`. For example, `GridBagLayout` uses `constraints` to associate a `GridBagConstraints` object to the component `comp`. `BorderLayout` uses `constraints` to associate a location string (like "Center") with the component.

public abstract Dimension maximumLayoutSize(Container target) ★

The `maximumLayoutSize()` method must return the maximum size of the `target` container under this layout manager. Previously, only minimum and preferred sizes were available. Now a container can have a maximum size. Once layout managers support the concept of maximum sizes, containers will not grow without bounds when additional space is available. If there is no actual maximum, the `Dimension` should have a width and height of the constant `Integer.MAX_VALUE`.

public abstract float getLayoutAlignmentX(Container target) ★

The `getLayoutAlignmentX()` method must return the alignment of `target` along the x axis. The return value should be between 0.0 and 1.0. Values nearer 0 mean that the container will be positioned closer to the left edge of the area available. Values nearer 1 mean that the container will be positioned closer to the right. The value 0.5 means the container should be centered.

public abstract float getLayoutAlignmentY(Container target) ★

The `getLayoutAlignmentY()` method must return the alignment of `target` along the y axis. The return value should be between 0.0 and 1.0. Values nearer 0 mean that the container will be positioned closer to the top of the area available. Values nearer 1 mean that the container will be positioned closer to the bottom. The value 0.5 means the container should be centered.

public abstract void invalidateLayout(Container target) ★

The `invalidateLayout()` method tells the layout manager that any layout information it has for `target` is invalid. This method will usually be implemented as a stub (i.e., `{}`). However, if the layout manager caches any information about `target` when this method is called, the manager should consider that information invalid and discard it.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

8. Input Fields

Contents:

There are two fundamental ways for users to provide input to a program: they can type on a keyboard, or they can select something (a button, a menu item, etc.) using a mouse. When you want a user to provide input to your program, you can display a list of choices to choose from or allow the user to interact with your program by typing with the keyboard. Presenting choices to the user is covered in Chapter 9, *Pick Me*. As far as keyboard input goes, the `java.awt` package provides two options. The `TextField` class is a single line input field, while the `TextArea` class is a multiline one. Both `TextField` and `TextArea` are subclasses of the class `TextComponent`, which contains all the common functionality of the two. `TextComponent` is a subclass of `Component`, which is a subclass of `Object`. So you inherit all of these methods when you work with either `TextField` or `TextArea`.

8.1 Text Component

By themselves, the `TextField` and `TextArea` classes are fairly robust. However, in order to reduce duplication between the classes, they both inherit a number of methods from the `TextComponent` class. The constructor for `TextComponent` is package private, so you cannot create an instance of it yourself. Some of the activities shared by `TextField` and `TextArea` through the `TextComponent` methods include setting the text, getting the text, selecting the text, and making it read-only.

TextComponent Methods

Contents

Both `TextField` and `TextArea` contain a set of characters whose content determines the current value of the `TextComponent`. The following methods are usually called in response to an external event.

public String getText ()

> The `getText()` method returns the current contents of the `TextComponent` as a `String` object.

public void setText (String text)

The `setText()` method sets the content of the `TextComponent` to `text`. If the `TextComponent` is a `TextArea`, you can embed newline characters (`\n`) in the `text` so that it will appear on multiple lines.

Text selection

Users can select text in `TextComponents` by pressing a mouse button at a starting point and dragging the cursor across the text. The selected text is displayed in reverse video. Only one block of text can be selected at any given time within a single `TextComponent`. Once selected, this block could be used to provide the user with some text-related operation such as cut and paste (on a `PopupMenu`).

Depending on the platform, you might or might not be able to get selected text when a `TextComponent` does not have the input focus. In general, the component with selected text must have input focus in order for you to retrieve any information about the selection. However, in some environments, the text remains selected when the component no longer has the input focus.

public int getSelectionStart ()

The `getSelectionStart()` method returns the initial position of any selected text. The position can be considered the number of characters preceding the first selected character. If there is no selected text, `getSelectionStart()` returns the current cursor position. If the start of the selection is at beginning of the text, the return value is 0.

public int getSelectionEnd ()

The `getSelectionEnd()` method returns the ending cursor position of any selected text--that is, the number of characters preceding the end of the selection. If there is no selected text, `getSelectionEnd()` returns the current cursor position.

public String getSelectedText ()

The `getSelectedText()` method returns the currently selected text of the `TextComponent` as a `String`. If nothing is selected, `getSelectedText()` returns an empty `String`, not `null`.

public void setSelectionStart (int position) ★

The `setSelectionStart()` method changes the beginning of the current selection to `position`. If `position` is after `getSelectionEnd()`, the cursor position moves to `getSelectionEnd()`, and nothing is selected.

public void setSelectionEnd (int position) ★

The `setSelectionEnd()` method changes the end of the current selection to `position`. If `position` is before `getSelectionStart()`, the cursor position moves to `position`, and nothing is selected.

public void select (int selectionStart, int selectionEnd)

> The `select()` method selects the text in the `TextComponent` from `selectionStart` to `selectionEnd`. If `selectionStart` is after `selectionEnd`, the cursor position moves to `selectionEnd`. Some platforms allow you to use `select()` to ensure that a particular position is visible on the screen.

public void selectAll ()

> The `selectAll()` method selects all the text in the `TextComponent`. It basically does a `select()` call with a `selectionStart` position of 0 and a `selectionEnd` position of the length of the contents.

Carets

Introduced in Java 1.1 is the ability to set and get the current insertion position within the text object.

public int getCaretPosition () ★

> The `getCaretPosition()` method returns the current text insertion position (often called the "cursor") of the `TextComponent`. You can use this position to paste text from the clipboard with the `java.awt.datatransfer` package described in Chapter 16, *Data Transfer*.

public void setCaretPosition (int position) ★

> The `setCaretPosition()` method moves the current text insertion location of the `TextComponent` to `position`. If the `TextComponent` does not have a peer yet, `setCaretPosition()` throws the `IllegalComponentStateException` run-time exception. If `position` < 0, this method throws the run-time exception `IllegalArgumentException`. If `position` is too big, the text insertion point is positioned at the end.
>
> Prior to Java version 1.1, the insertion location was usually set by calling `select(position, position)`.

Read-only text

By default, a `TextComponent` is editable. If a user types while the component has input focus, its contents will change. A `TextComponent` can also be used in an output-only (read-only) mode.

public void setEditable (boolean state)

> The `setEditable()` method allows you to change the current editable state of the `TextComponent` to `state`. `true` means the component is editable; `false` means read-only.

public boolean isEditable ()

> The `isEditable()` method tells you if the `TextComponent` is editable (`true`) or read-only (`false`).

The following listing is an applet that toggles the editable status for a `TextArea` and sets a label to show the current status. As you can see in Figure 8.1, platforms can change the display characteristics of the `TextComponent` to reflect whether the component is editable. (Windows 95 darkens the background. Motif and Windows NT do nothing.)

```
import java.awt.*;
import java.applet.*;
public class readonly extends Applet {
    TextArea area;
    Label label;
    public void init () {
        setLayout (new BorderLayout (10, 10));
        add ("South", new Button ("toggleState"));
        add ("Center", area = new TextArea ("Help Me", 5, 10));
        add ("North", label = new Label ("Editable", Label.CENTER));
    }
    public boolean action (Event e, Object o) {
        if (e.target instanceof Button) {
            if ("toggleState".equals(o)) {
               area.setEditable (!area.isEditable ());
               label.setText ((area.isEditable () ? "Editable" : "Read-only"));
               return true;
            }
        }
        return false;
    }
}
```

Figure 8.1: Editable and read-only TextAreas

[Graphic: Figure 8-1]

Miscellaneous methods

public synchronized void removeNotifiy ()

> The `removeNotify()` method destroys the peer of the `TextComponent` and removes it from the screen. Prior to the `TextComponent` peer's destruction, the current state is saved so that a subsequent call to `addNotify()` will put it back. (`TextArea` and `TextField` each have their own `addNotify()` methods.) These methods deal with the peer object, which hides the native platform's implementation of the component. If you override this method for a specific `TextComponent`, put in the customizations for your new class first, and call `super.removeNotify()` last.

protected String paramString ()

> When you call the `toString()` method of a `TextField` or `TextArea`, the default `toString()` method of `Component` is called. This in turn calls `paramString()`, which builds up the string to display. The `TextComponent` level potentially adds four items. The first is the current contents of the `TextComponent` (`getText()`). If the text is editable, `paramString()` adds the word *editable* to the string. The last two items included are the current selection range (`getSelectionStart()` and `getSelectionEnd()`).

TextComponent Events

With the 1.1 event model, you can register listeners for text events. A text event occurs when the component's content changes, either because the user typed something or because the program called a method like `setText()`. Listeners are registered with the `addTextListener()` method. When the content changes, the `TextListener.textValueChanges()` method is called through the protected method `processTextEvent()`. There is no equivalent to `TextEvent` in Java 1.0; you would have to direct keyboard changes and all programmatic changes to a common method yourself.

In addition to `TextEvent` listeners, Key, mouse, and focus listeners are registered through the `Component` methods `addKeyListener()`, `addMouseListener()`, `addMouseMotionListener()`, and `addFocusListener()`, respectively. Listeners and 1.1 event handling

public synchronized void addTextListener(TextListener listener) ★

> The `addTextListener()` method registers `listener` as an object interested in receiving notifications when a `TextEvent` passes through the `EventQueue` with this `TextComponent` as its target. The `listener.textValueChanged()` method is called when these events occur. Multiple listeners can be registered.
>
> The following applet, `text13`, demonstrates how to use a `TextListener` to handle the events that occur when a `TextField` is changed. Whenever the user types into the `TextField`, a `TextEvent` is delivered to the `textValueChanged()` method, which prints a message on the Java console. The applet includes a button that, when pressed, modifies the text field `tf` by calling `setText()`. These changes also generate a `TextEvent`.

```
// Java 1.1 only
import java.applet.*;
import java.awt.*;
import java.awt.event.*;
class TextFieldSetter implements ActionListener {
    TextField tf;
    TextFieldSetter (TextField tf) {
        this.tf = tf;
    }
    public void actionPerformed(ActionEvent e) {
        if (e.getActionCommand().equals ("Set")) {
            tf.setText ("Hello");
        }
    }
}
public class text13 extends Applet implements TextListener {
    TextField tf;
    int i=0;
    public void init () {
        Button b;
        tf = new TextField ("Help Text", 20);
        add (tf);
        tf.addTextListener (this);
        add (b = new Button ("Set"));
        b.addActionListener (new TextFieldSetter (tf));
    }
    public void textValueChanged(TextEvent e) {
        System.out.println (++i + ": " + e);
    }
}
```

public void removeTextListener(TextListener listener) ★

The `removeTextListener()` method removes `listener` as an interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent`s with this `TextComponent` as its target. `processEvent()` then passes the events along to any listeners for processing. When you subclass `TextComponent`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processTextEvent(TextEvent e) ★

The `processTextEvent()` method receives all `TextEvent`s with this `TextComponent` as its target. `processTextEvent()` then passes them along to any listeners for processing. When you subclass `TextField` or `TextArea`, overriding the `processTextEvent()` method allows you to process all text events yourself, before sending them to any listeners. There is no equivalent to `processTextEvent()` within the 1.0 event model.

If you override `processTextEvent()`, remember to call the method `super.processTextEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9. Pick Me

Contents:

Three AWT components let you present a list of choices to users: `Choice`, `List`, and `Checkbox`. All three components implement the `ItemSelectable` interface (Java1.1). These components are comparable to selection mechanisms in modern GUIs so most readers will be able to learn them easily, but I'll point out some special enhancements that they provide.

`Choice` and `List` are similar; both offer a list of choices for the user to select. `Choice` provides a pull-down list that offers one selection at a time, whereas `List` is a scrollable list that allows a user to make one or multiple selections. From a design standpoint, which you choose depends at least partially on screen real estate; if you want the user to select from a large group of alternatives, `Choice` requires the least space, `List` requires somewhat more, while `Checkbox` requires the most. `Choice` is the only component in this group that does not allow multiple selections. A `List` allows multiple or single selection; because each `Checkbox` is a separate component, checkboxes inherently allow multiple selection. In order to create a list of mutually exclusive checkboxes, in which only one box can be selected at a time (commonly known as radio buttons), you can put several checkboxes together into a `CheckboxGroup`, which is discussed at the end of this chapter.

9.1 Choice

The `Choice` component provides pop-up/pull-down lists. It is the equivalent of Motif's OptionMenu or Windows MFC's ComboBox. (Java 1.1 departs from the MFC world.) With the `Choice` component, you can provide a short list of choices to the user, while taking up the space of a single item on the screen. When the component is selected, the complete list of available choices appears on the screen. After the user has selected an option, the list is removed from the screen and the selected item is displayed. Selecting any item automatically deselects the previous selection.

Component Methods

Constructors

public Choice ()

There is only one constructor for `Choice`. When you call it, a new instance of `Choice` is created. The component is initially empty, with no items to select. Once you add some items using `addItem()` (version 1.0) or `add()` (version 1.1) and display the `Choice` on the screen, it will look something like the leftmost component in Figure 9.1. The center component shows what a `Choice` looks like when it is selected, while the one on the right shows what a `Choice` looks like before any items have been added to it.

Figure 9.1: How Choices are displayed

[Graphic: Figure 9-1]

Items

public int getItemCount () ★
public int countItems () ☆

The `getItemCount()` method returns the number of selectable items in the `Choice` object. In Figure 9.1, `getItemCount()` would return 6.

`countItems()` is the Java 1.0 name for this method.

public String getItem (int index)

The `getItem()` method returns the text for the item at position `index` in the `Choice`. If `index` is invalid--either `index` < 0 or `index` >= `getItemCount()`--the `getItem()` method throws the `ArrayIndexOutOfBoundsException` run-time exception.

public synchronized void add (String item) ★
public synchronized void addItem (String item) ☆

`add()` adds `item` to the list of available choices. If `item` is already an option in the `Choice`, this method adds it again. If `item` is `null`, `add()` throws the run-time exception `NullPointerException`. The first `item` added to a `Choice` becomes the initial (default) selection.

`addItem()` is the Java 1.0 name for this method.

public synchronized void insert (String item, int index) ★

`insert()` adds `item` to the list of available choices at position `index`. An index of 0 adds the item at the beginning. An index larger than the number of choices adds the item at the end. If `item` is `null`, `insert()` throws the run-time exception `NullPointerException`. If `index` is negative, `insert()` throws the run-time exception `IllegalArgumentException`.

public synchronized void remove (String item) ★

`remove()` removes `item` from the list of available choices. If `item` is present in `Choice` multiple times, a call to `remove()` removes the first instance. If `item` is `null`, `remove()` throws the run-time exception `NullPointerException`. If `item` is not found in the `Choice`, `remove()` throws the `IllegalArgumentException` run-time exception.

public synchronized void remove (int position) ★

`remove()` removes the item at `position` from the list of available choices. If `position` is invalid--either `position` < 0 or `position` >= `getItemCount()`--`remove()` throws the run-time exception `ArrayIndexOutOfBoundsException`.

public synchronized void removeAll () ★

The `removeAll()` method removes every option from the `Choice`. This allows you to refresh the list from scratch, rather than creating a new `Choice` and repopulating it.

Selection

The `Choice` has one item selected at a time. Initially, it is the first item that was added to the `Choice`.

public String getSelectedItem ()

The `getSelectedItem()` method returns the currently selected item as a `String`. The text returned is the parameter used in the `addItem()` or `add()` call that put the option in the `Choice`. If `Choice` is empty, `getSelectedItem()` returns `null`.

public Object[] getSelectedObjects () ★

The getSelectedObjects() method returns the currently selected item as an Object array, instead of a String. The array will either be a one-element array, or null if there are no items. This method is required by the ItemSelectable interface and allows you to use the same method to look at the items selected by a Choice, List, or Checkbox.

public int getSelectedIndex ()

The getSelectedIndex() method returns the position of the currently selected item. The Choice list uses zero-based indexing, so the position of the first item is zero. The position of the last item is the value of countItems()-1. If the list is empty, this method returns -1.

public synchronized void select (int position)

This version of the select() method makes the item at position the selected item in the Choice. If position is too big, select() throws the run-time exception IllegalArgumentException. If position is negative, nothing happens.

public void select (String string)

This version of select() makes the item with the label string the selected item. If string is in the Choice multiple times, this method selects the first. If string is not in the Choice, nothing happens.

Miscellaneous methods

public synchronized void addNotify ()

The addNotify() method creates the Choice's peer. If you override this method, call super.addNotify() first, then add your customizations for the new class. You will then be able to do everything you need with the information about the newly created peer.

protected String paramString ()

When you call the toString() method of a Choice, the default toString() method of Component gets called. This in turn calls paramString() which builds up the string to display. At the Choice level, paramString() appends the currently selected item (the result of getSelectedItem()) to the output. Using the first Choice instance in Figure 9.1, the results would be:

```
java.awt.Choice[139,5,92x27,current=Dialog]
```

Choice Events

The primary event for a Choice occurs when the user selects an item in the list. With the 1.0 event model, selecting an item generates an ACTION_EVENT, which triggers a call to the action() method. Once the

Choice has the input focus, the user can change the selection by using the arrow or keyboard keys. The arrow keys scroll through the list of choices, triggering the KEY_ACTION, ACTION_EVENT, and KEY_ACTION_RELEASE event sequence, which in turn invokes the keyDown(), action(), and keyUp() methods, respectively. If the mouse is used to choose an item, no mouse events are triggered as you scroll over each item, and an ACTION_EVENT occurs only when a specific choice is selected.

With the 1.1 event model, you register ItemListener with addItemListener(). Then when the user selects the Choice, the ItemListener.itemStateChanged() method is called through the protected Choice.processItemEvent() method. Key, mouse, and focus listeners are registered through the Component methods of addKeyListener(), addMouseListener(), and addFocusListener(), respectively. Action

public boolean action (Event e, Object o)

> The action() method for a choice signifies that the user selected an item. e is the Event instance for the specific event, while o is the String from the call to addItem() or add() that represents the current selection. Here's a trivial implementation of the method:

```
public boolean action (Event e, Object o) {
    if (e.target instanceof Choice) {
        System.out.println ("Choice is now set to " + o);
    }
    return false;
}
```

Keyboard

The keyboard events for a Choice can be generated once the Choice has the input focus. In addition to the KEY_ACTION and KEY_ACTION_RELEASE events you get with the arrow keys, an ACTION_EVENT is generated over each entry.

public boolean keyDown (Event e, int key)

> The keyDown() method is called whenever the user presses a key and the Choice has the input focus. e is the Event instance for the specific event, while key is the integer representation of the character pressed. The identifier for the event (e.id) for keyDown() could be either Event.KEY_PRESS for a regular key or Event.KEY_ACTION for an action-oriented key (i.e., arrow or function key). If you check the current selection in this method through the method getSelectedItem() or getSelectedIndex(), you will be given the previously selected item because the Choice's selection has not changed yet. keyDown() is not called when the Choice is changed by using the mouse.

public boolean keyUp (Event e, int key)

> The keyUp() method is called whenever the user releases a key. e is the Event instance for the specific

event, while `key` is the integer representation of the character pressed. The identifier for the event (`e.id`) for `keyUp()` could be either `KEY_RELEASE` for a regular key or `KEY_ACTION_RELEASE` for an action oriented key (i.e., arrow or function key).

Mouse

Ordinarily, the `Choice` component does not trigger any mouse events. Focus

Ordinarily, the `Choice` component does not trigger any focus events. Listeners and 1.1 event handling

With the 1.1 event model, you register listeners for different event types; the listeners are told when the event happens. These methods register listeners, and let the `Choice` component inspect its own events.

public void addItemListener(ItemListener listener) ★

The `addItemListener()` method registers `listener` as an object interested in being notified when an `ItemEvent` passes through the `EventQueue` with this `Choice` as its target. The `listener.itemStateChanged()` method is called when an event occurs. Multiple listeners can be registered.

public void removeItemListener(ItemListener listener) ★

The `removeItemListener()` method removes `listener` as a interested listener. If `listener` is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent`s with this `Choice` as its target. `processEvent()` then passes them along to any listeners for processing. When you subclass `Choice`, overriding `processEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processEvent()`, remember to call `super.processEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processItemEvent(ItemEvent e) ★

The `processItemEvent()` method receives all `ItemEvent`s with this `Choice` as its target. `processItemEvent()` then passes them along to any listeners for processing. When you subclass `Choice`, overriding `processItemEvent()` allows you to process all events yourself, before sending them to any listeners. In a way, overriding `processItemEvent()` is like overriding `handleEvent()` using the 1.0 event model.

If you override `processItemEvent()`, remember to call the method `super.processItemEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

The following simple applet below demonstrates how a component can receive its own events by overriding `processItemEvent()`, while still allowing other objects to register as listeners. `MyChoice11` is a subclass of `Choice` that processes its own item events. `choice11` is an applet that uses the `MyChoice11` component and registers itself as a listener for item events.

```
// Java 1.1 only
import java.awt.*;
import java.applet.*;
import java.awt.event.*;
class MyChoice11 extends Choice {
    MyChoice11 () {
        super ();
        enableEvents (AWTEvent.ITEM_EVENT_MASK);
    }
    protected void processItemEvent(ItemEvent e) {
        ItemSelectable ie = e.getItemSelectable();
        System.out.println ("Item Selected: " + ie.getSelectedObjects()[0]);
        // If you do not call super.processItemEvent()
        // no listener will be notified
        super.processItemEvent (e);
    }
}
public class choice11 extends Applet implements ItemListener {
    Choice c;
    public void init () {
        String []fonts;
        fonts = Toolkit.getDefaultToolkit().getFontList();
        c = new MyChoice11();
        for (int i = 0; i < fonts.length; i++) {
            c.add (fonts[i]);
        }
        add (c);
        c.addItemListener (this);
   }
    public void itemStateChanged(ItemEvent e)  {
        ItemSelectable ie = e.getItemSelectable();
        System.out.println ("State Change: " + ie.getSelectedObjects()[0]);
    }
}
```

A few things are worth noticing. `MyChoice11` calls `enableEvents()` in its constructor to make sure that item events are delivered, even if nobody registers as a listener: `MyChoice11` needs to make sure that it receives events, even in the absence of listeners. Its `processItemEvent()` method ends by calling the superclass's `processItemEvent()` method, with the original item event. This call ensures that normal item event processing occurs; `super.processItemEvent()` is responsible for distributing the event to any registered listeners. The alternative would be to implement the whole registration and event distribution mechanism inside `myChoice11`, which is precisely what object-oriented programming is supposed to avoid, or being absolutely sure that you will only use `MyChoice11` in situations in which there won't be any listeners, drastically limiting the usefulness of this class.

`choice11` doesn't contain many surprises. It implements `ItemListener`, the listener interface for item events; provides the required `itemStateChanged()` method, which is called whenever an item event occurs; and calls `MyChoice11`'s method `addItemListener()` to register as a listener for item events. (`MyChoice11` inherits this method from the `Choice` class.)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

10. Would You Like to Choose from the Menu?

Contents:

In Chapter 6, *Containers*, I mentioned that a `Frame` can have a menu. Indeed, to offer a menu in the AWT, you have to attach it to a `Frame`. With versions 1.0.2 and 1.1, Java does not support menu bars within an applet or any other container. We hope that future versions of Java will allow menus to be used with other containers. Java 1.1 goes partway toward solving this problem by introducing a `PopupMenu` that lets you attach context menus to any `Component`. Java 1.1 also adds `MenuShortcut` events, which represent keyboard accelerator events for menus.

Implementing a menu in a `Frame` involves connections among a number of different objects: `MenuBar`, `Menu`, `MenuItem`, and the optional `CheckboxMenuItem`. Several of these classes implement the `MenuContainer` interface. Once you've created a few menus, you'll probably find the process quite natural, but it's hard to describe until you see what all the objects are. So this chapter describes most of the menu classes first and then shows an example demonstrating their use.

All the components covered in previous chapters were subclasses of `Component`. Most of the objects in this chapter subclass `MenuComponent`, which encapsulates the common functionality of menu objects. The `MenuComponent` class hierarchy is shown in Figure 10.1.

Figure 10.1: MenuComponent class hierarchy

[Graphic: Figure 10-1]

To display a Menu, you must first put it in a MenuBar, which you add to a Frame. (Pop-up menus are different in that they don't need a Frame.) A Menu can contain MenuItem as well as other menus that form submenus. CheckboxMenuItem is a specialized MenuItem that (as you might guess) the user can toggle like a Checkbox. One way to visualize how all these things work together is to imagine a set of curtains. The different MenuItem components are the fabrics and panels that make up the curtains. The Menus are the curtains. They get hung from the MenuBar, which is like a curtain rod. Then you place the MenuBar curtain rod into the Frame (the window, in our metaphor), curtains and all.

It might puzzle you that a Menu is a subclass of MenuItem, not the other way around. This is because a Menu can appear on a Menu just like another MenuItem, which would not be possible if the hierarchy was the other way around. Figure 10.2 points out the different pieces involved in the creation of a menu: the MenuBar and various kinds of menu items, including a submenu.

Figure 10.2: The pieces that make up a Menu

[Graphic: Figure 10-2]

10.1 MenuComponent

MenuComponent is an abstract class that is the parent of all menu-related objects. You will never create an instance of the object. Nor are you likely to subclass it yourself--to make the subclass work, you'd have to provide your own peer on every platform where you want the application to run.

MenuComponent Methods

Constructor

public MenuComponent ()--cannot be called directly

> Since MenuComponent is an abstract class, you cannot create an instance of the object. This method is called when you create an instance of one of its children.

Fonts

public Font getFont ()

> The `getFont()` method retrieves the font associated with the `MenuComponent` from `setFont()`. If the current object's font has not been set, the parent menu's font is retrieved. If there is no parent and the current object's font has not been set, `getFont()` returns `null`.

public void setFont (Font f)

> The `setFont()` method allows you to change the font of the particular menu-related component to `f`. When a `MenuComponent` is first created, the initial font is `null`, so the parent menu's font is used.
>
> **NOTE:**

Some platforms do not support changing the fonts of menu items. Where supported, it can make some pretty ugly menus.

Names

The name serves as an alternative, nonlocalized reference identifier for menu components. If your event handlers compare menu label strings to an expected value and labels are localized for a new environment, the approach fails.

public String getName ()

> The `getName()` method retrieves the name of the menu component. Every instance of a subclass of `MenuComponent` is named when it is created.

public void setName (String name)

> The `setName()` method changes the current name of the component to `name`.

Peers

public MenuComponentPeer getPeer () ☆

> The `getPeer()` method returns a reference to the `MenuComponent` peer as a `MenuComponentPeer`.

public synchronized void removeNotify ()

The `removeNotify()` method destroys the peer of the `MenuComponent` and removes it from the screen. `addNotify()` will be specific to the subclass.

Events

Event handling is slightly different between versions. If using the 1.0 event model, use `postEvent()`. Otherwise, use `dispatchEvent()` to post an event to this `MenuComponent` or `processEvent()` to receive and handle an event. Remember not to mix versions within your programs.

public boolean postEvent (Event e) ☆

The `postEvent()` method posts `Event e` to the `MenuComponent`. The event is delivered to the `Frame` at the top of the object hierarchy that contains the selected `MenuComponent`. The only way to capture this event before it gets handed to the `Frame` is to override this method. There are no helper functions as there are for `Components`. Find out which `MenuComponent` triggered the event by checking `e.arg`, which contains its label, or `((MenuItem)e.target).getName()` for the nonlocalized name of the target.

```
public boolean postEvent (Event e) {
    // Use getName() vs. e.arg for localization possibility
    if ("About".equals (((MenuItem)e.target).getName()))
        playLaughingSound(); // Help request
    return super.postEvent (e);
}
```

If you override this method, in order for this `Event` to propagate to the `Frame` that contains the `MenuComponent`, you must call the original `postEvent()` method (`super.postEvent(e)`).

The actual value returned by `postEvent()` is irrelevant.

public final void dispatchEvent(AWTEvent e) ★

The `dispatchEvent()` method allows you to post new AWT events to this menu component's listeners. `dispatchEvent()` tells the `MenuComponent` to deal with the `AWTEvent e` by calling its `processEvent()` method. This method is similar to Java 1.0's `postEvent()` method. Events delivered in this way bypass the system's event queue. It's not clear why you would want to bypass the event queue, except possibly to deliver some kind of high priority event.

protected void processEvent(AWTEvent e) ★

The `processEvent()` method receives all `AWTEvent`s with a subclass of `MenuComponent` as its target. `processEvent()` then passes them along for processing. When you subclass a child class, overriding `processEvent()` allows you to process all events without having to provide listeners. However, remember to call `super.processEvent(e)` last to ensure regular functionality is still executed. This is like overriding `postEvent()` using the 1.0 event model.

Miscellaneous methods

public MenuContainer getParent ()

The `getParent()` method returns the parent `MenuContainer` for the `MenuComponent`. `MenuContainer` is an interface that is implemented by `Component` (in 1.1 only), `Frame`, `Menu`, and `MenuBar`. This means that `getParent()` could return any one of the four.

protected String paramString ()

The `paramString()` method of `MenuComponent` helps build up the string to display when `toString()` is called for a subclass. At the `MenuComponent` level, the current name of the object is appended to the output.

public String toString ()--can be called by user for subclass

The `toString()` method at the `MenuComponent` level cannot be called directly. This `toString()` method is called when you call a subclass's `toString()` and the specifics of the subclass is added between the brackets ([and]). At this level, the results would be:

```
java.awt.MenuComponent[aname1]
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

11. Scrolling

Contents:

This chapter describes how Java deals with scrolling. AWT provides two means for scrolling. The first is the fairly primitive `Scrollbar` object. It really provides only the means to read a value from a slider setting. Anything else is your responsibility: if you want to display the value of the setting (for example, if you're using the scrollbar as a volume control) or want to change the display (if you're using scrollbars to control an area that's too large to display), you have to do it yourself. The `Scrollbar` reports scrolling actions through the standard event mechanisms; it is up to the programmer to handle those events and perform the scrolling.

Unlike other components, which generate an `ACTION_EVENT` when something exciting happens, the `Scrollbar` generates five events: `SCROLL_LINE_UP`, `SCROLL_LINE_DOWN`, `SCROLL_PAGE_UP`, `SCROLL_PAGE_DOWN`, and `SCROLL_ABSOLUTE`. In Java 1.0, none of these events trigger a default event handler like the `action()` method. To work with them, you must override the `handleEvent()` method. With Java 1.1, you handle scrolling events by registering an `AdjustmentListener` with the `Scrollbar.addAdjustmentListener()` method; when adjustment events occur, the listener's `adjustmentValueChanged()` method is called.

Release 1.1 of AWT also includes a `ScrollPane` container object; it is a response to one of the limitations of AWT 1.0. A `ScrollPane` is like a `Panel`, but it has scrollbars and scrolling built in. In this sense, it's like `TextArea`, which contains its own scrollbars. You could use a `ScrollPane` to implement a drawing pad that could cover an arbitrarily large area. This saves you the burden of implementing scrolling yourself: generating scrollbars, handling their events, and figuring out how to redisplay the screen accordingly.

Both `Scrollbar` and `ScrollPane` take advantage of the `Adjustable` interface. `Adjustable` defines the common scrolling activities of the two classes. The `Scrollbar` class implements `Adjustable`; a `ScrollPane` has two methods that return an `Adjustable` object, one for each scrollbar. Currently, you can use the `ScrollPane`'s "adjustables" to find out the scrollbar settings in each direction. You can't change the settings or register `AdjustmentListener`s; the appropriate methods exist, but they don't do anything. It's not clear whether this is appropriate behavior or a bug (remember, an interface only lists methods that must be present but doesn't require them to do anything); it may change in a later release.

11.1 Scrollbar

Scrollbars come in two flavors: horizontal and vertical. Although there are several methods for setting the page size, scrollbar range (minimum and maximum values), and so on, basically all you can do is get and set the scrollbar's value. Scrollbars don't contain any area to display their value, though if you want one, you could easily attach a label.

To work with a `Scrollbar`, you need to understand the pieces from which it is built. Figure 11.1 identifies each of the pieces. At both ends are arrows, which are used to change the `Scrollbar` value the default amount (one unit) in the direction selected. The paging areas are used to change the `Scrollbar` value one page (ten units by default) at a time in the direction selected. The slider can be moved to set the scrollbar to an arbitrary value within the available range.

Figure 11.1: Scrollbar elements

[Graphic: Figure 11-1]

Scrollbar Methods

Constants

There are two direction specifiers for `Scrollbar`. The direction tells the `Scrollbar` which way to orient itself. They are used in the constructors, as a parameter to `setOrientation()`, and as the return value for the `getOrientation()` method.

public final static int HORIZONTAL

HORIZONTAL is the constant for horizontal orientation.

public final static int VERTICAL

VERTICAL is the constant for vertical orientation.

Constructors

public Scrollbar (int orientation, int value, int visible, int minimum, int maximum)

The Scrollbar constructor creates a Scrollbar with a direction of orientation and initial value of value. visible is the size of the slider. minimum and maximum are the range of values that the Scrollbar can be. If orientation is not HORIZONTAL or VERTICAL, the constructor throws the run-time exception IllegalArgumentException. If maximum is below the value of minimum, the scrollbar's minimum and maximum values are both set to minimum. If value is outside the range of the scrollbar, it is set to the limit it exceeded. The default line scrolling amount is one. The default paging amount is ten.

If you are using the scrollbar to control a visual object, visible should be set to the amount of a displayed object that is on the screen at one time, relative to the entire size of the object (i.e., relative to the scrollbar's range: maximum - minimum). Some platforms ignore this parameter and set the scrollbar to a fixed size.

public Scrollbar (int orientation)

This constructor for Scrollbar creates a Scrollbar with the direction of orientation. In Java 1.0, the initial settings for value, visible, minimum, and maximum are 0. In Java 1.1, the default value for visible is 10, and the default for maximum is 100; the other values default to 0. If orientation is not HORIZONTAL or VERTICAL, the constructor throws the run-time exception IllegalArgumentException. This constructor is helpful if you want to reserve space for the Scrollbar on the screen, to be configured later. You would then use the setValues() method to configure the scrollbar.

public Scrollbar ()

This constructor creates a VERTICAL Scrollbar. In Java 1.0, the initial settings for value, visible, minimum, and maximum are 0. In Java 1.1, the default value for visible is 10, and the default for maximum is 100; the other values default to 0. You would then use the `setValues()` method to configure the scrollbar.

Figure 11.2 shows both vertical and horizontal scrollbars. It also demonstrates a problem you'll run into if you're not careful. If not constrained by the `LayoutManager`, scrollbars can get very fat. The result is rarely pleasing. The solution is to place scrollbars in layout managers that restrict width for vertical scrollbars or height for horizontal ones. The side regions (i.e., everything except the center) of a border layout are ideal. In the long term, the solution will be scrollbars that give you their maximum size and layout managers that observe the maximum size.

Figure 11.2: Vertical and horizontal scrollbars

[Graphic: Figure 11-2]

Adjustable Methods

public int getOrientation ()

The `getOrientation()` method returns the current orientation of the scrollbar: either `Scrollbar.HORIZONTAL` or `Scrollbar.VERTICAL`.

public synchronized void setOrientation (int orientation) ★

The `setOrientation()` method changes the orientation of the scrollbar to `orientation`, which must be either `Scrollbar.HORIZONTAL` or `Scrollbar.VERTICAL`. If `orientation` is not `HORIZONTAL` or `VERTICAL`, this method throws the run-time exception `IllegalArgumentException`. It was not possible to change the orientation of a scrollbar prior to Java 1.1.

public int getVisibleAmount () ★
public int getVisible () ☆

The `getVisibleAmount()` method gets the `visible` setting of the `Scrollbar`. If the scrollbar's `Container` is resized, the `visible` setting is not automatically changed.

`getVisible()` is the Java 1.0 name for this method.

public synchronized void setVisibleAmount (int amount) ★

The `setVisibleAmount()` method changes the current `visible` setting of the `Scrollbar` to `amount`.

public int getValue ()

The `getValue()` method is probably the most frequently called method of `Scrollbar`. It returns the current value of the scrollbar queried.

public synchronized void setValue (int value)

The `setValue()` method changes the value of the scrollbar to `value`. If `value` exceeds a scrollbar limit, the scrollbar's new value is set to that limit. In Java 1.1, this method is synchronized; it was not in earlier versions.

public int getMinimum ()

The `getMinimum()` method returns the current minimum setting for the scrollbar.

public synchronized void setMinimum (int minimum) ★

The `setMinimum()` method changes the `Scrollbar`'s minimum value to `minimum`. The current setting for the `Scrollbar` may change to `minimum` if `minimum` increases above `getValue()`.

public int getMaximum ()

The `getMaximum()` method returns the current maximum setting for the scrollbar.

public synchronized void setMaximum (int maximum) ★

The `setMaximum()` method changes the maximum value of the `Scrollbar` to `maximum`. The current setting for the `Scrollbar` may change to `maximum` if `maximum` decreases below `getValue()`.

public synchronized void setValues (int value, int visible, int minimum, int maximum)

The `setValues()` method changes the `value`, `visible`, `minimum`, and `maximum` settings all at once. In Java 1.0.2, separate methods do not exist for changing `visible`, `minimum`, or `maximum`. The scrollbar's value is set to `value`, visible to `visible`, minimum to `minimum`, and maximum to `maximum`. If `maximum` is below the value of `minimum`, it is set to `minimum`. If `value` is outside the range of the scrollbar, it is set to the limit it exceeded. In Java 1.1, this method is synchronized; it was not in earlier versions.

public int getUnitIncrement () ★
public int getLineIncrement () ☆

The `getUnitIncrement()` method returns the current line increment. This is the amount the scrollbar will scroll if the user clicks on one of the scrollbar's arrows.

`getLineIncrement()` is the Java 1.0 name for this method.

public void setUnitIncrement (int amount) ★
public void setLineIncrement (int amount) ☆

The `setUnitIncrement()` method changes the line increment amount to `amount`.

`setLineIncrement()` is the Java 1.0 name for this method.

Changing the line increment amount was not possible in Java 1.0.2. This method acted like it returned successfully, and `getLineIncrement()` returned the new value, but the `Scrollbar` changed its value by only one (the default) when you clicked on one of the arrows. However, you could work around this defect by explicitly handling the `SCROLL_LINE_UP` and `SCROLL_LINE_DOWN` events: get the correct line increment, adjust the display appropriately, and then set call `setValue()` to correct the scrollbar's value. This workaround is not needed in Java 1.1.

public int getBlockIncrement () ★
public int getPageIncrement () ☆

The `getBlockIncrement()` method returns the current paging increment. This is the amount the scrollbar will scroll if the user clicks between the slider and one of the scrollbar's arrows.

`getPageIncrement()` is the Java 1.0 name for this method.

public void setBlockIncrement (int amount) ★
public void setPageIncrement (int amount) ☆

The `setBlockIncrement()` method changes the paging increment amount to `amount`.

`setPageIncrement()` is the Java 1.0 name for this method.

Changing the paging increment amount was not possible in Java 1.0.2. This method acts like it returns successfully, and `getPageIncrement()` returns the new value, but the `Scrollbar` changes its value only by 10 (the default) when you click on one of the paging areas. However, you can work around this defect by explicitly handling the `SCROLL_PAGE_UP` and `SCROLL_PAGE_DOWN` events: get the correct page increment, adjust the display appropriately, and then set call `setValue()` to correct the scrollbar's value. This workaround is not necessary in Java 1.1.

Miscellaneous methods

public synchronized void addNotify ()

The `addNotify()` method creates the `Scrollbar`'s peer. If you override this method, call `super.addNotify()` first. You will then be able to do everything you need with the information about the newly created peer.

protected String paramString ()

`Scrollbar` doesn't have its own `toString()` method; when you call the `toString()` method of a `Scrollbar`, you are actually calling the method `Component.toString()`. This in turn calls `paramString()`, which builds the string to display. For a `Scrollbar`, `paramString()` puts the scrollbar's value, visibility, minimum, maximum, and direction into the string. In Java 1.0, there is a minor bug in the output. Instead of displaying the scrollbar's `visible` setting (an integer), `paramString()` displays the component's `visible` setting (a boolean). (This is corrected in Java 1.1.) The following `String` is the result of calling `toString()` for a horizontal `Scrollbar` that hasn't been configured yet:

```
java.awt.Scrollbar[0,0,0x0,invalid,val=0,vis=true,min=0,max=0,horz]
```

Scrollbar Events

With the 1.0 event model, scrollbars generate five kinds of events in response to user interaction: `SCROLL_LINE_UP`, `SCROLL_LINE_DOWN`, `SCROLL_PAGE_UP`, `SCROLL_PAGE_DOWN`, and `SCROLL_ABSOLUTE`. The event that occurs depends on what the user did, as shown in Table 11.1; the event type is specified in the `id` field of the `Event` object passed to `handleEvent()`. However, as a programmer, you often do not care which of these five events happened. You care only about the scrollbar's new value, which is always passed as the `arg` field of the `Event` object.

Table 11.1: Scrollbar Events

Event Type (Event.id)	**Event Meaning**
`SCROLL_ABSOLUTE`	User drags slider.
`SCROLL_LINE_DOWN`	User presses down arrow.
`SCROLL_LINE_UP`	User presses up arrow.
`SCROLL_PAGE_DOWN`	User selects down paging area.
`SCROLL_PAGE_UP`	User selects up paging area.

Because scrollbar events do not trigger any default event handlers (like `action()`), it is necessary to override the `handleEvent()` method to deal with them. Unless your version of `handleEvent()` deals with all conceivable events, you must ensure that the original `handleEvent()` method is called. The simplest way is to have the return statement call `super.handleEvent()`.

Most `handleEvent()` methods first identify the type of event that occurred. The following two code blocks demonstrate different ways of checking for the `Scrollbar` events.

```
if ((e.id == Event.SCROLL_LINE_UP) ||
    (e.id == Event.SCROLL_LINE_DOWN) ||
    (e.id == Event.SCROLL_PAGE_UP) ||
    (e.id == Event.SCROLL_PAGE_DOWN) ||
    (e.id == Event.SCROLL_ABSOLUTE)) {
    // Then determine which Scrollbar was selected and act upon it
}
```

Or more simply:

```
if (e.target instanceof Scrollbar) {
    // Then determine which Scrollbar was selected and act upon it.
}
```

Although the second code block is simpler, the first is the better choice because it is more precise. For example, what would happen if mouse events are passed to scrollbars? Different Java platforms differ most in the types of events passed to different objects; Netscape Navigator 3.0 for Windows 95 sends `MOUSE_ENTER`, `MOUSE_EXIT`, and `MOUSE_MOVE` events to the `Scrollbar`.[1] The second code block executes for all the mouse events--in fact, any event coming from a `Scrollbar`. Therefore, it executes much more frequently (there can be many `MOUSE_MOVE` events), leading to poor interactive performance.

[1] MOUSE_UP, MOUSE_DOWN, and MOUSE_DRAG are not generated since these operations generate SCROLL events.

Another platform-specific issue is the way the system generates SCROLL_ABSOLUTE events. Some platforms generate many events while the user drags the scrollbar. Others don't generate the event until the user stops dragging the scrollbar. Some implementations wait until the user stops dragging the scrollbar and then generate a flood of SCROLL_ABSOLUTE events for you to handle. In theory, it does not matter which is happening, as long as your event-processing code is tight. If your event-processing code is time consuming, you may wish to start another thread to perform the work. If the thread is still alive when the next event comes along, flag it down, and restart the operation. Listeners and 1.1 event handling

With the 1.1 event model, you register an AdjustmentListener by calling the addAdjustmentListener() method. Then when the user moves the Scrollbar slider, the AdjustmentListener.adjustmentValueChanged() method is called through the protected Scrollbar.processAdjustmentEvent() method. Key, mouse, and focus listeners are registered through the three Component methods of addKeyListener(), addMouseListener(), and addFocusListener(), respectively. Because you need to register a separate listener for mouse events, you no longer have the problem of distinguishing between mouse events and slider events. An adjustment listener will never receive mouse events.

public void addAdjustmentListener(AdjustmentListener listener) ★

The addAdjustmentListener() method registers listener as an object interested in being notified when an AdjustmentEvent passes through the EventQueue with this Scrollbar as its target. The method listener.adjustmentValueChanged() is called when an event occurs. Multiple listeners can be registered.

public void removeAdjustmentListener(ItemListener listener) ★

The removeAdjustmentListener() method removes listener as a interested listener. If listener is not registered, nothing happens.

protected void processEvent(AWTEvent e) ★

The processEvent() method receives every AWTEvent with this Scrollbar as its target. processEvent() then passes it along to any listeners for processing. When you subclass Scrollbar, overriding processEvent() allows you to process all events yourself, before sending them to any listeners. In a way, overriding processEvent() is like overriding handleEvent() using the 1.0 event model.

If you override the `processEvent()` method, remember to call the `super.processEvent(e)` method last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

protected void processAdjustmentEvent(ItemEvent e) ★

The `processAdjustmentEvent()` method receives all `AdjustmentEvent`s with this `Scrollbar` as its target. `processAdjustmentEvent()` then passes them along to any listeners for processing. When you subclass `Scrollbar`, overriding `processAdjustmentEvent()` allows you to process all events yourself, before sending them to any listeners.

If you override `processAdjustmentEvent()`, you must remember to call `super.processAdjustmentEvent(e)` last to ensure that regular event processing can occur. If you want to process your own events, it's a good idea to call `enableEvents()` (inherited from `Component`) to ensure that events are delivered even in the absence of registered listeners.

Scrolling An Image

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

12. Image Processing

Contents:

The image processing parts of Java are buried within the `java.awt.image` package. The package consists of three interfaces and eleven classes, two of which are abstract. They are as follows:

- The `ImageObserver` interface provides the single method necessary to support the asynchronous loading of images. The interface implementers watch the production of an image and can react when certain conditions arise. We briefly touched on `ImageObserver` when we discussed the `Component` class (in Chapter 5, *Components*), because `Component` implements the interface.

- The `ImageConsumer` and `ImageProducer` interfaces provide the means for low level image creation. The `ImageProducer` provides the source of the pixel data that is used by the `ImageConsumer` to create an `Image`.

- The `PixelGrabber` and `ImageFilter` classes, along with the `AreaAveragingScaleFilter`, `CropImageFilter`, `RGBImageFilter`, and `ReplicateScaleFilter` subclasses, provide the tools for working with images. `PixelGrabber` consumes pixels from an `Image` into an array. The `ImageFilter` classes modify an existing image to produce another `Image` instance. `CropImageFilter` makes smaller images; `RGBImageFilter` alters pixel colors, while `AreaAveragingScaleFilter` and `ReplicateScaleFilter` scale images up and down using different algorithms. All of these classes implement `ImageConsumer` because they take pixel data as input.

- `MemoryImageSource` and `FilteredImageSource` produce new images. `MemoryImageSource` takes an array and creates an image from it. `FilteredImageSource` uses an `ImageFilter` to read and modify data from another image and produces the new image based on the original. Both `MemoryImageSource` and `FilteredImageSource` implement `ImageProducer` because they produce new pixel data.

- `ColorModel` and its subclasses, `DirectColorModel` and `IndexColorModel`, provide the palette of colors available when creating an image or tell you the palette used when using `PixelGrabber`.

The classes in the `java.awt.image` package let you create `Image` objects at run-time. These classes can be used to rotate images, make images transparent, create image viewers for unsupported graphics formats, and more.

12.1 ImageObserver

As you may recall from Chapter 2, *Simple Graphics*, the last parameter to the `drawImage()` method is the image's `ImageObserver`. However, in Chapter 2, *Simple Graphics* I also said that you can use `this` as the image observer and forget about it. Now it's time to ask the obvious questions: what is an image observer, and what is it for?

Because `getImage()` acquires an image asynchronously, the entire `Image` object might not be fully loaded when `drawImage()` is called. The `ImageObserver` interface provides the means for a component to be told asynchronously when additional information about the image is available. The `Component` class implements the `imageUpdate()` method (the sole method of the `ImageObserver` interface), so that method is inherited by any component that renders an image. Therefore, when you call `drawImage()`, you can pass `this` as the final argument; the component on which you are drawing serves as the `ImageObserver` for the drawing process. The communication between the image observer and the image consumer happens behind the scenes; you never have to worry about it, unless you want to write your own `imageUpdate()` method that does something special as the image is being loaded.

If you call `drawImage()` to display an image created in local memory (either for double buffering or from a `MemoryImageSource`), you can set the `ImageObserver` parameter of `drawImage()` to `null` because no asynchrony is involved; the entire image is available immediately, so an `ImageObserver` isn't needed.

ImageObserver Interface

Constants

The various flags associated with the `ImageObserver` are used for the `infoflags` argument to `imageUpdate()`. The flags indicate what kind of information is available and how to interpret the other arguments to `imageUpdate()`. Two or more flags are often combined (by an OR operation) to show that several kinds of information are available.

public static final int WIDTH

When the `WIDTH` flag is set, the `width` argument to `imageUpdate()` correctly indicates the image's width. Subsequent calls to `getWidth()` for the `Image` return the valid image width. If you call `getWidth()` before this flag is set, expect it to return -1.

public static final int HEIGHT

When the `HEIGHT` flag is set, the `height` argument to `imageUpdate()` correctly indicates the image's height. Subsequent calls to `getHeight()` for the `Image` return the valid image height. If you call `getHeight()` before this flag is set, expect it to return -1.

public static final int PROPERTIES

When the `PROPERTIES` flag is set, the image's properties are available. Subsequent calls to `getProperty()` return valid image properties.

public static final int SOMEBITS

When the `SOMEBITS` flag of `infoflags` (from `imageUpdate()`) is set, the image has started loading and at least some of its content are available for display. When this flag is set, the `x`, `y`, `width`, and `height` arguments to `imageUpdate()` indicate the bounding rectangle for the portion of the image that has been delivered so far.

public static final int FRAMEBITS

When the `FRAMEBITS` flag of `infoflags` is set, a complete frame of a multiframe image has been loaded and can be drawn. The remaining parameters to `imageUpdate()` should be ignored (`x`, `y`, `width`, `height`).

public static final int ALLBITS

When the `ALLBITS` flag of infoflags is set, the image has been completely loaded and can be drawn. The remaining parameters to `imageUpdate()` should be ignored (`x`, `y`, `width`, `height`).

public static final int ERROR

When the `ERROR` flag is set, the production of the image has stopped prior to completion because of a severe problem. `ABORT` may or may not be set when `ERROR` is set. Attempts to reload the image will fail. You might get an `ERROR` because the URL of the `Image` is invalid (file not found) or the image file itself is invalid (invalid size/content).

public static final int ABORT

When the `ABORT` flag is set, the production of the image has aborted prior to completion. If `ERROR` is not set, a subsequent attempt to draw the image may succeed. For example, an image would abort without an error if a network error occurred (e.g., a timeout on the HTTP connection).

Method

public boolean imageUpdate (Image image, int infoflags, int x, int y, int width, int height)

The `imageUpdate()` method is the sole method in the `ImageObserver` interface. It is called whenever information about an image becomes available. To register an image observer for an image, pass an object that implements the `ImageObserver` interface to `getWidth()`, `getHeight()`, `getProperty()`, `prepareImage()`, or `drawImage()`.

The `image` parameter to `imageUpdate()` is the image being rendered on the observer. The `infoflags` parameter is a set of `ImageObserver` flags ORed together to signify the current information available about `image`. The meaning of the `x`, `y`, `width`, and `height` parameters depends on the current `infoflags` settings.

Implementations of `imageUpdate()` should return `true` if additional information about the image is desired; returning `false` means that you don't want any additional information, and consequently, `imageUpdate()` should not be called in the future for this image. The default `imageUpdate()` method returns `true` if neither `ABORT` nor `ALLBITS` are set in the `infoflags`--that is, the method `imageUpdate()` is interested in further information if no errors have occurred and the image is not complete. If either flag is set, `imageUpdate()` returns `false`.

You should not call `imageUpdate()` directly--unless you are developing an `ImageConsumer`, in which case you may find it worthwhile to override the default `imageUpdate()` method, which all components inherit from the `Component` class.

Overriding imageUpdate

Instead of bothering with the `MediaTracker` class, you can override the `imageUpdate()` method and use it to notify you when an image is completely loaded. Example 12.1 demonstrates the use of `imageUpdate()`, along with a way to force your images to load immediately. Here's how it works: the `init()` method calls `getImage()` to request image loading at some time in the future. Instead of waiting for `drawImage()` to trigger the loading process, `init()` forces loading to start by calling `prepareImage()`, which also registers an image observer. `prepareImage()` is a method of the

`Component` class discussed in Chapter 5, *Components*.

The `paint()` method doesn't attempt to draw the image until the variable `loaded` is set to `true`. The `imageUpdate()` method checks the `infoflags` argument to see whether `ALLBITS` is set; when it is set, `imageUpdate()` sets `loaded` to `true`, and schedules a call to `paint()`. Thus, `paint()` doesn't call `drawImage()` until the method `imageUpdate()` has discovered that the image is fully loaded.

Example 12.1: imageUpdate Override.

```
import java.applet.*;
import java.awt.*;
import java.awt.image.ImageObserver;
public class imageUpdateOver extends Applet {
    Image image;
    boolean loaded = false;
    public void init () {
        image = getImage (getDocumentBase(), "rosey.jpg");
        prepareImage (image, -1, -1, this);
    }
    public void paint (Graphics g) {
        if (loaded)
            g.drawImage (image, 0, 0, this);
    }
    public void update (Graphics g) {
        paint (g);
    }
    public synchronized boolean imageUpdate (Image image, int infoFlags,
                    int x, int y, int width, int height) {
        if ((infoFlags & ImageObserver.ALLBITS) != 0) {
            loaded = true;
            repaint();
            return false;
        } else {
            return true;
        }
    }
}
```

Note that the call to `prepareImage()` is absolutely crucial. It is needed both to start image loading and to register the image observer. If `prepareImage()` were omitted, `imageUpdate()` would never be called, `loaded` would not be set, and `paint()` would never attempt to draw the image. As an alternative, you could use the `MediaTracker` class to force loading to start and monitor the loading process; that approach might give you some additional flexibility.

13. AWT Exceptions and Errors

Contents:

This chapter describes `AWTException`, `IllegalComponentStateException`, and `AWTError`. `AWTException` is a subclass of `Exception`. It is not used by any of the public classes in `java.awt`; you may, however, find it convenient to throw `AWTException` within your own code. `IllegalComponentStateException` is another `Exception` subclass, which is new to Java 1.1. This exception is used when you try to do something with a `Component` that is not yet appropriate. `AWTError` is a subclass of `Error` that is thrown when a serious problem occurs in AWT--for example, the environment is unable to get the platform's `Toolkit`.

13.1 AWTException

`AWTException` is a generic exception that can be thrown when an exceptional condition has occurred within AWT. None of the AWT classes throw this. If you subclass any of the AWT classes, you can throw an `AWTException` to indicate a problem. Using `AWTException` is slightly preferable to creating your own `Exception` subclass because you do not have to generate another class file. Since it is a part of Java, `AWTException` is guaranteed to exist on the run-time platform.

If you throw an instance of `AWTException`, like any other `Exception`, it must be caught in a `catch` clause or declared in the `throws` clause of the method.

AWTException Method

Constructor

public AWTException (String message)

> The sole constructor creates an `AWTException` with a detailed message of `message`. This message can be retrieved using `getMessage()`, which it inherits from `Exception` (and which is required by the `Throwable` interface). If you do not want a detailed message, `message` may be `null`.

Throwing an AWTException

An `AWTException` is used the same way as any other `Throwable` object. Here's an example:

```
if (someProblem) {
    throw new AWTException ("Problem Encountered While Initializing");
}
```

14. And Then There Were Applets

Contents:

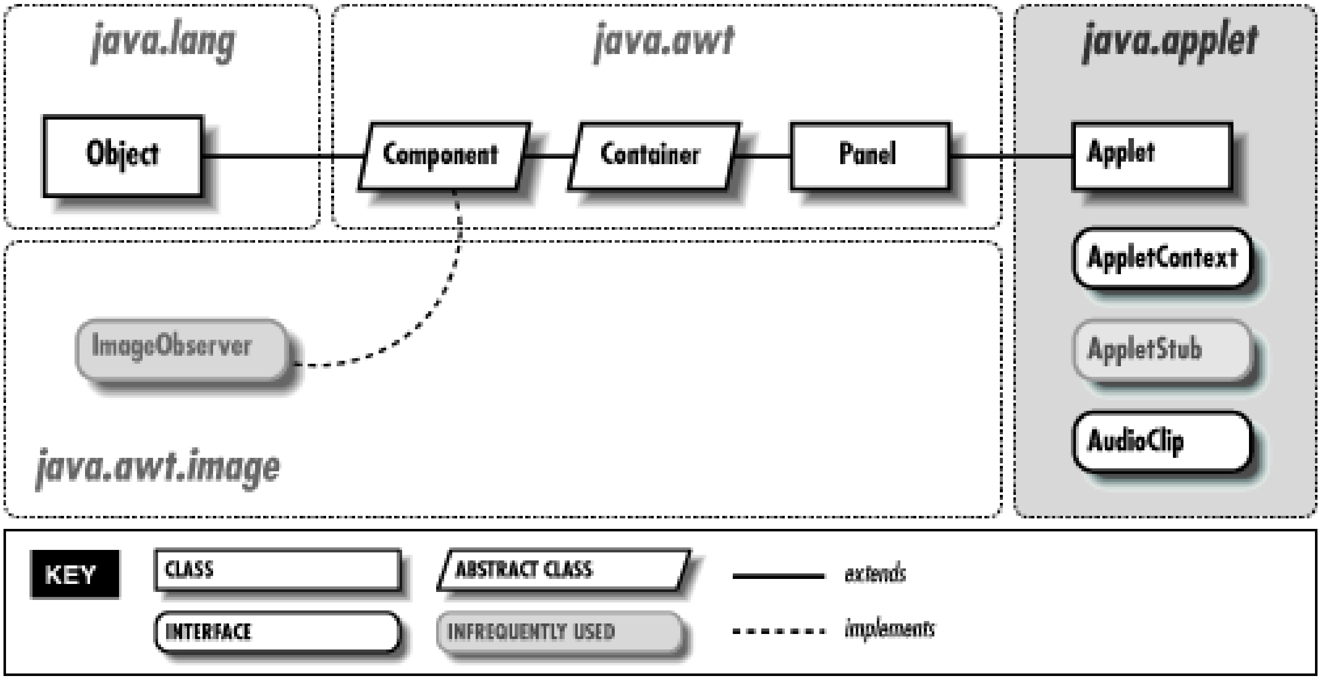
Although it is not part of the `java.awt` package, the `java.applet` package is closely related. The `java.applet` package provides support for running an applet in the context of a World Wide Web browser. It consists of one class (`Applet`) and three interfaces (`AppletContext`, `AudioClip`, and `AppletStub`). The `Applet` class supports the "applet life cycle" methods (`init()`, `start()`, `stop()`, `destroy()`) that you override to write an applet. `AudioClip` provides support for audio within applets. (Applications use the `sun.audio` package for audio support; `sun.audio` is also covered in this chapter.) The `AppletStub` and `AppletContext` interfaces provide a way for the applet to interact with its run-time environment. Many of the methods of `AppletStub` and `AppletContext` are duplicated in the `Applet` class.

14.1 What's a Java Applet?

Much of the initial excitement about Java centered around applets. Applets are small Java programs that can be embedded within HTML pages and downloaded and executed by a web browser. Because executing code from random Internet sites presents a security risk, Java goes to great lengths to ensure the integrity of the program executing and to prevent it from performing any unauthorized tasks.

An applet is a specific type of Java `Container`. The class hierarchy of an applet is shown in Figure 14.1.

Figure 14.1: Applet class hierarchy



When you are writing an applet, remember that you can use the features of its ancestors. In particular, remember to check the methods of the `Component`, `Container`, and `Panel` classes, which are inherited by the `Applet` class.

Applet Methods

All the methods of `Applet`, except `setStub()`, either need to be overridden or are methods based on one of the `java.applet` interfaces. The system calls `setStub()` to set up the context of the interfaces. The browser implements the `AppletContext` and `AppletStub` interfaces. Constructor

public Applet ()

> The system calls the `Applet` constructor when the applet is loaded and before it calls `setStub()`, which sets up the applet's stub and context. When you subclass `Applet`, you usually do not provide a constructor. If you do provide a constructor, you do not have access to the `AppletStub` or `AppletContext` and, therefore, may not call any of their methods.

AppletStub setup

public final void setStub (AppletStub stub)

> The `setStub()` method of `Applet` is called by the browser when the applet is loaded into the system. It sets the `AppletStub` of the applet to `stub`. In turn, the `AppletStub` contains the applet's `AppletContext`.

Applet information methods

Several methods of `Applet` provide information that can be used while the applet is running.

public AppletContext getAppletContext ()

> The `getAppletContext()` method returns the current `AppletContext`. This is part of the applet's stub, which is set by the system when `setStub()` is called.

public URL getCodeBase ()

> The `getCodeBase()` method returns the complete URL of the *.class* file that contains the applet. This method can be used with the `getImage()` or the `getAudioClip()` methods, described later in this chapter, to load an image or audio file relative to the *.class* file location.

public URL getDocumentBase ()

> The `getDocumentBase()` method returns the complete URL of the *.html* file that loaded the applet. This can be used with the `getImage()` or `getAudioClip()` methods, described later in this chapter, to load an image or audio file relative to the *.html* file.

public String getParameter (String name)

> The `getParameter()` method allows you to get run-time parameters from within the `<APPLET>` tag of the *.html* file that loaded the applet. Parameters are defined by HTML `<PARAM>` tags, which have the form:
>
> ```
> <PARAM name="parameter" value="value>
> ```
>
> If the `name` parameter of `getParameter()` matches the `name` string of a `<PARAM>` tag, `getParameter()` returns the tag's `value` as a string. If `name` is not found within the `<PARAM>` tags of the `<APPLET>`, `getParameter()` returns `null`. The argument `name` is not case sensitive; that is, it matches parameter names regardless of case. Remember that `getParameter()` always returns a string, even though the parameter values might appear as integers or floating point numbers in the HTML file. In some situations, it makes sense to pass multiple values in a single parameter; if you do this, you have to parse the parameter string manually. Using a `StringTokenizer` will make the job easier.
>
> Enabling your applets to accept parameters allows them to be customized at run-time by the HTML author, without providing the source code. This provides greater flexibility on the Web without requiring any recoding. Example 14.1 shows how an applet reads parameters from an HTML file. It contains three parts: the HTML file that loads the applet, the applet source code, and the output from the applet.

Example 14.1: Getting Parameters from an HTML File

```
<APPLET CODE=ParamApplet WIDTH=100 HEIGHT=100>
<PARAM NAME=one VALUE=1.0>
<PARAM name=TWO value=TOO>
</APPLET>
public class ParamApplet extends java.applet.Applet {
    public void init () {
        String param;
        float one;
        String two;
        if ((param = getParameter ("ONE")) == null) {
            one = -1.0f;  // Not present
        } else {
            one = Float.valueOf (param).longValue();
        }
        if ((param = getParameter ("two")) == null) {
            two = "two";
        } else {
            two = param.toUpperCase();
        }
        System.out.println ("One: " + one);
        System.out.println ("Two: " + two);
    }
}
One: 1
Two: TOO
```

public String getAppletInfo ()

The `getAppletInfo()` method lets an applet provide a short descriptive string to the browser. This method is frequently overridden to return a string showing the applet's author and copyright information. How (or whether) to display this information is up to the browser. With *appletviewer*, this information is displayed when the user selects the Info choice under the Applet menu. Neither Netscape Navigator nor Internet Explorer currently display this information.

public String[][] getParameterInfo ()

The `getParameterInfo()` method lets an applet provide a two-dimensional array of strings describing the parameters it reads from `<PARAM>` tags. It returns an array of three strings for each parameter. In each array, the first `String` represents the parameter name, the second describes the data type, and the third is a brief description or range of values. Like `getAppletInfo()`, how (or whether) to display this information is up to the browser. With appletviewer, this information is displayed when the user selects the Info choice under the Applet menu. Neither Netscape Navigator nor Internet Explorer currently display this information. The following code shows how an applet might use `getParameterInfo()` and `getAppletInfo()`:

```
public String getAppletInfo() {
    String whoami = "By John Zukowski (c) 1997";
    return whoami;
}
public String[][] getParameterInfo() {
    String[][] strings = {
        {"parameter1",    "String",      "Background Color name"},
        {"parameter2",    "URL",         "Image File"},
        {"parameter3",    "1-10",        "Number in Series"}
    };
    return strings;
}
```

public void showStatus (String message)

The `showStatus()` method displays `message` on the browser's status line, if it has one. Again, how to display this string is up to the browser, and the browser can overwrite it whenever it wants. You should only use `showStatus()` for messages that the user can afford to miss.

public boolean isActive ()

The `isActive()` method returns the current state of the applet. While an applet is initializing, it is not active, and calls to `isActive()` return `false`. The system marks the applet active just prior to calling `start()`; after this point, calls to `isActive()` return `true`.

public Locale getLocale () ★

The `getLocale()` method retrieves the current `Locale` of the applet, if it has one. Using a `Locale` allows you to write programs that can adapt themselves to different languages and different regional variants. If no `Locale` has been set, `getLocale()` returns the default `Locale`. The default `Locale` has a user language of English and no region. To change the default `Locale`, set the system properties `user.language` and `user.region`, or call `Locale.setDefault()` (`setDefault()` verifies access rights with the security manager).[1]

[1] For more on the `Locale` class, see *Java Fundamental Classes Reference,* by Mark Grand, from O'Reilly & Associates.

Applet life cycle

The browser calls four methods of the `Applet` class to execute the applet. These methods constitute the applet's life cycle. The default versions don't do anything; you must override at least one of them to create a useful applet.

public void init ()

> The `init()` method is called once when the applet is first loaded. It should be used for tasks that need to be done only once. `init()` is often used to load images or sound files, set up the screen, get parameters out of the HTML file, and create objects the applet will need later. You should not do anything that might "hang" or wait indefinitely. In a sense, `init()` does things that might otherwise be done in an applet's constructor.

public void start ()

> The `start()` method is called every time the browser displays the web page containing the applet. `start()` usually does the "work" of the applet. It often starts threads, plays sound files, or does computation. `start()` may also be called when the browser is de-iconified.

public void stop ()

> The `stop()` method is called whenever the browser leaves the web page containing the applet. It should stop or suspend anything that the applet is doing. For example, it should suspend any threads that have been created and stop playing any sound files. `stop()` may also be called when the browser is iconified.

public void destroy ()

> The `destroy()` method is called when the browser determines that it no longer needs to keep the applet around--in practice, when the browser decides to remove the applet from its cache or the browser exits. After this point, if the browser needs to display the applet again, it will reload the applet and call the applet's `init()` method. `destroy()` gives the applet a final opportunity to release any resources it is using (for example, close any open sockets). Most applets don't need to implement `destroy()`. It is always a good idea to release resources as soon as they aren't needed, rather than waiting for `destroy()`. There are no guarantees about when `destroy()` will be called; if your browser has a sufficiently large cache, the applet may stay around for a very long time.

Applet-sizing methods

public void resize(int width, int height)

> The `resize()` method changes the size of the applet space to `width` x `height`. The browser

must support changing the applet space or else the sizing does not change. Netscape Navigator does not allow an applet to change its size; the applet is sized to the region allocated by the `<APPLET>` tag, period.

Because `Applet` is a subclass of `Component`, it inherits the Java 1.1 method `setSize()`, which has the same function.

public void resize (Dimension dim)

This `resize()` method calls the previous version of `resize()` with a width of `dim.width` and a height of `dim.height`.

Images

We have discussed `Image` objects extensively in Chapter 2, *Simple Graphics*, and Chapter 12, *Image Processing*, and used them in many of our examples. When writing an applet, you can use the `getImage()` method directly. In applications, you must go through `Toolkit` (which the following methods call) to get images.

public Image getImage (URL url)

The `getImage()` method loads the image file located at `url`. `url` must be a complete and valid URL. The method returns a system-specific object that subclasses `Image` and returns immediately. The `Image` is not loaded until needed, either by `prepareImage()`, `MediaTracker`, or `drawImage()`.

public Image getImage (URL url, String filename)

The `getImage()` method loads the image file located at `url` in `filename`. The applet locates the file relative to the specified URL; that is, if the URL ends with a filename, the applet removes the filename and appends the `filename` argument to produce a new URL. `getImage()` returns a system-specific object that subclasses `Image` and returns immediately. The `Image` is not loaded until needed, either by `prepareImage()`, `MediaTracker`, or `drawImage()`.

In most cases, the `url` argument is a call to `getDocumentBase()` or `getCodeBase()`; most often, image files are located in the same directory as the HTML file, the applet's Java class file, or their own subdirectory.

Audio

Every Java platform is guaranteed to understand Sun's AU file format, which contains a single channel of 8000 Hz µLaw encoded audio data.[2] Java applets do not require any helper applications to play audio;

they use the browser's audio capabilities. You can use an independent application, like Sun's *audiotool*, to control the volume. Of course, the user's workstation or PC needs audio hardware, but these days, it's hard to buy a computer that isn't equipped for audio.

> [2] The AU format is explained in the Audio File Format FAQ (version 3.10) located at *ftp://ftp.cwi.nl/pub/audio/index.html* in files *AudioFormats.part1* and *AudioFormats.part2*.

The Java Media Framework API is rumored to provide support for additional audio formats, like Microsoft's *.wav* files or Macintosh/SGI *.aiff* audio files. At present, if you want your Java program to play audio files in other formats, you must first convert the audio file to the *.au* format, using a utility like SOX (Sound Exchange).[3] Once converted, your Java program can play the resulting *.au* file normally. (If you are interested in more information about audio, look in the *alt.binaries.sounds.d* newsgroup.)

> [3] SOX is available at http://www.spies.com/Sox. The current version of SOX is 10; version 11 is in gamma release. The UNIX source is located in *sox10.tar.gz* , while the DOS executable is *sox10dos.zip*.

The `Applet` class provides two ways to play audio clips. The first mechanism provides a method to load and play an audio file once:

public void play (URL url)

> The `play()` method downloads and plays the audio file located at `url`. `url` must be a complete and valid URL. If `url` is invalid, no sound is played. Some environments throw an exception if the URL is invalid, but not all. Calling `play()` within an applet's `destroy()` method usually has no effect; the applet and its resources will probably be deallocated before `play()` has time to download the audio file.

public void play (URL url, String filename)

> This version of `play()` downloads and plays the audio file located at `url` in the file `filename`. The applet locates the file relative to the specified URL; that is, if the URL ends with a filename, the applet removes the filename and appends the `filename` argument to produce a new URL. If the resulting URL is invalid, no sound is played. Some environments throw an exception if the URL is invalid, but not all.
>
> In most cases, the `url` argument is a call to `getDocumentBase()` or `getCodeBase()`; most often, sound files are located in the same directory as the HTML file or the applet's Java class file. For some reason, you cannot have a double dot (`..`) in the URL of an audio file; you can in the URL of an image file. Putting a double dot in the URL of an audio file raises a security exception in an applet causing `play()` to fail.

The following applet plays an audio file located relative to the HTML file from which the applet was loaded:

```
import java.net.*;
import java.applet.*;
public class audioTest extends Applet {
    public void init () {
        System.out.println ("Before");
        play (getDocumentBase(), "audio/flintstones.au");
        System.out.println ("After");
    }
}
```

The second way to play audio files splits the process into two steps: you get an `AudioClip` object and then play it as necessary. This procedure eliminates a significant drawback to `play()`: if you call `play()` repeatedly, it reloads the audio file each time, making the applet much slower.

public AudioClip getAudioClip (URL url)

The `getAudioClip()` method loads the audio file located at `url`. `url` must be a complete and valid URL. Upon success, `getAudioClip()` returns an instance of a class that implements the `AudioClip` interface. You can then call methods in the `AudioClip` interface (see AudioClip Interface) to play the clip. If an error occurs during loading (e.g., because the file was not found or the URL was invalid), `getAudioClip()` returns `null`.

`getAudioClip()` sounds similar to `getImage()`, and it is. However, Java currently loads audio clips synchronously; it does not start a separate thread as it does for images. You may want to create a helper class that loads audio clips in a separate thread.

The actual class of the `AudioClip` object depends on the platform you are using; you shouldn't need to know it. If you are curious, the *appletviewer* uses the class `sun.applet.AppletAudioClip`; Netscape Navigator uses the class `netscape.applet.AppletAudioClip`.

public AudioClip getAudioClip (URL url , String filename)

This version of the `getAudioClip()` method loads the audio file located at `url` in the file `filename`. The applet locates the file relative to the specified URL; that is, if the URL ends with a filename, the applet removes the filename and appends the `filename` argument to produce a new URL. If the resulting URL is invalid, the file is not loaded. Upon success, `getAudioClip()` returns an instance of a class that implements the `AudioClip` interface. You can then call methods in the `AudioClip` interface (see AudioClip Interface) to play the clip. If an error occurs during loading (e.g., because the file was not found or the URL was invalid), `getAudioClip()` returns `null`.

In most cases, the `url` argument is a call to `getDocumentBase()` or `getCodeBase()`; most often, sound files are located in the same directory as the HTML file or the applet's Java class file.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

15. Toolkit and Peers

Contents:

This chapter describes the `Toolkit` class and the purposes it serves. It also describes the `java.awt.peer` package of interfaces, along with how they fit in with the general scheme of things. The most important advice I can give you about the peer interfaces is not to worry about them. Unless you are porting Java to another platform, creating your own `Toolkit`, or adding any native component, you can ignore the peer interfaces.

15.1 Toolkit

The `Toolkit` object is an abstract class that provides an interface to platform-specific details like window size, available fonts, and printing. Every platform that supports Java must provide a concrete class that extends the `Toolkit` class. The Sun JDK provides a `Toolkit` for Windows NT/95 (`sun.awt.win32.MToolkit` [Java1.0] or `sun.awt.windows.MToolkit` [Java1.1]), Solaris/Motif (`sun.awt.motif.MToolkit`), and Macintosh (`sun.awt.macos.MToolkit`). Although the `Toolkit` is used frequently, both directly and behind the scenes, you would never create any of these objects directly. When you need a `Toolkit`, you ask for it with the static method `getDefaultToolkit()` or the `Component.getToolkit()` method.

You might use the `Toolkit` object if you need to fetch an image in an application (`getImage()`), get the font information provided with the `Toolkit` (`getFontList()` or `getFontMetrics()`), get the color model (`getColorModel()`), get the screen metrics (`getScreenResolution()` or `getScreenSize()`), get the system clipboard (`getSystemClipboard()`), get a print job (`getPrintJob()`), or ring the bell (`beep()`). The other methods of `Toolkit` are called for you by the system.

Toolkit Methods

Constructors

public Toolkit()--cannot be called by user

> Because `Toolkit` is an abstract class, it has no usable constructor. To get a `Toolkit` object, ask for your environment's default toolkit by calling the static method `getDefaultToolkit()` or call `Component.getToolkit()` to get the toolkit of a component. When the actual `Toolkit` is created for the native environment, the `awt` package is loaded, the `AWT-Win32` and `AWT--Callback-Win32` or `AWT-Motif` and `AWT-Input` threads (or the appropriate threads for your environment) are created, and the threads go into infinite loops for screen maintenance and event handling.

Pseudo-Constructors

public static synchronized Toolkit getDefaultToolkit ()

The `getDefaultToolkit()` method returns the system's default `Toolkit` object. The default `Toolkit` is identified by the `System` property `awt.toolkit`, which defaults to an instance of the `sun.awt.motif.MToolkit` class. On the Windows NT/95 platforms, this is overridden by the Java environment to be `sun.awt.win32.MToolkit` (Java1.0) or `sun.awt.windows.MToolkit` (Java1.1). On the Macintosh platform, this is overridden by the environment to be `sun.awt.macos.MToolkit`. Most browsers don't let you change the system property `awt.toolkit`. Since this is a static method, you don't need to have a `Toolkit` object to call it; just call `Toolkit.getDefaultToolkit()`.

Currently, only one `Toolkit` can be associated with an environment. You are more than welcome to try to replace the one provided with the JDK. This permits you to create a whole new widget set, outside of Java, while maintaining the standard AWT API.

System information

public abstract ColorModel getColorModel ()

The `getColorModel()` method returns the current `ColorModel` used by the system. The default `ColorModel` is the standard RGB model, with 8 bits for each of red, green, and blue. There are an additional 8 bits for the alpha component, for pixel-level transparency.

public abstract String[] getFontList ()

The `getFontList()` method returns a `String` array of the set Java fonts available with this `Toolkit`. Normally, these fonts will be understood on all the Java platforms. The set provided with Sun's JDK 1.0 (with Netscape Navigator and Internet Explorer, on platforms other than the Macintosh) contains TimesRoman, Dialog, Helvetica, Courier (the only fixed-width font), DialogInput, and ZapfDingbat.

In Java 1.1, `getFont()` reports all the 1.0 font names. It also reports Serif, which is equivalent to TimesRoman; San Serif, which is equivalent to Helvetica; and Monospaced, which is equivalent to Courier. The names TimesRoman, Helvetica, and Courier are still supported but should be avoided. They have been deprecated and may disappear in a future release. Although the JDK 1.1 reports the existence of the ZapfDingbat font, you can't use it. The characters in this font have been remapped to Unicode characters in the range `\u2700` to `\u27ff`.

public abstract FontMetrics getFontMetrics (Font font)

The `getFontMetrics()` method returns the `FontMetrics` for the given `Font` object. You can use this value to compute how much space would be required to display some text using this `font`. You can use this version of `getFontMetrics()` (unlike the similar method in the `Graphics` class) prior to drawing anything on the screen.

public int getMenuShortcutKeyMask() ★

The `getMenuShortcutKeyMask()` method identifies the accelerator key for menu shortcuts for the user's platform. The return value is one of the modifier masks in the `Event` class, like `Event.CTRL_MASK`. This method is used internally by the `MenuBar` class to help in handling menu selection events. See Chapter 10, *Would You Like to Choose from the Menu?* for more information about dealing with menu accelerators.

public abstract PrintJob getPrintJob (Frame frame, String jobtitle, Properties props) ★

The `getPrintJob()` method initiates a print operation, `PrintJob`, on the user's platform. After getting a `PrintJob` object, you can use it to print the current graphics context as follows:

```
// Java 1.1 only
PrintJob p = getToolkit().getPrintJob (aFrame, "hi", aProps);
Graphics pg = p.getGraphics();
printAll (pg);
pg.dispose();
p.end();
```

With somewhat more work, you can print arbitrary content. See Chapter 17, *Printing*, for more information about printing. The `frame` parameter serves as the parent to any print dialog window, `jobtitle` serves as the identification string in the print queue, and `props` serves as a means to provide platform-specific properties (default printer, page order, orientation, etc.). If `props` is `(Properties)null`, no properties will be used. `props` is particularly interesting in that it is used both for input and for output. When the environment creates a print dialog, it can read default values for printing options from the properties sheet and use that to initialize the dialog. After `getPrintJob()` returns, the properties sheet is filled in with the actual printing options that the user requested. You can then use these option settings as the defaults for subsequent print jobs.

The actual property names are `Toolkit` specific and may be defined by the environment outside of Java. Furthermore, the environment is free to ignore the `props` parameter altogether; this appears to be the case with Windows NT/95 platforms. (It is difficult to see how Windows NT/95 would use the properties sheet, since these platforms don't even raise the print dialog until you call the method `getGraphics()`.) Table 15.1 shows some of the properties recognized on UNIX platforms; valid property values are shown in a fixed-width font.

Table 15.1: UNIX Printing Properties

Property Name	**Meaning and Possible Values**
`awt.print.printer`	The name of the printer on your system to send the job to.
`awt.print.fileName`	The name of the file to save the print job to.
`awt.print.numCopies`	The number of copies to be printed.
`awt.print.options`	Other options to be used for the run-time system's print command.
`awt.print.destination`	Whether the print job should be sent to a `printer` or saved in a `file`.
`awt.print.paperSize`	The size of the paper on which you want to print--usually, `letter`.
`awt.print.orientation`	Whether the job should be printed in `portrait` or `landscape` orientation.

public static String getProperty (String key, String defaultValue) ★

The `getProperty()` method retrieves the `key` property from the system's *awt.properties* file (located in the *lib* directory under the *java.home* directory). If `key` is not a valid property, `defaultValue` is returned. This file is used to provide localized names for various system resources.

public abstract int getScreenResolution ()

The `getScreenResolution()` method retrieves the resolution of the screen in dots per inch. The sharper the resolution of the screen, the greater number of dots per inch. Values vary depending on the system and graphics mode.

The PrintJob.getPageResolution() method returns similar information for a printed page.

public abstract Dimension getScreenSize ()

The getScreenSize() method retrieves the dimensions of the user's screen in pixels for the current mode. For instance, a VGA system in standard mode will return 640 for the width and 480 for the height. This information is extremely helpful if you wish to manually size or position objects based upon the physical size of the user's screen. The PrintJob.getPageDimension() method returns similar information for a printed page.

public abstract Clipboard getSystemClipboard() ★

The getSystemClipboard() method returns a reference to the system's clipboard. The clipboard allows your Java programs to use cut and paste operations, either internally or as an interface between your program and objects outside of Java. For instance, the following code copies a String from a Java program to the system's clipboard:

```
// Java 1.1 only
Clipboard clipboard = getToolkit().getSystemClipboard();
StringSelection ss = new StringSelection("Hello");
clipboard.setContents(ss, this);
```

Once you have placed the string "Hello" on the clipboard, you can paste it anywhere. The details of Clipboard, StringSelection, and the rest of the java.awt.datatransfer package are described in Chapter 16, *Data Transfer*.

public final EventQueue getSystemEventQueue() ★

After checking whether the security manager allows access, this method returns a reference to the system's event queue.

protected abstract EventQueue getSystemEventQueueImpl() ★

getSystemEventQueueImpl() does the actual work of fetching the event queue. The toolkit provider implements this method; only subclasses of Toolkit can call it.

Images

The Toolkit provides a set of basic methods for working with images. These methods are similar to methods in the Applet class; Toolkit provides its own implementation for use by programs that don't have access to an AppletContext (i.e., applications or applets that are run as applications). Remember that you need an instance of Toolkit before you can call these methods; for example, to get an image, you might call Toolkit.getDefaultToolkit().getImage(`myImage.gif`).

public abstract Image getImage (String filename)

The getImage() method with a String parameter allows applications to get an image from the local filesystem. Its argument is either a relative or absolute filename for an image in a recognized image file format. The method returns immediately; the Image object that it returns is initially empty. When the image is needed, the system attempts to get filename and convert it to an image. To force the file to load immediately or to check for errors while loading, use the MediaTracker class.

NOTE:

This version of `getImage()` is not usable within browsers since it will throw a security exception because the applet is trying to access the local filesystem.

public abstract Image getImage (URL url)

The `getImage()` method with the `URL` parameter can be used in either applets or applications. It allows you to provide a URL for an image in a recognized image file format. Like the other `getImage()` methods, this method returns immediately; the `Image` object that it returns is initially empty. When the image is needed, the system attempts to load the file specified by `url` and convert it to an image. You can use the `MediaTracker` class to monitor loading and check whether any errors occurred.

public abstract boolean prepareImage (Image image, int width, int height, ImageObserver observer)

The `prepareImage()` method is called by the system or a program to force `image` to start loading. This method can be used to force an image to begin loading before it is actually needed. The `Image image` will be scaled to be `width` x `height`. A `width` and `height` of -1 means `image` will be rendered unscaled (i.e., at the size specified by the image itself). The `observer` is the `Component` on which `image` will be rendered. As the `image` is loaded across the network, the `observer`'s `imageUpdate()` method is called to inform the observer of the image's status.

public abstract int checkImage (Image image, int width, int height, ImageObserver observer)

The `checkImage()` method returns the status of the `image` that is being rendered on `observer`. Calling `checkImage()` only provides information about the image; it does not force the image to start loading. The `image` is being scaled to be `width` x `height`. Passing a `width` and `height` of -1 means the image will be displayed without scaling. The return value of `checkImage()` is some combination of `ImageObserver` flags describing the data that is now available. The `ImageObserver` flags are: `WIDTH`, `HEIGHT`, `PROPERTIES`, `SOMEBITS`, `FRAMEBITS`, `ALLBITS`, `ERROR`, and `ABORT`. Once `ALLBITS` is set, the image is completely loaded, and the return value of `checkImage()` will not change. For more information about these flags, see Chapter 12, *Image Processing*.

The following program loads an image; whenever `paint()` is called, it displays what information about that image is available. When the `ALLBITS` flag is set, `checkingImages` knows that the image is fully loaded, and that a call to `drawImage()` will display the entire image.

```
import java.awt.*;
import java.awt.image.*;
import java.applet.*;
public class checkingImages extends Applet {
    Image i;
    public void init () {
        i = getImage (getDocumentBase(), "ora-icon.gif");
    }
    public void displayChecks (int i) {
        if ((i & ImageObserver.WIDTH) != 0)
            System.out.print ("Width ");
        if ((i & ImageObserver.HEIGHT) != 0)
            System.out.print ("Height ");
        if ((i & ImageObserver.PROPERTIES) != 0)
            System.out.print ("Properties ");
        if ((i & ImageObserver.SOMEBITS) != 0)
```

```
            System.out.print ("Some-bits ");
        if ((i & ImageObserver.FRAMEBITS) != 0)
            System.out.print ("Frame-bits ");
        if ((i & ImageObserver.ALLBITS) != 0)
            System.out.print ("All-bits ");
        if ((i & ImageObserver.ERROR) != 0)
            System.out.print ("Error-loading ");
        if ((i & ImageObserver.ABORT) != 0)
            System.out.print ("Loading-Aborted ");
        System.out.println ();
    }
    public void paint (Graphics g) {
        displayChecks (Toolkit.getDefaultToolkit().checkImage(i, -1, -1, this));
        g.drawImage (i, 0, 0, this);
    }
}
```

Here's the output from running `checkingImages` under Java 1.0; it shows that the width and height of the image are loaded first, followed by the image properties and the image itself. Java 1.1 also displays `Frame-bits` once the image is loaded.

```
Width Height
Width Height Properties Some-bits
Width Height Properties Some-bits All-bits
Width Height Properties Some-bits All-bits
Width Height Properties Some-bits All-bits
... (Repeated Forever More)
```

public abstract Image createImage (ImageProducer producer)

This `createImage()` method creates an `Image` object from an `ImageProducer`. The `producer` parameter must be some class that implements the `ImageProducer` interface. Image producers in the `java.awt.graphics` package are `FilteredImageSource` (which, together with an `ImageFilter`, lets you modify an existing image) and `MemoryImageSource` (which lets you turn an array of pixel information into an image). The image filters provided with `java.awt.image` are `CropImageFilter`, `RGBImageFilter`, `AreaAveragingScaleFilter`, and `ReplicateScaleFilter`. You can also implement your own image producers and image filters. These classes are all covered in detail in Chapter 12, *Image Processing*.

The following code uses this version of `createImage()` to create a modified version of an original image:

```
Image i = Toolkit.getDefaultToolkit().getImage (u);
      TransparentImageFilter tf = new TransparentImageFilter (.5f);
Image j = Toolkit.getDefaultToolkit().createImage (
              new FilteredImageSource (i.getSource(), tf));
```

public Image createImage (byte[] imageData) ★

This `createImage()` method converts the entire byte array in `imageData` into an `Image`. This data must be in one of the formats understood by this AWT `Toolkit` (GIF, JPEG, or XBM) and relies on the "magic number" of the data to determine the image type.

public Image createImage (byte[] imageData, int offset, int length) ★

This `createImage()` method converts a subset of the byte data in `imageData` into an `Image`. Instead of starting at the beginning, this method starts at `offset` and goes to `offset+length-1`, for a total of `length` bytes. If `offset` is 0 and `length` is `imageData.length`, this method is equivalent to the previous method and converts the entire array.

The data in `imageData` must be in one of the formats understood by this AWT `Toolkit` (GIF, JPEG, or XBM) and relies on the "magic number" of the data to determine the image type.

NOTE:

For those unfamiliar with magic numbers, most data files are uniquely identified by the first handful or so of bytes. For instance, the first three bytes of a GIF file are "`GIF`". This is what `createImage()` relies upon to do its magic.

Miscellaneous methods

public abstract void beep () ★

The `beep()` method attempts to play an audio beep. You have no control over pitch, duration, or volume; it is like putting `echo ^G` in a UNIX shell script.

public abstract void sync ()

The `sync()` method flushes the display of the underlying graphics context. Normally, this is done automatically, but there are times (particularly when doing animation) when you need to `sync()` the display yourself.

16. Data Transfer

Contents:

One feature that was missing from Java 1.0 was the ability to access the system clipboard. It was impossible to cut and paste data from one program into another. Java 1.1 includes a package called `java.awt.datatransfer` that supports clipboard operations. Using this package, you can cut an arbitrary object from one program and paste it into another. In theory, you can cut and paste almost anything; in practice, you usually want to cut and paste text strings, so the package provides special support for string operations. The current version allows only one object to be on the clipboard at a time.

`java.awt.datatransfer` consists of three classes, two interfaces, and one exception. Objects that can be transferred implement the `Transferable` interface. The `Transferable` interface defines methods for working with different *flavors* of an object. The concept of flavors is basic to Java's clipboard model. Essentially, a flavor is a MIME content type. Any object can be represented in several different ways, each corresponding to a different MIME type. For example, a text string could be represented by a Java `String` object, an array of Unicode character data, or some kind of rich text that contains font information. The object putting the string on the clipboard provides whatever flavors it is capable of; an object pasting the string from the clipboard takes whatever flavor it can handle. Flavors are represented by the `DataFlavor` class, and the `UnsupportedFlavorException` is used when an object asks for a `DataFlavor` that is not available.

The `Clipboard` class represents the clipboard itself. There is a single system clipboard, but you can create as many private clipboards as you want. The system clipboard lets you cut and paste between arbitrary applications (for example, Microsoft Word and some Java programs). Private clipboards are useful within a single application, though you could probably figure out some way to export a clipboard to another application using RMI.

To put data on the clipboard, you must implement the `ClipboardOwner` interface, which provides a means for you to be notified when the data you write is removed from the clipboard. (There isn't any `ClipboardReader` interface; any object can read from the clipboard.) The final component of the `datatransfer` package is a special class called `StringSelection` that facilitates cutting and pasting text strings.

Cutting and pasting isn't the whole story; JavaSoft has also promised drag-and-drop capabilities, but this won't be in the initial release of Java 1.1.

16.1 DataFlavor

A `DataFlavor` represents a format in which data can be transferred. The `DataFlavor` class includes two common data flavors; you can create other flavors by extending this class. Flavors are essentially MIME content types and are represented by the standard MIME type strings. An additional content subtype has been added to represent Java classes; the content type of a Java object is:[1]

[1] The type name changed to `x-java-serialized-object` in the 1.1.1 release.

```
application/x-java-serialized-object
<classname>
```

For example, the content type of a `Vector` object would be:

```
application/x-java-serialized-object java.util.Vector
```

In addition to the content type, a `DataFlavor` also contains a *presentable name*. The presentable name is intended to be more comprehensible to humans than the MIME type. For example, the presentable name of a `VectorFlavor` object might just be "Vector", rather than the complex and lengthy MIME type given previously. Presentable names are useful when a program needs to ask the user which data flavor to use.

DataFlavor Methods

Variables

The `DataFlavor` class includes two public variables that hold "prebuilt" flavors representing different kinds of text objects. These flavors are used in conjunction with the `StringSelection` class.

Although these flavors are variables for all practical purposes, they are used as constants.

public static DataFlavor stringFlavor ★

The `stringFlavor` variable is the data flavor for textual data represented as a Java `String` object. Its MIME type is `application/x-javaserializedobject String`.

public static DataFlavor plainTextFlavor ★

The `plainTextFlavor` variable is the data flavor for standard, Unicode-encoded text. Its MIME type is `text/plain; charset=unicode`.

Constructors

The `DataFlavor` class has two constructors. One creates a `DataFlavor` given a MIME content type; the other creates a `DataFlavor` given a Java class and builds the MIME type from the class name.

public DataFlavor(String mimeType, String humanPresentableName) ★

The first constructor creates an instance of `DataFlavor` for the `mimeType` flavor of data. The `humanPresentableName` parameter should be a more user-friendly name. It might be used in a menu to let the user select a flavor from several possibilities. It might also be used to generate an error message when the `UnsupportedFlavorException` occurs. The `plainTextFlavor` uses "Plain Text" as its presentable name.

To read data from the clipboard, a program calls the `Transferable.getTransferData()` method. If the data is represented by a `DataFlavor` that doesn't correspond to a Java class (for example, `plainTextFlavor`), `getTransferData()` returns an `InputStream` for you to read the data from.

public DataFlavor(Class representationClass, String humanPresentableName) ★

The other constructor creates an instance of `DataFlavor` for the specific Java class `representationClass`. Again, the `humanPresentableName` provides a more user-friendly name for use in menus, error messages, or other interactions with users. The `stringFlavor` uses "Unicode String" as its presentable name.

A program calls `Transferable.getTransferData()` to read data from the clipboard. If the data is represented by a Java class, `getTransferData()` returns an instance of the representation class itself. It does not return a `Class` object. For example, if the data flavor is `stringFlavor`, `getTransferData()` returns a `String`.

Presentations

public String getHumanPresentableName() ★

The `getHumanPresentableName()` method returns the data flavor's presentable name; for example, `stringFlavor.getHumanPresentableName()` returns the string "Unicode String".

public void setHumanPresentableName(String humanPresentableName) ★

The `setHumanPresentableName()` method changes the data flavor's presentable name to a new `humanPresentableName`. It is hard to imagine why you would want to change a flavor's name.

public String getMimeType() ★

The `getMimeType()` method gets the MIME content type for the `DataFlavor` as a `String`.

public Class getRepresentationClass() ★

The `getRepresentationClass()` method returns the Java type that is used to represent data of this flavor (i.e., the type that would be returned by the `getTransferData()`method). It returns the type as a `Class` object, not an instance of the class itself. Note that all data flavors have a representation class, not just those for which the class is specified explicitly in the constructor. For example, the `plainTextFlavor.getRepresentationClass()` method returns the class `java.io.StringReader`.

public boolean isMimeTypeEqual(String mimeType) ★

The `isMimeTypeEqual()` method checks for string equality between `mimeType` and the data flavor's MIME type string. For some MIME types, this comparison may be too simplistic because character sets may not be present on types like `text/plain`. Therefore, this method would tell you that the MIME type `text/plain; charset=unicode` is different from `text/plain`.

public final boolean isMimeTypeEqual(DataFlavor dataFlavor) ★

The `isMimeTypeEqual()` method checks whether the MIME type of the `dataFlavor` parameter equals the current data flavor's MIME type. It calls the previous method, and therefore has the same weaknesses.

Protected methods

protected String normalizeMimeType(String mimeType) ★

The `normalizeMimeType()` method is used to convert a MIME type string into a standard form. Its argument is a MIME type, as a `String`; it returns the new normalized MIME type. You would never call `normalizeMimeType()` directly, but you might want to override this method if you are creating a subclass of `DataFlavor` and want to change the default normalization process. For example, one thing you might do with this is add the string `charset=US-ASCII` to the `text/plain` MIME type if it appears without a character set.

protected String normalizeMimeTypeParameter(String parameterName, String parameterValue) ★

The `normalizeMimeTypeParameter()` method is used to convert any parameters associated with MIME types into a standard form. Its arguments are a parameter name (for example, `charset`) and the parameter's value (for example, `unicode`). It returns `parameterValue` normalized. You would never call `normalizeMimeTypeParameter()` directly, but you might want to override this method if you are creating a subclass of `DataFlavor` and want to change the default normalization process. For example, parameter values may be case sensitive. You could write a method that would convert the value `Unicode` to the more appropriate form `unicode`.

While it may be more trouble than it's worth, carefully overriding these normalization methods might help you to get more predictable results from methods like `isMimeTypeEqual()`.

Miscellaneous methods

public boolean equals(DataFlavor dataFlavor) ★

The `equals()` method defines equality for flavors. Two `DataFlavor` objects are equal if their MIME type and representation class are equal.

18. java.applet Reference

Contents:

18.1 Introduction to the Reference Chapters

The preceding seventeen chapters cover just about all there is to know about AWT. We have tried to organize them logically, and provide all the information that you would expect in a reference manual--plus much more in the way of examples and practical information about how to do things effectively. However, there are many times when you just need a reference book, pure and simple: one that's organized alphabetically, and where you can find any method if you know the class and package that it belongs to, without having to second guess the author's organizational approach. That's what the rest of this book provides. It's designed to help you if you need to look something up quickly, and find a brief but accurate summary of what it does. In these sections, the emphasis is on *brief*; if you want a longer description, look in the body of the book.

The reference sections describe the following packages:

- `java.applet` (Chapter 18, *java.applet Reference*)
- `java.awt` (Chapter 19, *java.awt Reference*)
- `java.awt.datatransfer` (Chapter 20, *java.awt.datatransfer Reference*)

- `java.awt.event` (Chapter 21, *java.awt.event Reference*)
- `java.awt.image` (Chapter 22, *java.awt.image Reference*)
- `java.awt.peer` (Chapter 23, *java.awt.peer Reference*)

Within each package, classes and interfaces are listed alphabetically. There is a description and a pseudo-code definition for each class or interface. Each variable and method is listed and described. New Java 1.1 classes are marked with a black star (★), as are new methods and new variables. Of course, if a class is new, all its methods are new. We didn't mark individual methods in new classes. Methods that are deprecated in Java 1.1 are marked with a white star (☆).

Inheritance presents a significant problem with documenting object-oriented libraries, because the bulk of a class's methods tend to be hiding in the superclasses. Even if you're very familiar with object-oriented software development, when you're trying to look up a method under the pressure of some deadline, it's easy to forget that you need to look at the superclasses in addition to the class you're interested in itself. Nowhere is this problem worse than in AWT, where some classes (in particular, components and containers) inherit well over 100 methods, and provide few methods of their own. For example, the `Button` class contains seven public methods, none of which happens to be `setFont()`. The font used to display a button's label is certainly settable--but to find it, you have to look in the superclass `Component`.

So far, we haven't found a way around this problem. The description of each class has an abbreviated class hierarchy diagram, showing superclasses (all the way back to Object), immediate subclasses, and the interfaces that the class implements. Ideally, it would be nice to have a list of all the inherited methods--and in other parts of Java, that's possible. For AWT, the lists would be longer than the rest of this book, much too long to be practical, or even genuinely useful. Someday, electronic documentation may be able to solve this problem, but we're not there yet.

20. java.awt.datatransfer Reference

Contents:

Clipboard ★

Name

Clipboard ★

[Graphic: Figure from the text]

Description

The `Clipboard` class is a repository for a `Transferable` object and can be used for cut, copy, and paste operations. The system clipboard can be accessed by calling `Toolkit.getDefaultToolkit().getSystemClipboard()`. You can use this technique if you are interested in exchanging data between your application and other applications (Java or non-Java) running on the system. In addition, `Clipboard` can be instantiated directly, if "private" clipboards are needed.

Class Definition

```
public class java.awt.datatransfer.Clipboard
   extends java.lang.Object {
  // Variables
  protected Transferable contents;
  protected ClipboardOwner owner;
  // Constructors
  public Clipboard (String name);
  // Instance Methods
  public synchronized Transferable getContents (Object requestor);
  public String getName();
  public synchronized void setContents (Transferable contents, ClipboardOwner owner);
}
```

Variables

contents

protected Transferable contents

The object that the `Clipboard` contains, i.e., the object that has been cut or copied.

owner

protected ClipboardOwner owner

The object that owns the `contents`. When something else is placed on the clipboard, owner is notified via lostOwnership().

Constructors

Clipboard

public Clipboard (String name)

Parameters

> *name*
>
> > The name for this `Clipboard`.

Description

> Constructs a `Clipboard` object with the given `name`.

Instance Methods

getContents

public synchronized Transferable getContents (Object requestor)

Parameters

> *requestor*

The object asking for the contents.

Returns

An object that implements the `Transferable` interface.

Description

Returns the current contents of the `Clipboard`. You could use this method to paste data from the clipboard into your application.

getName

public String getName()

Returns

`Clipboard`'s name.

Description

Returns the name used when this clipboard was constructed. `Toolkit.getSystemClipboard()` returns a `Clipboard` named "System".

setContents

public synchronized void setContents (Transferable contents, ClipboardOwner owner)

Parameters

contents

New contents.

owner

Owner of the new contents.

Description

Changes the contents of the `Clipboard`. You could use this method to cut or copy data from your application to the clipboard.

Contents:

[TextEvent](#) ★

[TextListener](#) ★

[WindowAdapter](#) ★

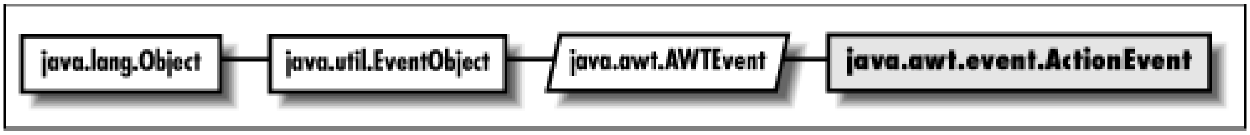
[WindowEvent](#) ★

[WindowListener](#) ★

ActionEvent ★

Name

ActionEvent ★



Description

Action events are fired off when the user performs an action on a component, such as pushing a button, double-clicking on a list item, or selecting a menu item. There is only one action event type, `ACTION_PERFORMED`.

Class Definition

```
public class java.awt.event.ActionEvent
   extends java.awt.AWTEvent {
  // Constants
  public final static int ACTION_FIRST;
  public final static int ACTION_LAST;
  public final static int ACTION_PERFORMED;
  public final static int ALT_MASK;
  public final static int CTRL_MASK;
  public final static int META_MASK;
  public final static int SHIFT_MASK;
  // Constructors
  public ActionEvent (Object source, int id, String command);
  public ActionEvent (Object source, int id, String command, int modifiers);
  // Instance Methods
  public String getActionCommand();
  public int getModifiers();
  public String paramString();
}
```

Constants

ACTION_FIRST

public final static int ACTION_FIRST

Specifies the beginning range of action event ID values.

ACTION_LAST

public final static int ACTION_LAST

Specifies the ending range of action event ID values.

ACTION_PERFORMED

public final static int ACTION_PERFORMED

The only action event type; it indicates that the user has performed an action.

ALT_MASK

public final static int ALT_MASK

A constant representing the ALT key. ORed with other masks to form `modifiers` setting of an `AWTEvent`.

CTRL_MASK

public final static int CTRL_MASK

A constant representing the Control key. ORed with other masks to form `modifiers` setting of an `AWTEvent`.

META_MASK

public final static int META_MASK

A constant representing the META key. ORed with other masks to form `modifiers` setting of an `AWTEvent`.

SHIFT_MASK

public final static int SHIFT_MASK

A constant representing the Shift key. ORed with other masks to form `modifiers` setting of an `AWTEvent`.

Constructors

ActionEvent

public ActionEvent (Object source, int id, String command)

Parameters

source

The object that generated the event.

id

The type ID of the event.

command

The action command string.

Description

Constructs an `ActionEvent` with the given characteristics.

public ActionEvent (Object source, int id, String command, int modifiers)

Parameters

source

The object that generated the event.

id

The type ID of the event.

command

The action command string.

modifiers

A combination of the key mask constants.

Description

Constructs an `ActionEvent` with the given characteristics.

Instance Methods

getActionCommand

public String getActionCommand()

Returns

The action command string for this `ActionEvent`.

Description

Generally the action command string is the label of the component that generated the event. Also, when localization is necessary, the action command string can provide a setting that does not get localized.

getModifiers

public int getModifiers()

Returns

A combination of the key mask constants.

Description

Returns the modifier keys that were held down when this action was performed. This enables you to perform special processing if, for example, the user holds down Shift while pushing a button.

paramString

public String paramString()

Returns

String with current settings of `ActionEvent`.

Overrides

`AWTEvent.paramString()`

Description

Helper method for `toString()` to generate string of current settings.

See Also

`ActionListener`, `AWTEvent`, `String`

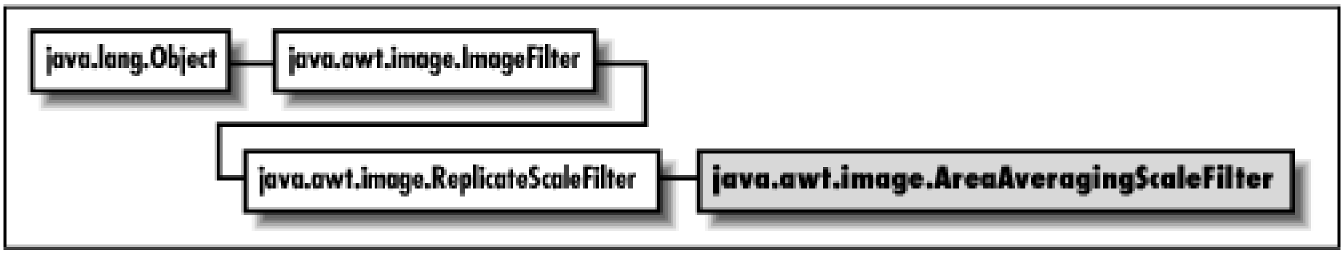
22. java.awt.image Reference

Contents:

AreaAveragingScaleFilter ★

Name

AreaAveragingScaleFilter ★



java.lang.Object
java.awt.image.ImageFilter
java.awt.image.ReplicateScaleFilter
java.awt.image.AreaAveragingScaleFilter

Description

The `AreaAveragingScaleFilter` class scales an image using a simple smoothing algorithm.

Class Definition

```
public class java.awt.image.AreaAveragingScaleFilter
    extends java.awt.image.ReplicateScaleFilter {
  // Constructor
  public AreaAveragingScaleFilter (int width, int height);
  // Instance Methods
  public void setHints (int hints);
  public void setPixels (int x, int y, int w, int h, ColorModel model,
    byte[] pixels, int off, int scansize);
  public void setPixels (int x, int y, int w, int h, ColorModel model,
    int[] pixels, int off, int scansize);
}
```

Constructor

AreaAveragingScaleFilter

public AreaAveragingScaleFilter (int width, int height)

Parameters

width

Width of scaled image.

height

Height of scaled image.

Description

Constructs an `AverageScaleFilter` that scales the original image to the specified size.

Instance Methods

setHints

public void setHints (int hints)

Parameters

hints

Flags indicating how data will be delivered.

Overrides

`ImageFilter.setHints(int)`

Description

Gives this filter hints about how data will be delivered.

setPixels

public void setPixels (int x, int y, int w, int h, ColorModel model, byte[] pixels, int off, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

w

Width of the rectangle of pixel data delivered with this method call.

h

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

off

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ReplicateScaleFilter.setPixels(int, int, int, int, ColorModel, byte[], int, int)`

Description

Receives a rectangle of image data from the `ImageProducer`; scales these pixels and delivers them to any `ImageConsumer`s.

public void setPixels (int x, int y, int w, int h, ColorModel model, int[] pixels, int off, int scansize)

Parameters

x

x-coordinate of top-left corner of pixel data delivered with this method call.

y

y-coordinate of top-left corner of pixel data delivered with this method call.

w

Width of the rectangle of pixel data delivered with this method call.

h

Height of the rectangle of pixel data delivered with this method call.

model

Color model of image data.

pixels

Image data.

off

Offset from beginning of the pixels array.

scansize

Size of each line of data in pixels array.

Overrides

`ReplicateScaleFilter.setPixels(int, int, int, int, ColorModel, int[], int, int)`

Description

Receives a rectangle of image data from the `ImageProducer`; scales these pixels and delivers them to any `ImageConsumer`s.

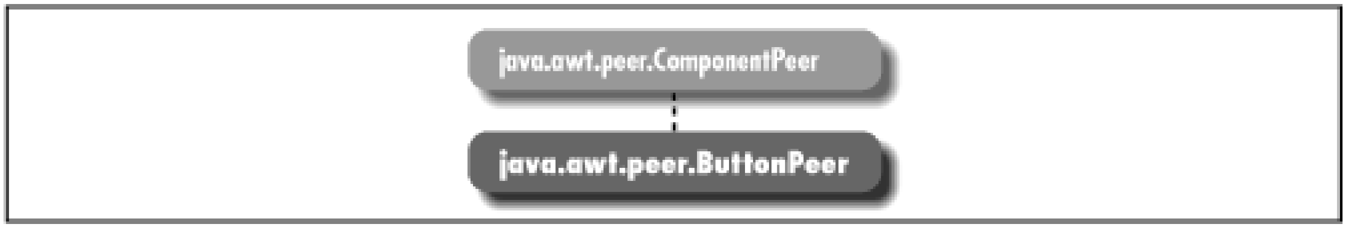
Contents:

ButtonPeer

Name

ButtonPeer



Description

`ButtonPeer` is an interface that defines the basis for buttons.

Interface Definition

```
public abstract interface java.awt.peer.ButtonPeer
extends java.awt.peer.ComponentPeer {
  // Interface Methods
  public abstract void setLabel (String label);
}
```

Interface Methods

setLabel

public abstract void setLabel (String label)

Parameters

label

New text for label of button's peer.

Description

Changes the text of the label of button's peer.

See Also

`ComponentPeer`, `String`

B. HTML Markup For Applets

Contents:

B.1 The Applet Tag

The introduction of Java created the need for additional HTML tags. In the alpha release of Java, the HotJava browser used the `<APP>` tag to include applets within HTML files. However, `<APP>` was unacceptable to the standards committee because it could have an infinite number of parameters. It was replaced by the `<APPLET>` tag, used in conjunction with the `<PARAM>` tag. Apparently, the standards folks did not like the `<APPLET>` tag either, so you can expect it to be replaced eventually, although at this point, there is no agreement about its successor, and it is highly unlikely that any production browser would stop supporting `<APPLET>`.

The syntax of the `<APPLET>` tag is shown below; the order of the parameters does not matter:

```
<APPLET
    [ALIGN = alignment]
    [ALT = alternate-text]
    CODE = applet-filename or OBJECT = serialized-applet
    [CODEBASE = applet-directory-url]
    [ARCHIVE = filename.zip/filename.jar]
    HEIGHT = applet-pixel-height
    [HSPACE = horizontal-pixel-margin]
    [MAYSCRIPT = true/false]
    [NAME = applet-name]
    [VSPACE = vertical-pixel-margin]
    WIDTH = applet-pixel-width
>
<PARAM NAME=parameter1 VALUE=value1>
```

```
<PARAM NAME=parameter2 VALUE=value2>
<PARAM NAME=parameter3 VALUE=value3>
...
[alternate-html]
</APPLET>
```

`<APPLET>`

The `<APPLET>` tag specifies where and how to display an applet within the HTML document. If the browser does not understand the `<APPLET>` and `<PARAM>` tags, it displays the `alternate-html`. (It displays the `alternate-html` because it doesn't understand the surrounding tags and ignores them. There's no magic to the `alternate-html` itself.) If a browser does understand `<APPLET>` but cannot run Java (for example, a browser on Windows 3.1) or Java has been disabled, the browser displays the `alternate-html` or the `alternate-text` specified by the optional `ALT` parameter. The `CODE`, `WIDTH`, and `HEIGHT` parameters are required. Parameters within the `<APPLET>` tag are separated by spaces, not by commas.

`</APPLET>`

Closes the `<APPLET>` tag. Anything prior to `</APPLET>` is considered `alternate-html` if it is not a `<PARAM>` tag. The `alternate-html` is displayed when Java is disabled, when Java cannot be run in the current browser, or when the browser does not understand the `<APPLET>` tag.

The following parameters may appear inside the `<APPLET>` tag.

`ALIGN`

`alignment`, optional. Specifies the applet's alignment on the Web page. Valid values are: `left`, `right`, `top`, `texttop`, `middle`, `absmiddle`, `baseline`, `bottom`, `absbottom`. Default: `left`. The alignment values have the same meanings as they do in the `<IMG>` tag.

`ALT`

`alternate-text`, optional. The alternate text is displayed when the browser understands the `<APPLET>` tag but is incapable of executing applets, either because Java is disabled or not supported on the platform. Support of this tag is browser dependent; most browsers just display the `alternate-html` since that is not restricted to text.

`ARCHIVE`

`filename.zip/filename.jar`, optional. Points to a comma-separated list of uncompressed ZIP or JAR files that contain one or more Java classes. Each file is downloaded once to the user's disk and searched for the class named in the CODE parameter, and any helper classes required to execute that class. JAR files may be signed to grant additional access. (JAR files are Java archives, a new archive format defined in Java 1.1. JAR files support features like digital signatures and compression. While they are not yet in wide use, they should become an important way of distributing sets of Java classes.)

CODE

applet-filename. This parameter or the OBJECT parameter is required. Name of applet *.class* file. The *.class* extension is not required in the <APPLET> tag but is required in the class's actual filename. The filename has to be a quoted string only if it includes whitespace.

CODEBASE

applet-directory-url, optional. Relative or absolute URL specifying the directory in which to locate the *.class* file or ZIP archive for the applet. Default: html directory.

HEIGHT

applet-pixel-height, required. Initial height of applet in pixels. Many browsers do not allow applets to change their height.

HSPACE

horizontal-pixel-margin, optional. Horizontal margin left and right of the applet, in pixels.

MAYSCRIPT

Required for applets that wish to use LiveConnect and the netscape.javascript classes to interact with JavaScript. Set to true to communicate with JavaScript. Set to false, or omit this parameter to disable communication with JavaScript. Both Java and JavaScript must be enabled in the browser.

NAME

applet-name, optional. Allows simultaneously running applets to communicate by this name. Default: the applet's class name.

OBJECT

serialized-applet. This parameter or the CODE parameter is required. Name of applet saved to a file as a serialized object. When loaded, `init()` is not called again but `start()` is. Parameters for running the applet are taken from this `<APPLET>` tag, not the original.

`VSPACE`

`vertical-pixel-margin`, optional. Vertical margin above and below the applet, in pixels.

`WIDTH`

`applet-pixel-width`, required. Initial width of applet in pixels. Many browsers do not allow applets to change their width.

The `<PARAM>` tag may appear between the `<APPLET>` and `</APPLET>` tags:

`<PARAM>`

The `<PARAM>` tag allows the HTML author to provide run-time parameters to the applet as a series of `NAME` and `VALUE` pairs. The `NAME` is case insensitive, a `String`. See Chapter 14, *And Then There Were Applets* for a discussion of how to read parameters in an applet. Quotes are required around the parameter name or its value if there are any embedded spaces. There can be an infinite number of `<PARAM>` tags, and they all must appear between `<APPLET>` and `</APPLET>`

The special parameter name `CABBASE` is used for sending CAB files with Internet Explorer 3.0. CAB files are similar to ZIP files but are compressed into a CABinet file and can store audio and image files, in addition to classes. (For a full explanation see: http://207.68.137.43/workshop/java/overview.htm.) When *.class* files are placed within a CAB file, they are decompressed at the local end. Here's an example:

```
<APPLET CODE="oreilly.class" WIDTH=400 HEIGHT=400>
<PARAM NAME="cabbase" VALUE="ora.cab>
</APPLET>
```

The special parameter name `ARCHIVES` is reserved for sending JAR files. JAR files can also be specified using the `ARCHIVES` parameter to the `<APPLET>` tag.[1] Here's an example:

[1] For a full explanation see http://www.javasoft.com/products/JDK/1.1/docs/guide/jar/index.html.

```
<APPLET CODE="oreilly.class" WIDTH=400 HEIGHT=400>
<PARAM NAME="archives" VALUE="ora.jar>
```

```
</APPLET>
```

D. Image Loading

Contents:

D.1 How Images are Loaded

You have seen how easy it is to display an image on screen and have probably guessed that there's more going on behind the scenes. The `getImage()` and `drawImage()` methods trigger a series of events that result in the image being available for display on the `ImageObserver`. The image is fetched asynchronously in another thread. The entire process[1] goes as follows:

> [1] This summary covers Sun's implementation (JDK). Implementations that don't derive from the JDK may behave completely differently.

1. The call to `getImage()` triggers `Toolkit` to call `createImage()` for the image's `InputStreamImageSource` (which is a `URLImageSource` in this case; it would be a `FileImageSource` if we were loading the image from a local file).

2. The `Toolkit` registers the image as being "desired." Desired just means that something will eventually want the image loaded. The system then waits until an `ImageObserver` registers its interest in the image.

3. The `drawImage()` method (use of `MediaTracker` or `prepareImage()`) registers an `ImageObserver` as interested.

4. Registering an `ImageObserver` kicks the image's `ImageRepresentation` into action; this is the start of the loading process, although image data isn't actually transferred until step 9. `ImageRepresentation` implements the `ImageConsumer` interface.

5. The start of production registers the image source (`ImageProducer` `URLImageSource`) with the `ImageFetcher` and also registers the `ImageRepresentation` as an `ImageConsumer` for the image.

6. The `ImageFetcher` creates a thread to get the image from its source.

7. The `ImageFetcher` reads data and passes it along to the `InputStreamImageSource`, which is a `URLImageSource`.

8. The `URLImageSource` determines that `JPEGImageDecoder` is the proper `ImageDecoder` for converting the input stream into an `Image`. (Other `ImageDecoders` are used for other image types, like GIF.)

9. The `ImageProducer` starts reading the image data from the source; it calls the `ImageConsumer` (i.e., the `ImageRepresentation`) as it processes the image. The most important method in the `ImageConsumer` interface is `setPixels()`, which delivers pixel data to the consumer for rendering onscreen.

10. As the `ImageConsumer` (i.e., the `ImageRepresentation`) gets additional information, it notifies the `ImageObserver` via `imageUpdate()` calls.

11. When the image is fully acquired across the network, the thread started by the `ImageFetcher` stops.

As you see, there are a lot of unfamiliar moving pieces. Many of them are from the `java.awt.image` package and are discussed in Chapter 12, *Image Processing*. Others are from the `sun.awt.image` package; they are hidden in that you don't need to know anything about them to do image processing in Java. However, if you're curious, we'll briefly summarize these classes in the next section.

1. Introduction

Contents:

Java is a relatively new programming language. However, many of the features that make up the language are not new at all. Java's designers borrowed features from a variety of older languages, such as Smalltalk and Lisp, in order to achieve their design goals.

Java is designed to be both robust and secure, so that it can be used to write small, hosted programs, or *applets*, that can be run safely by hosting programs such as Web browsers and cellular phones. Java also needs to be portable, so that these programs can run on many different kinds of systems. What follows is a list of the important features that Java's designers included to create a robust, secure, and portable language.

- Java is a simple language. It borrows most of its syntax from C/C++, so it is easy for C/C++ programmers to understand the syntax of Java code. But that is where the similarities end. Java does not support troublesome features from C/C++, so it is much simpler than either of those languages. In fact, if you examine the features of Java, you'll see that it has more in common with languages like Smalltalk and Lisp.

- Java is a statically typed language, like C/C++. This means that the Java compiler can perform static type checking and enforce a number of usage rules.

- Java is fully runtime-typed as well. The Java runtime system keeps track of all the objects in the system, which makes it possible to determine their types at runtime. For example, casts from one object type to another are verified at runtime. Runtime typing also makes it possible to use completely new, dynamically loaded objects with some amount of type safety.

- Java is a late-binding language, like Smalltalk, which means that it binds method calls to their definitions at runtime. Runtime binding is essential for an object-oriented language, where a subclass can override methods in its superclass, and only the runtime system can determine which method should be invoked. However, Java also supports the performance benefits of early binding. When the compiler can determine that a method cannot be overridden by subclassing, the method definition is bound to the method call at compile-time.

- Java takes care of memory management for applications, which is unlike C/C++, where the programmer is responsible for explicit memory management. Java supports the dynamic allocation of arrays and objects, and then takes care of reclaiming the storage for objects and arrays when it is safe to do so, using a technique called *garbage collection*. This eliminates one of the largest sources of bugs in C/C++ programs.

- Java supports object references, which are like pointers in C/C++. However, Java does not allow any manipulation of references. For example, there is no way that a programmer can explicitly dereference a reference or use pointer arithmetic. Java implicitly handles dereferencing references, which means that they can be used to do most of the legitimate things that C/C++ pointers can do.

- Java uses a single-inheritance class model, rather than the error-prone multiple-inheritance model used by C++. Instead, Java provides a feature called an *interface* (borrowed from Objective C) that specifies the behavior of an object without defining its implementation. Java supports multiple inheritance of interfaces, which provides many of the benefits of multiple inheritance, without the associated problems.

- Java has support for multiple threads of execution built into the language, so there are mechanisms for thread synchronization and explicit waiting and signaling between threads.

- Java has a powerful exception-handling mechanism, somewhat like that in newer implementations of C++. Exception handling provides a way to separate error-handling code from normal code, which leads to cleaner, more robust applications.

- Java is both a compiled and an interpreted language. Java code is compiled to Java byte-codes, which are then executed by a Java runtime environment, called the Java virtual machine. The specifications of the Java language and the virtual machine are fully defined; there are no implementation-dependent details. This architecture makes Java an extremely portable language.

- Java uses a three-layer security model to protect a system from untrusted Java code. The byte-code verifier reads byte-codes before they are run and makes sure that they obey the basic rules of the Java language. The class loader takes care of bringing compiled Java classes into the runtime interpreter. The security manager handles application-level security, by controlling whether or not a program can access resources like the filesystem, network ports, external processes, and the windowing system.

As you can see, Java has quite a list of interesting features. If you are a C/C++ programmer, many of the constructs of the Java language that are covered in this book should look familiar to you. Just be warned that you shouldn't take all of these constructs at face value, since many of them are different in Java than they are in C/C++.

1.1 A "Hello World" Program

Before diving into the various constructs provided by the Java language, you should have at least a general understanding of the Java programming environment. In the fine tradition of all language reference manuals, here is a short Java program that outputs "Hello world!" and then exits:

```
/*
 * Sample program to print "Hello World"
 */
class HelloWorld {             // Declare class HelloWorld
    public static void main(String argv[]) {
        System.out.println("Hello World!");
    }
}
```

This example begins with a comment that starts with `/*` and ends with `*/`. This type of comment is called a *C-style comment*. The example also uses another kind of comment that begins with `//` and ends at the end of the line. This kind of comment is called a *single-line comment*; it is identical to that style of comment in C++. Java supports a third type of comment, called a *documentation comment*, that provides for the extraction of comment text into a machine-generated document.

Comments aside, the example consists of a single class declaration for the class called `HelloWorld`. If you are unfamiliar with classes, you can think of a class as a collection of variables and pieces of executable code called *methods* for the purposes of this discussion. In Java, most executable code is part of a method. Methods are identical to virtual member functions in C++, except that they can exist only as part of a class. Methods are also similar to functions, procedures, and subroutines in other programming languages.

The `HelloWorld` class contains a single method named `main()`. When you ask the Java interpreter to run a Java program, you tell it what code to run by giving it the name of a class. The Java interpreter then loads the class and searches it for a method named `main()` that has the same attributes and parameters as shown in the example. The interpreter then calls that `main()` method.

In the declaration of `main()`, the name `main` is preceded by the three keywords: `public`, `static`, and `void`. The `public` modifier makes the `main()` method accessible from any class. The `static` modifier, when applied to a method, means that the method can be called independently of an instance of a class. The `void` keyword means that the method returns no value. The `main()` method of an application should always be declared with these three keywords. Although the meanings of these keywords is similar to their meanings in C++, there are some differences in the meaning of the keyword `static` as used in Java and C++.

The `main()` method contains a single line of executable code that calls the `println()` method of the object `System.out`. Passing the argument `"Hello World!"` to the `println()` method results in "Hello World!" being output. `System.out` is an object that encapsulates an application's standard output. It is similar in purpose to `stdout` in C and `cout` in C++. Java also has `System.in` and `System.err` objects that are similar in purpose to `stdin` and `stderr` in C and `cin` and `cerr` in C++, respectively.

2. Lexical Analysis

When the Java compiler compiles a program, the first thing it does is determine the structure of the program. The compiler reads the characters in the program source and then applies rules to recognize progressively larger chunks of the file, such as identifiers, expressions, statements, and classes. The process of discovering the organization of the program is divided into two components:

- The *lexical analyzer*. This component looks for sequences of characters called *tokens* that form identifiers, literals, operators, and the like.
- The *parser*. This component is responsible for discovering higher levels of organization in the sequences of tokens discovered by lexical analysis.

This chapter describes the rules governing the lexical analysis of Java programs. The rules governing the parsing of Java programs are described over the course of subsequent chapters.

The lexical analysis rules for Java can appear slightly ambiguous. Where ambiguity occurs, the rules for interpreting character sequences specify that conflicts are resolved in favor of the interpretation that matches the most characters. That's a bit confusing, so an example should help. Take the character sequence:

```
+++
```

The ambiguity is that the sequence could potentially be interpreted as either + followed by ++ or the other way around; both are valid tokens. But according to the lexical analysis rules that insist that tokenization favor the longest character match, Java interprets the character sequence as:

```
++ +
```

Because ++ is longer than +, Java first recognizes the token ++ and then the +.

These rules can produce undesired results when character sequences are not separated by white space. For example, the following sequence is ambiguous:

```
x++y
```

The programmer probably intended this sequence to mean "`x + (+y)`", but the lexical analyzer always produces the token sequence "`x ++ y`". This sequence is syntactically incorrect.

Java lexical analysis consists of two phases: pre-processing and tokenization. The pre-processing phase is discussed in the following section. The tokenization phase is responsible for recognizing the tokens in the pre-processed input and is discussed later in this chapter.

2.1 Pre-Processing

A Java program is a sequence of characters. These characters are represented using 16-bit numeric codes defined by the Unicode standard.[1] Unicode is a 16-bit character encoding standard that includes representations for all of the characters needed to write all major natural languages, as well as special symbols for mathematics. Unicode defines the codes 0 through 127 to be consistent with ASCII. Because of that consistency, Java programs can be written in ASCII without any need for programmers to be aware of Unicode.

> [1] Unicode is defined by an organization called the Unicode Consortium. The defining document for Unicode is *The Unicode Standard, Version 2.0* (published by Addison-Wesley, ISBN 0-201-48345-9). More recent information about Unicode is available at *http://unicode.org/*.

Java is based on Unicode to allow Java programs to be useful in as many parts of the world as possible. Internally, Java programs store characters as 16-bit Unicode characters. The benefits of using Unicode are currently difficult to realize, however, because most operating environments do not support Unicode. And those environments that do support Unicode generally do not include fonts that cover more than a small subset of the Unicode character set.

Since most operating environments do not support Unicode, Java uses a pre-processing phase to make sure that all of the characters of a program are in Unicode. This pre-processing comprises two steps:

- Translate the program source into Unicode characters if it is in an encoding other than Unicode. Java defines escape sequences that allow all characters that can be represented in Unicode to be represented in other character encodings, such as ASCII or EBCDIC. The escape sequences are recognized by the compiler, even if the program is already represented in Unicode.

- Divide the stream of Unicode characters into lines.

Conversion to Unicode

The first thing a Java compiler does is translate its input from the source character encoding (e.g., ASCII or EBCDIC) into Unicode. During the conversion process, Java translates escape sequences of the form `\u` followed by four hexadecimal digits into the Unicode characters indicated by the given hexadecimal values. These escape sequences let you represent Unicode characters in whatever character set you are using for your source code, even if it is not Unicode. For example, `\u0000` is a way of representing the NUL character.

More formally, the compiler input is converted from a stream of *EscapedSourceCharacters* into a stream of Unicode characters. *EscapedSourceCharacter* is defined as:

[Graphic: Figure from the text]

HexDigit is either a *Digit* or one of the following letters: `A`, `a`, `B`, `b`, `C`, `c`, `D`, `d`, `E`, `e`, `F`, or `f`.

A *Digit* is one of the following characters: `0`, `1`, `2`, `3`, `4`, `5`, `6`, `7`, `8`, or `9`.

As you can see, the definition of *EscapedSourceCharacter* specifies that the `` `u' `` in the escape sequence can occur multiple times. Multiple occurrences have the same meaning as a single occurrence of `` `u' ``.

If the program source is already in Unicode, this conversion step is still performed in order to process these `\u` escapes.

The Java language specification recommends, but does not require, that the classes that come with Java use the `\u`*xxxx* escapes when called upon to display a character that would not otherwise be displayable.

Division of the Input Stream into Lines

The second step of pre-processing is responsible for recognizing sequences of characters that terminate lines. The character sequence that indicates the end of a line varies with the operating environment. By recognizing end-of-line character sequences during pre-processing, Java makes sure that subsequent compilation steps do not need to be concerned with multiple representations for the end of a line.

In this step, the lexical analyzer recognizes the combinations of carriage return (`\u000D`) and line feed (`\u000A`) characters that are in widespread use as end-of-line indicators:

[Graphic: Figure from the text]

As always, ambiguities in lexical rules are resolved by matching the longest possible sequence of characters. That means that the sequence of a carriage return character followed by a linefeed character is always recognized as a one-line terminator, never as two.

3. Data Types

Contents:

A *data type* defines the set of values that an expression can produce or a variable can contain. The data type of a variable or expression also defines the operations that can be performed on the variable or expression. The type of a variable is established by the variable's declaration, while the type of an expression is determined by the definitions of its operators and the types of their operands.

Conceptually, there are two types of data in Java programs: primitive types and reference types. The primitive types are self-contained values that can be contained in a variable. The primitive types are comprised of integer types, floating-point types, and the `boolean` type. Of these, the integer types and floating-point types are considered arithmetic types, since arithmetic can be performed on them. Reference types contain values that point to or identify arrays or objects. The syntax for specifying a type is:

[Graphic: Figure from the text]

References Arithmetic Types; Boolean Type; Floating-point types; Integer types; Interface method return type; Interface Variables; Local Variables; Method return type; Primitive Types; Reference Types; Variables

3.1 Primitive Types

A primitive data type represents a single value, such as a number, a character, or a Boolean value. Java has primitive types for arithmetic and Boolean data:

[Graphic: Figure from the text]

References Arithmetic Types; Boolean Type

Arithmetic Types

Unlike in C/C++, all of the arithmetic data types in Java are specified to have representations that are independent of the particular computer running a Java program. This guarantees that numeric computations made by Java programs produce the same results on all platforms.

There are two kinds of arithmetic types: integer and floating-point.

The integer types are: `byte`, `short`, `int`, `long`, and `char`. Like C/C++, character data is considered an integer type because of its representation and because arithmetic operations can be performed on `char` data. Unlike C/C++, however, `short int` and `long int` are not valid data types in Java. In addition, `signed` and `unsigned` do not have any special meaning in Java.

The floating-point data types are `float` and `double`.

The formal definition of an arithmetic type is:

[Graphic: Figure from the text]

References Integer types; Floating-point types

Integer types

Java provides integer data types in a variety of sizes. Unlike C/C++, however, the sizes of these types are part of the language specification; they are not platform-dependent. Formally:

[Graphic: Figure from the text]

The values represented by these types are specified in Table 3-1. The representation shown is used on all platforms and is independent of the native platform architecture.

Table 3.1: Integer Types and Their Representations

Type	**Representation**	**Range**
`byte`	8-bit, signed, two's complement	-128 to 127
`short`	16-bit, signed, two's complement	-32768 to 32767
`int`	32-bit, signed, two's complement	-2147483648 to 2147483647
`long`	64-bit, signed, two's complement	-9223372036854775808 to 9223372036854775807
`char`	16-bit, unsigned, Unicode	`'\u0000'` to `'\uffff'`

All of the signed integer types in Java use a two's complement representation. Two's complement is a binary encoding for integers, which has the following properties:

- The leftmost bit is the sign bit. If the sign bit is 1, the number is negative.
- Positive numbers have the usual binary representation.
- Negating a number involves complementing all of the bits in the number and then adding 1 to the result.
- The most negative value does not have a positive equivalent.

The `java.lang` package includes the `Byte`, `Short`, `Integer`, `Long`, and `Character` classes. These classes provide object wrappers for `byte`, `short`, `int`, `long`, and `char` values, respectively. Each of these classes defines `static` `MIN_VALUE` and `MAX_VALUE` variables for its minimum and maximum values.

Java performs all integer arithmetic using `int` or `long` operations. A value that is of type `byte`, `short`, or `char` is widened to an `int` or a `long` before the arithmetic operation is performed.

A value of any integer type can be cast (i.e., converted) to a value of any other integer type. Integer types, however, cannot be cast to a `boolean` value, nor can the `boolean` type be cast to an integer-type value. A value of a signed integer type can be assigned to a value of the same or wider type without a cast. In this case, the value is automatically widened to the appropriate type. Table 3-2 shows whether an assignment from a particular integer type to another integer type can be done directly or if it requires a type cast.

Table 3.2: Assignment Compatibility Between Integer Types

To/From	**`byte`**	**`char`**	**`short`**	**`int`**	**`long`**
`byte`	Assignable	Cast needed	Cast needed	Cast needed	Cast needed
`char`	Cast needed	Assignable	Cast needed	Cast needed	Cast needed
`short`	Assignable	Cast needed	Assignable	Cast needed	Cast needed
`int`	Assignable	Assignable	Assignable	Assignable	Cast needed
`long`	Assignable	Assignable	Assignable	Assignable	Assignable

The principle underlying the above table is that assignments that do not lose information do not require a type cast. Assigning a `short` value to an `int` without a cast is allowed because all of the values that can be represented by a `short` can also be represented by `int`. However, assigning an `int` value to a `short` is not allowed without a cast because it involves going from a 32-bit signed quantity to a 16-bit signed quantity. Similarly, a `byte` value cannot be assigned to `char` without a cast. `byte` is an 8-bit signed quantity, so it can represent negative numbers. However, `char` is a 16-bit unsigned quantity, so it cannot represent negative numbers.

Java provides the following kinds of operators for integer values:

- Comparison operators
- Arithmetic operators
- Increment and decrement operators
- Bitwise logical operators

If all of the operands of an operator are of an integer type, the operation is performed as an integer operation. Normally, integer operations are performed with a precision of 32 bits. If at least one of the operands of an integer operation is a `long`, however, the operation is performed with a precision of 64 bits.

When an integer operation overflows or underflows, there is no indication given that the overflow or underflow occurred.

If the right-hand operand (the divisor) of a division or remainder operation is 0, Java throws an `ArithmeticException`. Division by zero is the only circumstance that can cause an integer operation to throw an exception.

Floating-point types

Like C/C++, Java provides two sizes of floating-point numbers: single precision and double precision.

Formally:

[Graphic: Figure from the text]

Java uses the single precision 32-bit IEEE 754 format to represent `float` data and the double precision 64-bit IEEE 754 format to represent `double` data.[1] These representations are used on all platforms, whether or not there is native support for the formats. The values represented by these types are shown in Table 3-3.

> [1] The IEEE 754 floating-point data representation and operations on it are defined in *IEEE Standard for Binary Floating-Point Arithmetic*, ANSI/IEEE Std. 754-1985 (IEEE, New York). The standard can be ordered by calling (908) 981-0060 or writing to IEEE, 445 Hoes Lane, PO Box 1331, Piscataway, NJ 08855-1331, USA.

Table 3.3: Floating-Point Types and Their Representations

Type	**Representation**	**Range**
`float`	32-bit, IEEE 754	1.40239846e-45 to 3.40282347e+38
`double`	64-bit, IEEE 754	4.94065645841246544e-324 to 1.79769313486231570e+308

Normally, non-zero `float` values are represented as:

```
sign*mantissa*2^exponent
```

where `sign` is +1 or -1, `mantissa` is a positive integer less than 2^24, and `exponent` is an integer in the inclusive range -149 to 104.

Non-zero `double` values are represented as:

```
sign*mantissa*2^exponent
```

where `sign` is +1 or -1, `mantissa` is a positive integer less than 2^53, and `exponent` is an integer in the inclusive range -1045 to 1000.

In addition, the IEEE 754 standard defines three special values:

Positive infinity

> This value is produced when a `float` or `double` operation overflows, or a positive value is divided by zero. Positive infinity is by definition greater than any other `float` or `double` value.

Negative infinity

> This value is produced when a `float` or `double` operation overflows, or a negative value is divided by zero. Negative infinity is by definition less than any other `float` or `double` value.

Not-a-number (NaN)

> This value is produced by the `float` and `double` operations such as the division of zero by zero. When NaN is one of the operands for an operation, most arithmetic operations return NaN as the result. Since NaN is unordered, most comparison operators (e.g., `<`, `<=`, `==`, `>=`, `>`) return `false` when one of their arguments is NaN. The exception is `!=`, which returns `true` when one of its arguments is NaN.

The `java.lang` package includes `Float` and `Double` classes that provide object wrappers for `float` and `double` values. Each class defines the three special values as symbolic constants: `POSITIVE_INFINITY`, `NEGATIVE_INFINITY`, and `NaN`. Each class also defines `MIN_VALUE` and `MAX_VALUE` constants for its minimum and maximum values.

Floating-point operations never throw exceptions. Operations that overflow produce positive or negative infinity. Operations that underflow produce positive or negative zero. Operations that have no defined result produce not-a-number.

Both `float` and `double` data types have distinct representations for positive and negative zero. These values compare as equal `(0.0 == -0.0)`. Positive and negative zero do produce different results for some arithmetic operations, however: `1.0/0.0` produces positive infinity, while `1.0/-0.0` produces negative infinity.

A `float` value can be assigned to a `double` variable without using a type cast, but assigning a `double` value to a `float` variable does require a cast. Conversion from a `float` or `double` value to any other data type also requires a cast. Either of the floating-point data types can be cast to any other arithmetic type, but they cannot be cast to `boolean`. When a floating-point number is cast to an integer type, it is truncated (i.e., rounded toward zero).

Java provides the following kinds of operators for floating-point values:

- Comparison operators
- Arithmetic operators
- Increment and decrement operators

If any of the arguments of an operation are of a floating-point type, the operation is performed as a floating-point operation. In other words, any of the integer operands are converted to floating point before the operation takes place. Floating-point operations are normally performed with a precision of 32 bits. However, if at least one of the operands of the operation is a `double`, the operation is performed with a precision of 64 bits.

References Additive Operators; Assignment Operators; Conditional Operator; Equality Comparison Operators; Double; Float; Floating-point literals; Increment/Decrement Operators; Multiplicative Operators; Relational Comparison Operators; Unary Operators

Boolean Type

The `boolean` data type represents two values: `true` and `false`. These values are keywords in Java. The `java.lang` package includes a `Boolean` class that provides an object wrapper for `boolean` values. This `Boolean` class defines the constant objects `Boolean.TRUE` and `Boolean.FALSE`.

Java provides the following kinds of operators for `boolean` values:

- Equality and inequality operators
- Boolean logical operators

The following Java constructs require a `boolean` value to specify a condition:

- `if`
- `while`
- `for`
- `do`
- The conditional operator `? :`

Unlike C/C++, any attempt to substitute a different type for `boolean` in these constructs is treated as an error by Java.

No other data type can be cast to or from `boolean`. In particular, using the integer 1 to represent `true` and 0 to represent `false` does not work in Java. Though Java does not provide conversions between `boolean` and other types, it is possible to provide explicit logic to accomplish the same thing:

```
int i;
i != 0             // This is true if i is not equal to zero
boolean b;
b ? 1 : 0          // If b is true produce 1; otherwise 0
```

4. Expressions

Contents:

Expressions in Java are used to fetch, compute, and store values. To fetch a value, you use a type of expression called a primary expression. To compute and store values, you use the various operators described in this chapter. In Java, expressions are most often used in methods and constructors; they can also appear in field variable initializers and static initializers.

Most expressions, when they are evaluated, produce values that can be used by other expressions. The one exception is an expression that calls a method declared with the `void` return type. An expression that invokes a `void` method cannot be embedded in another expression. The evaluation of an expression can also produce side effects, such as variable assignments and increment and decrement operations.

The value produced by an expression can be either a pure value or a variable or array element. The distinction is that a *pure value* cannot be used to store a value, while a variable or array element can.[1] An expression that produces a variable or an array element can be used anywhere that an expression that produces a pure value can be used.

This chapter refers to values as being either pure values or variables. Saying that a value is a pure value means that it is a value such as 24 that contains information, but cannot be used as the target of an assignment expression. Saying that a value is a variable means that it is something like `var` or `ar[i]` that can be used as the target of an assignment. The generic term "value" is used to mean either a variable or a pure value.

The formal definition of an expression is:

[Graphic: Figure from the text]

The above diagram may seem deceptively simple; why is such a definition even necessary? Expressions in Java are defined with a number of mutually recursive railroad diagrams. You can think of the *Expression* definition as being both the lowest-level definition and the highest-level definition of these mutually recursive diagrams. In other words, `a=b[i]+c[i]` is an expression, as are `b[i]`, `c[i]`, `a`, `b`, `c`, and `i`. This first diagram defines an expression to be an *AssignmentExpression*, which is the final definition used to describe Java expressions.

References Assignment Operators

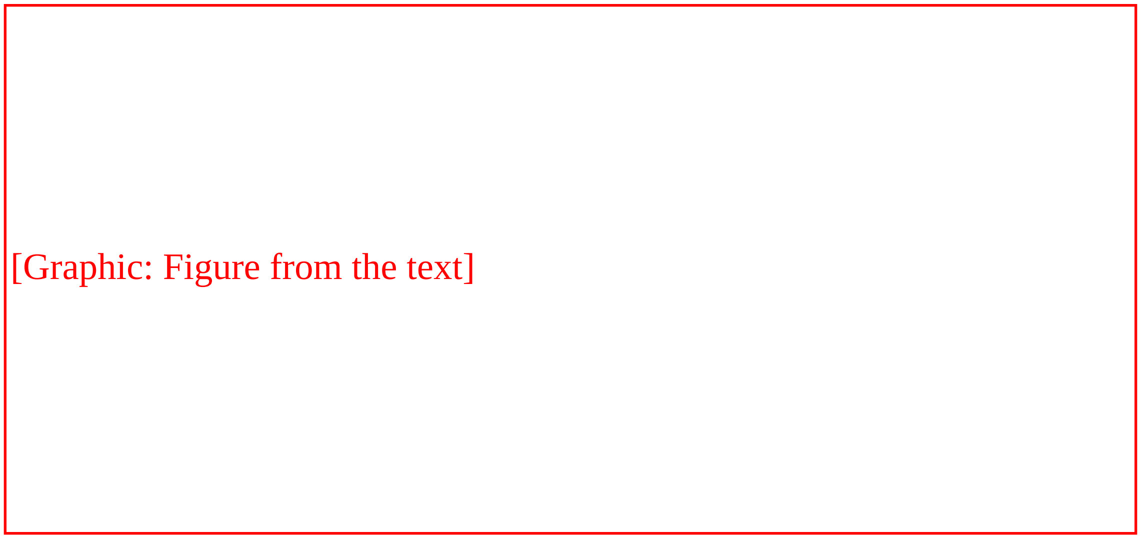
4.1 Primary Expressions

A primary expression is the most elementary type of expression. Primary expressions are constructs that fetch or create values, but do not directly perform computations on them:

[Graphic: Figure from the text]

Terms are those primary expressions that produce values, by doing such things as accessing fields in classes, invoking methods, and accessing array elements:

[1] Note that Java's distinction between pure values and variable and array elements is similar to the distinction in C and C++ between rvalues and lvalues.



References Allocation Expressions; *Expression* 4; *FieldExpression* 4.1.6; Identifiers; Index Expressions; Literals; Method Call Expression; Class Literals

this

The keyword `this` can be used only in the body of a constructor or an instance method (i.e., a method that is not declared `static`), or in the initializer for an instance variable. A `static` method is not associated with an object, so `this` makes no sense in such a method and is treated as an undefined variable. If `this` is used in an inappropriate place, a compile-time error occurs.

The value produced by `this` is a reference to the object associated with the expression that is being evaluated. The type of the primary expression `this` is a reference to the class in which it appears.

One common use for `this` is to allow access to a field variable when there is a local variable with the same name. For example:

```
int foo;
void setFoo(int foo) {
    this.foo = foo;
}
```

Another common usage is to implement a callback mechanism. Passing `this` to another object allows that object to call methods in the object associated with the calling code. For example, to allow an object inside of an applet to be able to access parameters passed to the applet in the HTML `<applet>` tag, you can use code like the following:

```
public class MyApplet extends Applet {
    ...
    Foo foo;
    public void init() {
        foo = new Foo(this);
    ...
    }
}
class Foo {
    Applet app;
    ...
    Foo(Applet app) {
        this.app = app;
    }
    ...
    void doIt() {
        String dir = app.getParameter("direction");
        ...
    }
    ...
}
```

Another use for the keyword `this` is in a special kind of *FieldExpression* that refers to an enclosing instance of this object. A reference to an enclosing instance is written as the class name of the enclosing instance followed by a dot and the keyword `this` (as described in 5.3.7.2 Member classes). Consider the following code:

```
public class ImageButton extends Canvas {
    ...
    private class MyImage extends Image {
        Image fileImage;
        MyImage(String fileName) throws IOException {
            URL url = new URL(fileName);
            ImageProducer src = (ImageProducer)url.getContent();
            Image fileImage = createImage(src);
            prepareImage(this, ImageButton.this);
        }
    ...
```

The call to `prepareImage()` takes two arguments. The first argument is a reference to `this` instance of the `MyImage` class. The second argument is a reference to this object's enclosing instance, which is an instance of the `ImageButton` class.

References Constructors; Constructor implementation; *FieldExpression* 4.1.6; Inner Classes; Methods

super

The keyword `super` can be used only in the body of a constructor or an instance method (i.e., a method that is not declared `static`), or in the initializer for an instance variable. In addition, `super` cannot appear in the class `Object` because `Object` has no superclass. If `super` is used in an inappropriate place, a compile-time error occurs.

In most cases, the primary expression `super` has a value that is equivalent to casting the value of the primary expression `this` to the superclass of the class in which it appears. In other words, `super` causes the object to be treated as an instance of its superclass. The type of the primary expression `super` is a reference to the superclass of the class in which it appears.

There are two situations in which `super` produces a result that is different than what would be produced by casting `this` to its superclass:

- When `super` is used to explicitly call a constructor in the superclass from a constructor in the class, the field variables for the class are initialized when the superclass's constructor returns.

- If a class contains a method that overrides a method declared in its superclass, calling the method by casting `this` to the superclass results in a call to the overriding method. However, calling the method with the special reference provided by `super` calls the overridden method in the superclass.

The main purpose of `super` is to allow the behavior of methods and constructors to be extended, rather than having to be totally replaced. Consider the following example:

```
class A {
    public int foo(int x) {
        return x*x;
    }
    public int bar(int x) {
        return x*8;
    }
}
class B extends A{
    public int foo(int x) {
        return super.foo(x)+x;
    }
    public int bar(int x){
        return x*5;
    }
}
```

The `foo()` method in class `B` extends the behavior of the `foo()` method in class `A` by calling that method and performing further computations on its result. On the other hand, the `bar()` method in class `B` totally replaces the behavior of the `bar()` method in class `A`.

References Constructors; Constructor implementation; Methods

null

The primary expression `null` produces a special object reference value that does not refer to any object, but is assignment-compatible with all object reference types.

An operation on an object reference that does not attempt to access the referenced object works the same way for `null` as it does for other object reference values. For example:

```
foo == null
```

However, any operation that attempts to access an object through a `null` reference throws a `NullPointerException`. The one exception to this rule is the string concatenation operator (`+`), which converts a `null` operand to the string literal `"null"`.

References Runtime exceptions; String Concatenation Operator +

Literal Expressions

A primary expression that consists of a literal produces a pure value. The data type of this pure value is the data type of the literal.

References Literals

Parenthetical Expressions

A primary expression that consists of a parenthesized expression produces the same pure value as the expression in parentheses. The data type of this pure value is also the same as the data type of the expression in parentheses. A parenthetical expression can only produce a pure value. Thus, the following code produces an error:

```
(x) = 5;          // Illegal
```

References *Expression* 4

Field Expressions

A *field expression* is a primary expression that fetches such things as local variables, formal parameters, and field variables. A field expression can evaluate to a pure value or a variable. The data type of a field expression is the data type of the pure value, variable, or array element produced by the following expression.

[Graphic: Figure from the text]

[Graphic: Figure from the text]

Essentially, a field expression can be a simple identifier, a primary expression followed by an identifier, or a class or interface name followed by an identifier. Here's an example of a field expression that consists of a simple *Identifier* :

```
myVar
```

Before the Java compiler can decide what to do with a lone identifier such as this, it must first match it with a declaration. The compiler first looks in the method where the identifier appears for a local variable or formal parameter with the same name as the identifier. If the compiler finds a matching local variable or formal parameter, the field expression produces the matching variable or parameter.

If the identifier does not match a local variable or a formal parameter, it is expected to match the name of a field variable in the class in which it occurs.

If the matching variable is declared `final`, the field expression produces the pure value specified by the variable's initializer. Otherwise, the field expression produces the matching field variable. If the method that the identifier appears in is declared `static`, the matching variable must also be declared `static` or the compiler declares an error.

A lone identifier that matches the name of a field variable is equivalent to:

```
this.Identifier
```

This form of a field expression can be used to access a field variable that is shadowed by a local variable or a formal parameter. For example:

```
class Shadow {
    int value;
    Shadow(int value) {
        this.value=value;
    }
}
```

In the above example, the identifier `value` is used as both the name of a field variable and the name of a formal parameter in the constructor. Within the constructor, the unqualified identifier `value` refers to the formal parameter, not to the field variable. In order to access the field variable, you have to qualify `value` with `this`.

In addition to allowing an object to refer to itself, the keyword `this` has another use in field expressions. The construct *ClassOrInterfaceName*`.this` identifies the enclosing instance of an object that is an instance of an inner class.[2] Consider the following example:

> [2] Since this construct fetches an object reference, you might expect it to be a primary expression. However, due to the way in which inner classes are implemented, this construct is actually a field expression.

```
public class ImageButton extends Canvas {
    ...
    private class MyImage extends Image {
        Image fileImage;
        MyImage(String fileName) throws IOException {
            URL url = new URL(fileName);
            ImageProducer src = (ImageProducer)url.getContent();
            Image fileImage = createImage(src);
            prepareImage(this, ImageButton.this);
        }
    ...
```

The call to `prepareImage()` takes two arguments. The first argument is a reference to `this` instance of the `MyImage` class. The second argument is a reference to this object's enclosing instance, which is an instance of the `ImageButton` class.

Here are some examples of field expressions that consist of a *PrimaryExpression* and an *Identifier*:

```
this.myVar
size().height
```

```
(new Foo()).bar
```

A primary expression that appears at the beginning of a field expression must produce a reference to an object. The identifier to the right of the dot must be the name of a field variable in the object referred to by the primary expression. If, at runtime, the primary expression in a field expression produces the value `null`, a `NullPointerException` is thrown.

Here's an example of a field expression that consists of a *ClassOrInterfaceName* and an *Identifier*:

```
Double.POSITIVE_INFINITY
```

A field expression that begins with *ClassOrInterfaceName* produces a field variable of the specified class. If the field variable is not declared `static`, the specified class must either be the same class in which the field expression appears or a superclass of that class.

Such a field expression is approximately equivalent to:

```
((ClassOrInterfaceName)this).Identifier
```

If *ClassOrInterfaceName* specifies a class or interface defined in a different package than the package in which the field expression appears, the class name must be qualified by the package in which the class is defined. For example:

```
java.awt.Event.MOUSE_UP
```

However, if an import statement imports the specified class, the package name is not necessary.

ClassOrInterfaceName can refer to an inner class or a nested top-level class or interface by qualifying the name of the class or interface with the name of the enclosing class. For example, consider the following declaration:

```
public class A {
    public class B {
    }
}
```

Based on this declaration, you can create a new instance of `B` as follows:

```
new A.B()
```

Most field expressions produce variables when they are evaluated. This means that the field expression can be used as the left operand of an assignment operator. A field expression produces a pure value, rather than a variable, if the identifier at the end of the field expression is a field variable that is declared `final`. Such a field expression returns a pure value because the value of a `final` variable cannot be modified. A field expression that produces a pure value cannot be the left operand of an assignment operator, or the operand of the `++` or `- -` operators. Here's an erroneous example:

```
final int four=4
four++
```

This is equivalent to:

```
4++
```

As such, it causes the Java compiler to issue an error message.

When the Java compiler detects an expression that uses the value of a local variable that may not have been initialized, it issues an error message. For example:

```
{
    int x;
    if (testForSomething())
        x = 4;
    System.out.println(x);    // Compiler complains
}
```

The compiler complains about the use of `x` in the `println()` method because `x` may not have been given an explicit value when the program reaches that statement. Even though there is an assignment to `x` in the preceding statement, the compiler recognizes that the assignment may not have been performed, since it is enclosed within a conditional statement. The Java language specification requires that a compiler issue an error message when it detects an uninitialized local variable.

References Identifiers; Inheritance; Inner Classes; Interface Variables; Local Variables; Packages; Primary Expressions; Runtime exceptions; Variables

Index Expressions

An *index expression* is a primary expression that produces an array element when it is evaluated. The value produced by an index expression is a variable; it can be used as the left operand of an assignment expression. The data type of an index expression is the data type of the array element produced by the expression:

[Graphic: Figure from the text]

When the compiler evaluates an index expression, the term to the left of the square brackets is evaluated before the expression inside of the square brackets. If the term produces the value `null`, a `NullPointerException` is thrown.

Array indexing uses an `int`-valued expression between the square brackets. If the type of the expression is `byte`, `char`, or `short`, the value is automatically converted to `int`. An array index cannot be of type `long`. The value of the array index must be in the range zero to one less than the length of the array. An array object detects an out-of-range index value and throws an `ArrayIndexOutOfBoundsException`.

Because of the precedence of Java expressions, an array allocation expression can only be indexed when the expression is enclosed in parentheses. For example:

```
(new int[6])[3]
```

This expression refers to the fourth element of the newly created array. Leaving out the parentheses results in the following:

```
new int[6][3]
```

This is not an index expression, but an array allocation expression that allocates an array of 3 arrays of 6 integers.

References Array Allocation Expressions; Array Types; *Expression* 4; *Term* 4.1; Exceptions

Method Call Expression

A *method call expression* is a primary expression that invokes a method:

[Graphic: Figure from the text]

[Graphic: Figure from the text]

A method call expression produces the pure value returned by the method; the type of this value is specified by the return type in the method declaration. But if the method has the return type `void`, the expression does not produce a value.

The *PrimaryExpression*, if present, is evaluated first. Then expressions provided as method arguments are evaluated from left to right. Finally, the method is invoked.

When a method call is made to a method that is not `static`, the call is made through an object reference:

- If the method call expression does not contain a *PrimaryExpression* or *ClassOrInterfaceName* before the method name, the method call is made implicitly through the object referenced by the keyword `this`. This form of a method call expression is treated as if it were written:

  ```
  this.Identifier(...)
  ```

- If the method call expression contains a *PrimaryExpression* before the method name, the call is made through the object reference produced by the *PrimaryExpression*.

- If the method call expression contains a *ClassOrInterfaceName* before the method name, then the specified class must either be the same class in which the method call expression appears or a superclass of that class. In this case, the method call is made through the object referenced by the keyword `this`. This form of a method call expression is treated as if it were written:

  ```
  ((ClassOrInterfaceName)this).Identifier(...)
  ```

When a method call is made to a `static` method, the call is made through a class or interface type:

- If the method call expression does not contain a *PrimaryExpression* or *ClassOrInterfaceName* before the method name, the method call is made implicitly through the class that contains the call.

- If the method call expression contains a *PrimaryExpression* before the method name, the call is made through the class of the object reference produced by the *PrimaryExpression*.

- If the method call expression contains a *ClassOrInterfaceName* before the method name, the method call is made through the specified class or interface type.

The rules for supplying actual values for the formal parameters of a method are similar to the rules for assignment. A particular value can be specified as the actual value of a formal parameter if and only if it is assignment-compatible with the type of the formal parameter. You can use a type cast to make a value assignment compatible with a formal parameter.

The process that the Java compiler uses to select the actual method that will be invoked at runtime is rather involved. The compiler begins by finding any methods that have the specified name. If the method call has been made through an object reference, the compiler searches in the class of that object reference. If the call has been made through a specific class or interface name, the compiler searches in that class or interface. The compiler searches all of the methods defined in the particular class or interface, as well as any methods that are inherited from superclasses or super-interfaces. At this point, the compiler is searching for both `static` and non-`static` methods, since it does not know which type of method is being called.

If the compiler finds more than one method, that means the method is overloaded. Consider this example:

```
public class MyMath {
    public int square(int x) { return x*x; }
    public long square(long x) { return x*x; }
    public float square(float x) { return x*x; }
    public double square(double x) { return x*x; }
    public double hypotenuse(double x, double y) {
        return Math.sqrt(x*x + y*y);
    }
}
```

In the above example, the `square()` method is overloaded, while `hypotenuse()` is not.

If the method is overloaded, the compiler then determines which of the methods has formal parameters that are compatible with the given arguments. If more than one method is compatible with the given arguments, the method that most closely matches the given parameters is selected. If the compiler cannot select one of the methods as a better match than the others, the method selection process fails and the compiler issues an error message. Note that the return types of overloaded methods play no part in selecting which method is to be invoked.

After the compiler successfully selects the method that most closely matches the specified arguments, it knows the name and signature of the method that will be invoked at runtime. It does not, however, know for certain what class that method will come from. Although the compiler may have selected a method from `MyMath`, it is possible that a subclass of `MyMath` could define a method that has the same name and the same number and types of parameters as the selected method. In this case, the method in the subclass overrides the method in `MyMath`. The compiler cannot know about overriding methods, so it generates runtime code that dynamically selects the appropriate method.

Here are the details of the three-step method selection process:

Step One

> The method definitions are searched for methods that, taken in isolation, could be called by the method call expression. If the method call expression uses an object reference, the search takes place in the class of that object reference. If the expression uses a specific class or interface name, the search takes place in that class or interface. The search includes all of the methods defined in the particular class or interface, as well as any methods inherited from superclasses or super-interfaces. The search also includes both `static` and non-`static` methods.
>
> A method is a candidate if it meets the following criteria:
>
> - The name of the method is the same as the name specified in the method call expression.
> - The method is accessible to the method call expression, based on any access modifiers specified in the method's declaration.
> - The number of formal parameters declared for the method is the same as the number of actual arguments provided in the method call expression.
> - The data type of each actual parameter is assignment-compatible with the corresponding formal parameter.
>
> Consider the following expression that calls a method defined in the preceding example:
>
> ```
> MyMath m;
> m.square(3.4F)
> ```
>
> Here is how the Java compiler uses the above criteria to decide which method the expression actually calls:
>
> - The name `square` matches four methods defined in the `MyMath` class, so the compiler must decide which one of those methods to invoke.
> - All four methods are declared `public`, so they are all accessible to the above expression and are thus all still viable candidates.

- The method call expression provides one argument. Since the four methods under consideration each take one argument, there are still four possible choices.

- The method call expression is passing a `float` argument. Because a `float` value cannot be assigned to an `int` or a `long` variable, the compiler can eliminate the versions of `square()` that take these types of arguments. That still leaves two possible methods for the above expression: the version of `square()` that takes a `float` argument and the one that takes a `double` argument.

Step Two

If more than one method meets the criteria in Step One, the compiler tries to determine if one method is a more specific match than the others. If there is no method that matches more specifically, the selection process fails and the compiler issues an error message.

Given two methods, `A()` and `B()`, that are both candidates to be invoked by the same method call expression, `A()` is more specific than `B()` if:

- The class in which the method `A()` is declared is the same class or a subclass of the class in which the method `B()` is declared.

- Each parameter of `A()` is assignment-compatible with the corresponding parameter of `B()`.

Let's go back to our previous example. We concluded by narrowing the possible methods that the expression `m.square(3.4F)` might match to the methods in `MyMath` named `square()` that take either a `float` or a `double` argument. Using the criteria of this step, we can further narrow the possibilities. These methods are declared in the same class, but the version of `square()` that takes a `float` value is more specific than the one that takes a `double` value. It is more specific because a `float` value can be assigned to a `double` variable, but a `double` value cannot be assigned to a `float` variable without a type cast.

There are some cases in which it is not possible to choose one method that is more specific than others. When this happens, the Java compiler treats the situation as an error and issues an appropriate error message.

For example, consider a situation where the compiler needs to choose between two methods declared as follows:

```
double foo(float x, double y)
double foo(double x, float y)
```

Neither method is more specific than the other. The first method is not more specific because the type of its second parameter is `double` and `double` values cannot be assigned to `float` variables. The second method is not more specific because of a similar problem with its first parameter.

Step Three

After successfully completing the previous two steps, the Java compiler knows that the expression in our example will call a method named `square()` and that the method will take one `float` argument. However, the compiler does not know if the method called at runtime will be the one defined in the `MyMath` class. It is possible that a subclass of `MyMath` could define a method that is also called `square()` and takes a single `float` argument. This method in a subclass would override the method in `MyMath`. If the variable `m` in the expression `m.square(3.4F)` refers to such a subclass, the method defined in the subclass is called instead of the one defined in `MyMath`.

The Java compiler generates code to determine at runtime which method named `square()` that takes a single `float` argument it should call. The Java compiler must always generate such runtime code for method call expressions, unless it is able to determine at compile time the exact method to be invoked at runtime.

There are four cases in which the compiler can know exactly which method is to be called at runtime:

- The method is called through an object reference, and the type of the reference is a `final` class. Since the type of the reference is a `final` class, Java does not allow any subclasses of that class to be defined. Therefore, the object reference will always refer to an object of the class declared `final`. The Java compiler knows the actual class that the reference will refer to, so it can know the actual method to be called at runtime.

- The method is invoked through an object reference, and the type of the reference is a class that defines or inherits a `final` method that has the method name, number of parameters, and types of parameters determined by the preceding steps. In this case, the compiler knows the actual method to be called at runtime because `final` methods cannot be overridden.

- The method is a `static` method. When a method is declared static, it is also implicitly declared final. Thus, the compiler can be sure that the method to be called at runtime is the one defined in or inherited by the specified class that has the method name, number of parameters, and types of parameters determined by the preceding steps.

- The compiler is able to deduce that a method is invoked through an object reference that will always refer to the same class of object at runtime. One way the compiler might deduce this is through data flow analysis.

If none of the above cases applies to a method call expression, the Java compiler must generate runtime code to determine the actual method to be invoked. The runtime selection process begins by getting the class of the object through which the method is being invoked. This class is searched for a method that has the same name and the same number and types of parameters as the method selected in Step Two. If this class does not contain such a definition, its immediate superclass is searched. If the immediate superclass does not contain an appropriate definition, its superclasses are searched, and so on up the inheritance hierarchy. This search process is called *dynamic method lookup*.

Dynamic method lookup always begins with the class of the actual object being referenced. The type of the reference being used to access the object does not influence where the search for a method begins. The one exception to this rule occurs when the keyword `super` is used as part of the method call expression. The form of this type of method call expression is:

```
super.Identifier(...)
```

In this case, dynamic method lookup begins by searching the superclass of the class that the calling code appears in.

Now that we've gone through the entire method selection process, let's consider an example that illustrates the process:

```
class A {}
class B extends A {}
class C extends B {}
class D extends C {}
class W {
    void foo(D d) {System.out.println("C");}
}
class X extends W {
    void foo(A a) {System.out.println("A");}
    void foo(B b) {System.out.println("X.B");}
}
class Y extends X {
    void foo(B b) {System.out.println("Y.B");}
}
class Z extends Y {
    void foo(C c) {System.out.println("D");}
}
```

```
public class CallSelection {
    public static void main(String [] argv) {
        Z z = new Z();
        ((X) z).foo(new C());
    }
}
```

In the class CallSelection, the method main() contains a call to a method named foo(). This method is called through an object reference. Although the object refers to an instance of the class Z, it is treated as an instance of the class X because the reference is type cast to the class X. The process of selecting which method to call proceeds as follows:

1. The compiler finds all of the methods named foo() that are accessible through an object of class X: foo(A), foo(B), and foo(D). However, because a reference to an object of class C cannot be assigned to a variable of class D, foo(D) is not a candidate to be invoked by the method call expression.

2. Now the compiler must choose one of the two remaining foo() methods as more specific than the other. Both methods are defined in the same class, but foo(B) is more specific than foo(A) because a reference to an object of class B can be assigned to a variable declared with a type of class A.

3. At runtime, the dynamic method lookup process finds that it has a reference to an object of class Z. The fact that the reference is cast to class X is not significant, since dynamic lookup is concerned with the class of an object, not the type of the reference used to access the object. The definition of class Z is searched for a method named foo() that takes one parameter that is a reference to an object of class B. No such method is found in the definition of class Z, so its immediate superclass, class Y, is searched. Such a method is found in class Y, so that method is invoked.

Here is another example that shows some ambiguous and erroneous method call expressions:

```
class A {}
class B extends A {}
class AmbiguousCall {
    void foo(B b, double x){}
    void foo(A a, int i){}
    void doit() {
        foo(new A(), 8);   // Matches foo(A, int)
        foo(new A(), 8.0); // Error: doesn't match anything
        foo(new B(), 8);   // Error: ambiguous, matches both
        foo(new B(), 8.0); // Matches foo(B, double)
    }
}
```

Class Literals

A *class literal* is an expression that produces a reference to a `Class` object that identifies a specified data type. Class literals are not supported prior to Java 1.1. Here's the syntax for a class literal:

[Graphic: Figure from the text]

If the type in a class literal is a reference type, the class literal produces a reference to the `Class` object that defines the specified reference type. The following are some examples of this type of class literal:

```
String.class
java.util.Stack.class
myNewClass.class
```

Such a class literal can throw a `NoClassDefFoundError` if the specified class is not available.

You can also call `Class.forName()` with the name of a specified reference type to retrieve the `Class` object for that type. For example:

```
Class.forName("java.util.Stack")
```

A class literal and a call to `Class.forName()` for the same reference type return the same `Class` object. There are certain situations when it makes sense to use a class literal, while in other cases a call to `Class.forName()` is more appropriate. Here are the differences between the two techniques for retrieving a `Class` object:

- A class literal cannot contain an expression, so it always refers to the same type. However, the argument passed to `Class.forName()` can be an expression that produces different strings that name different classes.

- The class or interface name passed to `Class.forName()` must be fully qualified by its package name. The class or interface name in a class literal, however, does not typically need to include a package name because the Java compiler can use information provided in package and import directives to deduce the package name.

- The name of an inner class can be used directly with a class literal. Because of the way that inner-class names are encoded, however, when an inner-class name is passed to `Class.forName()`, the name must contain dollar signs ($) in place of dots (`.`).

- The efficiency of a class literal is comparable to a field reference; it is more efficient than the method call required by `Class.forName()`.

If the type in a class literal is `void` or a primitive type, the class literal produces a reference to a unique `Class` object that represents `void` or the specified type. The special `Class` object that represents `void` or a primitive type can be distinguished from a `Class` object that represents a reference type by calling its `isPrimitive()` method. This method only returns `true` if the `Class` object represents `void` or a primitive type. The `getName()` method of a special `Class` object returns a string that contains the name of the primitive type represented by the object. The easiest way to determine the primitive type of a special `Class` object is to compare it to the `TYPE` variables of the primitive wrapper classes. The following comparisons always produce `true`:

```
boolean.class == Boolean.TYPE
byte.class == Byte.TYPE
short.class == Short.TYPE
int.class == Integer.TYPE
long.class == Long.TYPE
char.class == Character.TYPE
float.class == Float.TYPE
double.class == Double.TYPE
void.class == Void.TYPE
```

5. Declarations

Contents:

A declaration is a construct that associates a name with storage that contains specified data or a specified type of data. More specifically, declarations associate names with classes, interfaces, methods, and variables. In addition, the declaration of a class, interface, or method defines the actual class, interface, or method that is associated with the name. Methods and variables can only be declared within classes and interfaces, so this chapter covers method and variable declarations in the context of class and interface declarations.

Every name has a *lexical scope*. The scope of a declaration determines the portions of a program in which the declaration is applicable.

A declaration can be preceded by modifiers that specify attributes of the name or of the data associated with the name. One such attribute for a name is its accessibility. The accessibility modifiers specify the other classes that can access the data associated with the name. The `static` modifier specifies an attribute for data; it indicates whether the data is associated with a class or with individual instances of a class.

Because Java is an object-oriented programming language, this chapter also describes the object-oriented model used by the language. An understanding of this model is necessary for a complete understanding of class and interface declarations.

5.1 Naming Conventions

The Java language has no requirements for choosing names, aside from the lexical requirements for identifiers stated in Identifiers. However, there are certain conventions that you should follow when choosing names; these conventions are the ones used by Sun in much of the Java API. Following these conventions makes your programs easier to read, as many programmers are already accustomed to reading programs that use them:

- If an identifier is logically made up of multiple words, the first letter of each word other than the first is uppercase and the rest of the letters are lowercase (e.g., `aSimpleExample`). Sun is consistent about following this convention.
- The first letter of the name of a class or interface is uppercase, while the first letter of all other names is lowercase. Sun is also consistent about following this convention.
- The names of final variables that are intended to represent symbolic constants are all uppercase; logical words contained in the name are separated by underscore characters (e.g., `MAX_LEGAL_VALUE`). Sun uses this convention quite often, but is not entirely consistent.
- Some Java programmers have adopted the additional convention of beginning the names of instance variables with an underscore (e.g., `_value`).
- Avoid the use of `$` in names to prevent confusion with compiler-generated names. Sun is consistent about following this convention.

6. Statements and Control Structures

Contents:

A statement is the construct used to control the flow of program execution in Java:

[Graphic: Figure from the text]

Statements are executed in sequence, unless a statement alters the flow of control. Statements usually correspond to executable code.

References Blocks; The break Statement; The continue Statement; The Empty Statement; Expression Statements; The if Statement; Iteration Statements; Labeled Statements; The return Statement; The switch Statement; The synchronized Statement; The throw Statement; The try Statement

6.1 Blocks

A block is a sequence of zero or more statements, local variable declarations, or local class declarations enclosed in curly braces:

[Graphic: Figure from the text]

The bodies of methods, constructors, static initializers, and instance initializers are blocks. A variable declaration in a block causes a local variable to be defined, while a class declaration in a block causes a local class to be defined. A block is itself a kind of statement, so a block can contain other blocks. Here is an example of a block:

```
{
    int tmp = x;
    x = y;
    y = tmp;
}
```

The statements in a block are executed in the sequence in which they occur, unless a statement that alters the sequence of execution is executed. If, as a result of such a statement, the Java compiler can determine that a statement will never be executed, the compiler is required to produce an error message about the unreachable statement.

The one exception to this rule allows `if` statements that have constant Boolean expressions. The compiler recognizes `if` statements that have constant Boolean expressions and does not generate code for the portion of the statement that can never be executed. This mechanism can be used for conditional compilation; it is similar to the C/C++ preprocessor features that are used for this purpose.

References Constant Expressions; Constructors; Instance Initializers; Local Classes; Local Variables; Methods; *Statement* 6; Static Initializers; The switch Statement

Local Variables

Local variables declared in a block exist only from their declaration to the end of the block. A local variable declaration cannot include any modifiers except the `final` modifier. In other words, a variable declaration in a block cannot include any of the following keywords: `public`, `protected`, `private`, `static`, `transient`, or `volatile`. The syntax that permits the use of the `final` modifier with local variables is new as of Java 1.1; the usage is not permitted with earlier versions of the language.

The syntax of a local variable declaration is:

[Graphic: Figure from the text]

A local variable declaration is really made up of two distinct things:

- A type, which can be either a primitive type or a reference type.
- Any number of identifiers that name variables. Each name can be followed by pairs of square brackets to indicate an array variable, as well as an optional initializer for the variable.

A local variable declared within a block that has an initializer is initialized when its declaration is executed. Within the body of a method or constructor, its formal parameters are treated as local variables. Formal parameters are initialized when a method is called. A local variable can also be declared in the header of a `for` statement.

The following are some examples of local variable declarations:

```
int x;
double[] k, m[];
```

References Variable initializers; *Expression* 4; Identifiers; Interface Variables; *Type* 3; The for Statement; Variables

Final local variables

If a local variable is declared with the `final` modifier, the variable is a named constant value. As such, it must be assigned an initial value. Any assignment to a `final` local variable, other than the one that provides its initial value, is a compile-time error. The initial value for a `final` local variable is typically provided by an initializer that is part of the variable's declaration. For example:

```
final int X = 4;
```

A `final` local variable that is not initialized in its declaration is called a *blank final*. A blank final must be assigned a value exactly once. The compiler uses flow analysis that takes `if` statements and iteration statements into account to ensure that a blank final is assigned a value exactly once. Thus, it is possible to have multiple assignments to a blank final, so long as exactly one of them can be executed. For example, here is an instance initializer that sets the value of a blank final:

```
{
    final int DAYS_IN_YEAR;
    if (isLeapYear(new Date()))
        DAYS_IN_YEAR = 366;
    else
        DAYS_IN_YEAR = 365;
    ...
}
```

Local variables that are declared `final` are not supported prior to Java 1.1.

References Instance Initializers; The do Statement; The for Statement; The if Statement; The while Statement; Variable modifiers

Local variable type

A local variable declaration must always specify the type of the variable. If the declaration of a local variable uses a primitive type, the variable contains a value of the specified primitive type. If the declaration uses a reference type, the variable contains a reference to the specified type of object.

The presence of square brackets in a variable declaration, after either the type or the variable name, indicates that the variable contains a reference to an array. For example:

```
int a[];        // a is an array of int
int[] b;        // b is also an array of int
```

It is also possible to declare a variable to contain an array of arrays, or more generally, arrays nested to any level. Each pair of square brackets in the declaration corresponds to a dimension of the array; it makes no difference whether the brackets appear after the type or the variable name. For example:

```
int[][][] d3;      // Each of these is an array of
int[][] f3[];      // arrays of arrays of integers
int[] g3[][];
int h3[][][];
int[] j3, k3[];    // An array and an array of arrays
```

References Array Types; Primitive Types; Reference Types

Local variable name

The identifier that follows the variable type is the name of the local variable. When a local variable definition is in effect, all occurrences of that name are taken to mean the local variable. If a local variable is declared with the same name as a class, an interface, or a field of the class in which the local variable is declared, the definition of the class, interface, or field is hidden. Fields that are hidden by a local variable can be referenced using the keyword `this`. For example:

```
class myClass {
    int value;
    void doit(int x) {
        int value;
        value = x*4;                // Set local variable
        this.value = value + 1;     // Set field variable
}
```

A block cannot have multiple local variables with the same name. This means that a local variable cannot be declared at a point in a block where a local variable with the same name is already defined. For example, consider the following code:

```
myMethod(char c){
    int j;          // Okay
    char c;         // Error
    int j;          // Error
    {
        int j;      // Error
    }
    {
        int x;      // Okay
    }
    {
        int x;      // Okay
    }
    int x;          // Okay
}
```

In the above example, the declaration of `c` as a local variable is an error because it occurs in a method that has a formal parameter with that name. The second declaration of `j` is an error because there is already a local variable defined with that name. The third declaration of `j` as a local variable is also an error for the same reason; the nested block sees all of the declarations that are visible in the enclosing block, including the declaration of `j` in the outer block.

The first declaration of `x` is fine because there is no previous declaration of `x` for it to conflict with. The second declaration of `x` is also fine because there is no previous declaration of `x` in the enclosing block for it to conflict with. The first declaration of `x` occurs in a nested block, so it is not visible in the enclosing block. The third declaration of `x` is also fine because the preceding declarations occurred in nested blocks; they are not visible in the enclosing block.

References Identifiers; this

Local variable initializers

A local variable declaration can contain an initializer. If the variable is of a non-array type, the expression in the initializer is evaluated and the variable is set to the result of the expression, as long as the result is assignment-compatible with the variable. If the variable is of an array type, the initializer must be an array initializer, as described in Variable initializers. If the variable is declared `final`, the initializer sets the value of the named constant.

A local variable declaration with an initializer is similar in effect to a local variable declaration without an initializer immediately followed by an assignment statement that sets the declared variable. Take the following example:

```
int a = 4;
```

This is equivalent to:

```
int a;
a = 4;
```

If a local variable has an initializer, the value of the variable is set to the value of the initializer when the declaration is executed.

Any attempt to access the value of a local variable before its value is set by an assignment statement or an initializer is treated as an error by the Java compiler. For example:

```
int foo(int x) {
    int a = x + 1;
    int b, c;
    if (a > 4)
        b = 3;
    a = a * c;        // Error: c not initialized
    a = b * 8 + a;    // Error: b might not be initialized
```

This example contains two errors. First, the compiler complains about the expression `a*c` because `c` is not initialized. The compiler also complains about the expression `b* 8+a` because the preceding assignment to `b` may not executed, depending on the value of `a`. If the compiler cannot guarantee that a local variable will be initialized, it generates an error message when the variable is used.

References Variable initializers; Assignment Operators

Local Classes

Local classes declared in a block exist only in the scope of that block. Local classes are not supported prior to Java 1.1 Here's the syntax of a local class declaration:

[Graphic: Figure from the text]

A local class can access local variables in the enclosing block that are declared `final`. A local class can also access instance variables of the enclosing class if they are not declared inside of a `static` method or static initializer.

There is an alternate syntax for a local class that allows an anonymous local class to be defined. This syntax is available as part of an allocation expression.

References Allocation Expressions; Anonymous classes; Local classes; Local Variables; Class Declarations; Variables

Local class modifiers

The keywords `abstract` and `final` can be used in the declaration of a local class. These modifiers have the following meanings:

`abstract`

> If a local class is declared `abstract`, no instances of the class may be created. A local class declared `abstract` may contain `abstract` methods. Classes not declared `abstract` may not contain `abstract` methods and must override any `abstract` methods they inherit with methods that are not `abstract`. Classes that implement an interface and are not declared `abstract` must contain or inherit methods that are not `abstract` that have the same name, have the same number of parameters, and have corresponding parameter types as the methods declared in the interfaces that the class implements.

`final`

> If a local class is declared `final`, it cannot be subclassed. In other words, it cannot appear in the `extends` clause of another class.

References Class Modifiers; Inner class modifiers

Local class members

The body of a local class cannot declare any `static` variables, `static` methods, `static` classes, or static initializers. Beyond those restrictions, the remainder of the declaration is the same as that for a top-level class declaration, which is described in Class Declarations.

7. Program Structure

Contents:

This chapter discusses the higher levels of program structure for Java programs. The two levels of organization discussed in this chapter are compilation units and packages. A *compilation unit* contains the source code for one or more classes or interfaces. A *package* is a collection of related compilation units.

This chapter also discusses the two most common top-level Java program architectures: applications and applets. An *application* is a stand-alone Java program that can be run directly from the command line (or other operating system environment). An *applet* is a Java program that must be run from within another program, such as a Web browser. In the future, applets will even be hosted by other environments, such as cellular phones and personal digital assistants.

7.1 Compilation Units

A compilation unit is the highest-level syntactic structure that Java recognizes:

[Graphic: Figure from the text]

Only one of the classes or interfaces declared in a compilation unit can be declared `public`.

A compilation unit usually corresponds to a single source code file. However, the Java language specification allows compilation units to be stored in a database. If compilation units are stored in a database, the limit of one `public` class or interface per compilation unit does not apply, as long as there is a way to extract the compilation units from the database and place them in individual files that contain no more than one `public` class or interface per file. This exception to the one `public` class or interface per compilation unit rule is useful if you are implementing a Java development environment.

Every compilation unit is part of exactly one package. That package is specified by the `package` directive that appears at the beginning of the compilation unit. If there is no `package` directive, the compilation unit is part of the default package.

References *ClassDeclaration* 5.4; Class Modifiers; The import Directive; Interface Declarations; Interface Modifiers; *PackageDirective* 7.2

8. Threads

Contents:

Threads provide a way for a Java program to do multiple tasks concurrently. A thread is essentially a flow of control in a program and is similar to the more familiar concept of a process. An operating system that can run more than one program at the same time uses processes to keep track of the various programs that it is running. However, processes generally do not share any state, while multiple threads within the same application share much of the same state. In particular, all of the threads in an application run in the same address space, sharing all resources except the stack. In concrete terms, this means that threads share field variables, but not local variables.

When multiple processes share a single processor, there are times when the operating system must stop the processor from running one process and start it running another process. The operating system must execute a sequence of events called a *context switch* to transfer control from one process to another. When a context switch occurs, the operating system has to save a lot of information for the process that is being paused and load the comparable information for the process being resumed. A context switch between two processes can require the execution of thousands of machine instructions. The Java virtual machine is responsible for handling context switches between threads in a Java program. Because threads share much of the same state, a context switch between two threads typically requires the execution of less than 100 machine instructions.

There are a number of situations where it makes sense to use threads in a Java program. Some programs must be able to engage in multiple activities and still be able to respond to additional input from the user. For example, a web browser should be able to respond to user input while fetching an image or playing a sound. Because threads can be suspended and resumed, they can make it easier to control multiple activities, even if the activities do not need to be concurrent. If a program models real world objects that display independent, autonomous behavior, it makes sense to use a separate thread for each object. Threads can also implement asynchronous methods, so that a calling method does not have to wait for the method it calls to complete before continuing with its own activity.

Java applets make considerable use of threads. For example, an animation is generally implemented with a separate thread. If an applet has to download extensive information, such as an image or a sound, to initialize itself, the initialization can take a long time. This initialization can be done in a separate thread to prevent the initialization from interfering with the display of the applet. If an applet needs to process messages from the network, that work generally is done in a separate thread so that the applet can continue painting itself on the screen and responding to mouse and keyboard events. In addition, if each message is processed separately, the applet uses a separate thread for each message.

For all of the reasons there are to use threads, there are also some compelling reasons not to use them. If a program uses inherently sequential logic, where one operation starts another operation and then must wait for the other operation to complete before continuing, one thread can implement the entire sequence. Using multiple threads in such a case results in a more complex program with no accompanying benefits. There is considerable overhead in creating and starting a thread, so if an operation involves only a few primitive statements, it is faster to handle it with a single thread. This can even be true when the operation is conceptually asynchronous. When multiple threads share objects, the objects must use synchronization mechanisms to coordinate thread access and maintain consistent state. Synchronization mechanisms add complexity to a program, can be difficult to tune for optimal performance, and can be a source of bugs.

8.1 Using Thread Objects

The `Thread` class in the `java.lang` package creates and controls threads in Java programs. The execution of Java code is always under the control of a `Thread` object. The `Thread` class provides a `static` method called `currentThread()` that provides a reference to the `Thread` object that controls the current thread of execution.

References Thread

Associating a Method with a Thread

The first thing you need to do to make a `Thread` object useful is to associate it with a method you want it to run. Java provides two ways of associating a method with a `Thread`:

- Declare a subclass of `Thread` that defines a `run()` method.

- Pass a reference to an object that implements the `Runnable` interface to a `Thread` constructor.

For example, if you need to load the contents of a URL as part of an applet's initialization, but the applet can provide other functionality before the content is loaded, you might want to load the content in a separate thread. Here is a class that does just that:

```
import java.net.URL;
class UrlData extends Thread   {
    private Object data;
    private URL url
    public UrlData(String urlName) throws MalformedURLException {
        url = new URL(urlName);
        start();
    }
    public void run(){
        try {
            data = url.getContent();
        } catch (java.io.IOException  e) {
        }
    }
    public Object getUrlData(){
        return data;
    }
}
```

The `UrlData` class is declared as a subclass of `Thread` so that it can get the contents of the URL in a separate thread. The constructor creates a `java.net.URL` object to fetch the contents of the URL, and then calls the `start()` method to start the thread. Once the thread is started, the constructor returns; it does not wait for the contents of the URL to be fetched. The `run()` method is executed after the thread is started; it does the real work of fetching the data. The `getUrlData()` method is an access method that returns the value of the `data` variable. The value of this variable is `null` until the contents of the URL have been fetched, at which time it contains a reference to the actual data.

Subclassing the `Thread` class is convenient when the method you want to run in a separate thread does not need to belong to a particular class. Sometimes, however, you need the method to be part of a particular class that is a subclass of a class other than `Thread`. Say, for example, you want a graphical object that is displayed in a window to alternate its background color between red and blue once a second. The object that implements this behavior needs to be a subclass of the `java.awt.Canvas` class. However, at the same time, you need a separate thread to alternate the color of the object once a second.

In this situation, you want to tell a `Thread` object to run code in another object that is not a subclass of the `Thread` class. You can accomplish this by passing a reference to an object that implements the `Runnable` interface to the constructor of the `Thread` class. The `Runnable` interface requires that an object has a `public` method called `run()` that takes no arguments. When a `Runnable` object is passed to the constructor of the `Thread` class, it creates a `Thread` object that calls the `Runnable` object's `run()` method when the thread is started. The following example shows part of the code that implements an object that alternates its background color between red and blue once a second:

```
class AutoColorChange extends java.awt.Canvas implements Runnable {
    private Thread myThread;
    AutoColorChange () {
        myThread = new Thread(this);
        myThread.start();
        ...
    }
    public void run() {
        while (true) {
            setBackground(java.awt.Color.red);
            repaint();
            try {
                myThread.sleep(1000);
            } catch (InterruptedException e) {}
            setBackground(java.awt.Color.blue);
            repaint();
            try {
                myThread.sleep(1000);
            } catch (InterruptedException e) {}
        }
    }
}
```

The `AutoChangeColor` class extends `java.awt.Canvas`, alternating the background color between red and blue once a second. The constructor creates a new `Thread` by passing the current object to the `Thread` constructor, which tells the `Thread` to call the `run()` method in the `AutoChangeColor` class. The constructor then starts the new thread by calling its `start()` method, so that the color change happens asynchronously of whatever else is going on. The class has an instance variable called `myThread` that contains a reference to the `Thread` object, so that can control the thread. The `run()` method takes care of changing the background color, using the `sleep()` method of the `Thread` class to temporarily suspend the thread and calling `repaint()` to redisplay the object after each color change.

References Runnable; Thread

Controlling a Thread

As shown in the previous section, you start a `Thread` by calling its `start()` method. Before the `start()` method is called, the `isAlive()` method of the `Thread` object always returns `false`. When the `start()` method is called, the `Thread` object becomes associated with a scheduled thread in the underlying environment. After the `start()` method has returned, the `isAlive()` method always returns `true`. The `Thread` is now scheduled to run until it dies, unless it is suspended or in another unrunnable state.

It is actually possible for `isAlive()` to return `true` before `start()` returns, but not before `start()` is called. This can happen because the `start()` method can return either before the started `Thread` begins to run or after it begins to run. In other words, the method that called `start()` and the new thread are now running concurrently. On a multiprocessor system, the `start()` method can even return at the same time the started `Thread` begins to run.

`Thread` objects have a parent-child relationship. The first thread created in a Java environment does not have a parent `Thread`. However, after the first `Thread` object is created, the `Thread` object that controls the thread used to create another `Thread` object is considered to be the parent of the newly created `Thread`. This parent-child relationship is used to supply some default values when a `Thread` object is created, but it has no further significance after a `Thread` has been created.

References Thread

Stopping a thread

A thread dies when one of the following things happens:

- The `run()` method called by the `Thread` returns.
- An exception is thrown that causes the `run()` method to be exited.
- The `stop()` method of the `Thread` is called.

The `stop()` method of the `Thread` class works by throwing a `ThreadDeath` object in the `run()` method of the thread. Normally, you should not catch `ThreadDeath` objects in a `try` statement. If you need to catch `ThreadDeath` objects to detect that a `Thread` is about to die, the `try` statement that catches `ThreadDeath` objects should rethrow them.

When an object (`ThreadDeath` or otherwise) is thrown out of the `run()` method for the `Thread`, the `uncaughtException()` method of the `ThreadGroup` for that `Thread` is called. If the thrown object is an instance of the `ThreadDeath` class, the thread dies, and the thrown object is ignored. Otherwise, if the thrown object is of any other class, `uncaughtException()` calls the thrown object's `printStackTrace()` method, the thread dies, and the thrown object is ignored. In either case, if there are other nondaemon threads running in the system, the current program continues to run.

References Errors; The try Statement; Thread; ThreadGroup

Interrupting a thread

In some situations, you need to kill a thread in a way that allows it to complete what it is currently doing before dying. For example, if a thread is in the middle of processing a transaction, you might want the transaction to complete before the thread dies. The `Thread` class provides support for this in the form of the `interrupt()` method.

There are a number of methods in the Java API, such as `wait()` and `join()`, that are declared as throwing an `InterruptedException`. Both of these methods temporarily suspend the execution of a thread. In Java 1.1, if a thread is waiting for one of these methods to return and another thread calls `interrupt()` on the waiting thread, the method that is waiting throws an `InterruptedException`.

The `interrupt()` method sets an internal flag in a `Thread` object. Before the `interrupt()` method is called, the `isInterrupted()` method of the `Thread` object always returns `false`. After the `interrupt()` method is called, `isInterrupted()` returns `true`.

Prior to version 1.1, the methods in the Java API that are declared as throwing an `InterruptedException` do not actually do so. However, the `isInterrupted()` method does return `True` if the thread has been interrupted. Thus, if the code in the `run()` method for a thread periodically calls `isInterrupted()`, the thread can respond to a call to `interrupt()` by shutting down in an orderly fashion.

References Other exceptions; Thread

Thread priority

One of the attributes that controls the behavior of a thread is its priority. Although Java does not guarantee much about how threads are scheduled, it does guarantee that a thread with a priority that is higher than that of another thread will be scheduled to run at least as often, and possibly more often, than the thread with the lower priority. The priority of a thread is set when the `Thread` object is created, by passing an argument to the constructor that creates the `Thread` object. If an explicit priority is not specified, the `Thread` inherits the priority of its parent `Thread` object.

You can query the priority of a `Thread` object by calling its `getPriority()` method. Similarly, you can set the priority of a `Thread` using its `setPriority()` method. The priority you specify must be greater than or equal to `Thread.MIN_PRIORITY` and less than or equal to `Thread.MAX_PRIORITY`.

Before actually setting the priority of a `Thread` object, the `setPriority()` method checks the maximum allowable priority for the `ThreadGroup` that contains the `Thread` by calling `getMaxPriority()` on the `ThreadGroup`. If the call to `setPriority()` tries to set the priority to a value that is higher than the maximum allowable priority for the `ThreadGroup`, the priority is instead set to the maximum priority. It is possible for the current priority of a `Thread` to be greater than the maximum allowable priority for the `ThreadGroup`. In this case, an attempt to raise the priority of the `Thread` results in its priority being lowered to the maximum priority.

References Thread; ThreadGroup

Daemon threads

A daemon thread is a thread that runs continuously to perform a service, without having any connection with the overall state of the program. For example, the thread that runs the garbage collector in Java is a daemon thread. The thread that processes mouse events for a Java program is also a daemon thread. In general, threads that run application code are not daemon threads, and threads that run system code are daemon threads. If a thread dies and there are no other threads except daemon threads alive, the Java virtual machine stops.

A `Thread` object has a `boolean` attribute that specifies whether or not a thread is a daemon thread. The daemon attribute of a thread is set when the `Thread` object is created, by passing an argument to the constructor that creates the `Thread` object. If the daemon attribute is not explicitly specified, the `Thread` inherits the daemon attribute of its parent `Thread` object.

The daemon attribute is queried using the `isDaemon()` method; it is set using the `setDaemon()` method.

References Thread

Yielding

When a thread has nothing to do, it can call the `yield()` method of its `Thread` object. This method tells the scheduler to run a different thread. The value of calling `yield()` depends largely on whether the scheduling mechanism for the platform on which the program is running is preemptive or nonpreemptive.

By choosing a maximum length of time a thread can continuously, a *preemptive* scheduling mechanism guarantees that no single thread uses more than its fair share of the processor. If a thread runs for that amount of time without yielding control to another thread, the scheduler preempts the thread and causes it to stop running so that another thread can run.

A *nonpreemptive* scheduling mechanism cannot preempt threads. A nonpreemptive scheduler relies on the individual threads to yield control of the processor frequently, so that it can provide reasonable performance. A thread explicitly yields control by calling the `Thread` object's `yield()` method. More often, however, a thread implicitly yields control when it is forced to wait for something to happen elsewhere.

Calling a Thread object's yield() method during a lengthy computation can be quite valuable on a platform that uses a nonpreemptive scheduling mechanism, as it allows other threads to run. Otherwise, the lengthy computation can prevent other threads from running. On a platform that uses a preemptive scheduling mechanism, calling yield() does not usually make any noticeable difference in the responsiveness of threads.

Regardless of the scheduling algorithm that is being used, you should not make any assumptions about when a thread will be scheduled to run again after it has called yield(). If you want to prevent a thread from being scheduled to run until a specified amount of time has elapsed, you should call the sleep() method of the Thread object. The sleep() method takes an argument that specifies a minimum number of milliseconds that must elapse before the thread can be scheduled to run again.

References Thread

Controlling groups of threads

Sometimes it is necessary to control multiple threads at the same time. Java provides the ThreadGroup class for this purpose. Every Thread object belongs to a ThreadGroup object. By passing an argument to the constructor that creates the Thread object, the ThreadGroup of a thread can be set when the Thread object is created. If an explicit ThreadGroup is not specified, the Thread belongs to the same ThreadGroup as its parent Thread object.

9. Exception Handling

Contents:

Exception handling is a mechanism that allows Java programs to handle various exceptional conditions, such as semantic violations of the language and program-defined errors, in a robust way. When an exceptional condition occurs, an *exception* is thrown. If the Java virtual machine or run-time environment detects a semantic violation, the virtual machine or run-time environment implicitly throws an exception. Alternately, a program can throw an exception explicitly using the `throw` statement. After an exception is thrown, control is transferred from the current point of execution to an appropriate `catch` clause of an enclosing `try` statement. The `catch` clause is called an exception handler because it handles the exception by taking whatever actions are necessary to recover from it.

9.1 Handling Exceptions

The `try` statement provides Java's exception-handling mechanism. A `try` statement contains a block of code to be executed. Putting a block in a `try` statement indicates that any exceptions or other abnormal exits in the block are going to be handled appropriately. A `try` statement can have any number of optional `catch` clauses that act as exception handlers for the `try` block. A `try` statement can also have a `finally` clause. The `finally` block is always executed before control leaves the `try` statement; it cleans up after the `try` block. Note that a `try` statement must have either a `catch` clause or a `finally` clause.

Here is an example of a `try` statement that includes a `catch` clause and a `finally` clause:

```
try {
    out.write(b);
} catch (IOException e) {
    System.out.println("Output Error");
} finally {
    out.close();
}
```

If `out.write()` throws an `IOException`, the exception is caught by the `catch` clause. Regardless of whether `out.write()` returns normally or throws an exception, the `finally` block is executed, which ensures that `out.close()` is always called.

A `try` statement executes the block that follows the keyword `try`. If an exception is thrown from within the `try` block and the `try` statement has any `catch` clauses, those clauses are searched, in order, for one that can handle the exception. If a `catch` clause handles an exception, that `catch` block is executed.

However, if the `try` statement does not have any `catch` clauses that can handle the exception (or does not have any `catch` clauses at all), the exception propagates up through enclosing statements in the current method. If the current method does not contain a `try` statement that can handle the exception, the exception propagates up to the invoking method. If this method does not contain an appropriate `try` statement, the exception propagates up again, and so on. Finally, if no `try` statement is found to handle the exception, the currently running thread terminates.

A `catch` clause is declared with a parameter that specifies the type of exception it can handle. The parameter in a `catch` clause must be of type `Throwable` or one of its subclasses. When an exception occurs, the `catch` clauses are searched for the first one with a parameter that matches the type of the exception thrown or is a superclass of the thrown exception. When the appropriate `catch` block is executed, the actual exception object is passed as an argument to the `catch` block. The code within a `catch` block should do whatever is necessary to handle the exceptional condition.

The `finally` clause of a `try` statement is always executed, no matter how control leaves the `try` statement. Thus it is a good place to handle clean-up operations, such as closing files, freeing resources, and closing network connections.

Compiler
Double
Float
Integer
Long
Math

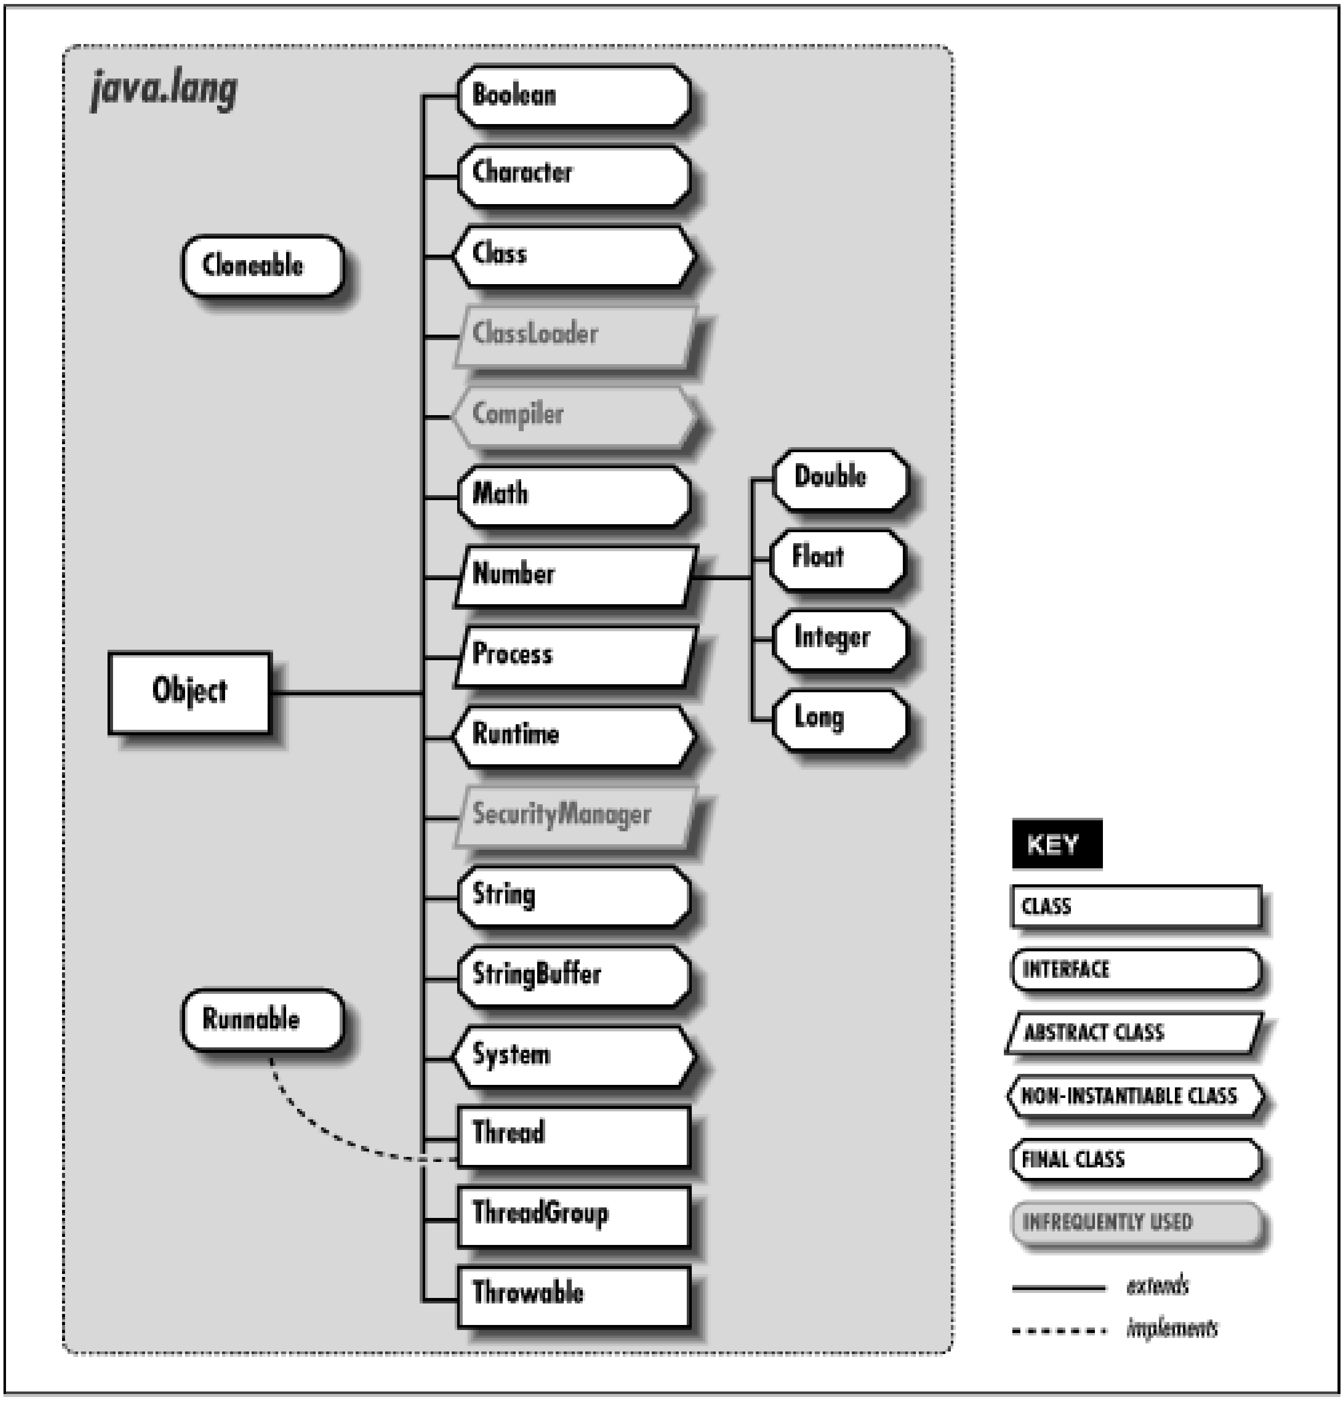
The package `java.lang` contains classes and interfaces that are essential to the Java language. These include:

- `Object`, the ultimate superclass of all classes in Java
- `Thread`, the class that controls each thread in a multithreaded program
- `Throwable`, the superclass of all error and exception classes in Java
- Classes that encapsulate the primitive data types in Java
- Classes for accessing system resources and other low-level entities
- `Math`, a class that provides standard mathematical methods
- `String`, the class that is used to represent strings

Because the classes in the `java.lang` package are so essential, the `java.lang` package is implicitly imported by every Java source file. In other words, you can refer to all of the classes and interfaces in `java.lang` using their simple names.

Figure 10.1 shows the class hierarchy for the `java.lang` package.

Figure 10.1: The java.lang package



Boolean

Name

Boolean

Synopsis

Class Name:

`java.lang.Boolean`

Superclass:

`java.lang.Object`

Immediate Subclasses:

None

Interfaces Implemented:

`java.io.Serializable`

Availability:

JDK 1.0 or later

Description

The `Boolean` class provides an object wrapper for a `boolean` value. This is useful when you need to treat a `boolean` value as an object. For example, there are a number of utility methods that take a reference to an `Object` as one of their arguments. You cannot specify a `boolean` value for one of these arguments, but you can provide a reference to a `Boolean` object that encapsulates the `boolean` value. Furthermore, as of JDK 1.1, the `Boolean` class is necessary to support the Reflection API and class literals.

Class Summary

```
public final class java.lang.Boolean {
    // Constants
    public final static Boolean FALSE;
    public final static Boolean TRUE;
    public final static Class TYPE;                    // New in 1.1
    // Constructors
    public Boolean(boolean value);
    public Boolean(String s);
    // Class Methods
    public static boolean getBoolean(String name);
    public static Boolean valueOf(String s);
    // Instance Methods
    public boolean booleanValue();
    public boolean equals(Object obj);
    public int hashCode();
    public String toString();
}
```

Constants

TRUE

public static final Boolean TRUE

Description

> A constant `Boolean` object that has the value `true`.

FALSE

public static final Boolean FALSE

Description

> A constant `Boolean` object that has the value `false`.

TYPE

`public static final Class TYPE`

Availability

New as of JDK 1.1

Description

The `Class` object that represents the type `boolean`. It is always true that `Boolean.TYPE == boolean.class`.

Constructors

Boolean

`public Boolean(boolean value)`

Parameters

`value`

The `boolean` value to be made into a `Boolean` object.

Description

Constructs a `Boolean` object with the given value.

`public Boolean(String s)`

Parameters

`s`

The string to be made into a `Boolean` object.

Description

Constructs a `Boolean` object with the value specified by the given string. If the string equals `'true'` (ignoring case), the value of the object is `true`; otherwise it is `false`.

Class Methods

getBoolean

`public static boolean getBoolean(String name)`

Parameters

`name`

The name of a system property.

Returns

The `boolean` value of the system property.

Description

This methods retrieves the `boolean` value of a named system property.

valueOf

`public static Boolean valueOf(String s)`

Parameters

`s`

The string to be made into a `Boolean` object.

Returns

A `Boolean` object with the value specified by the given string.

Description

This method returns a `Boolean` object with the value `true` if the string equals `"true"` (ignoring case); otherwise the value of the object is `false`.

Instance Methods

booleanValue

`public boolean booleanValue()`

Returns

> The `boolean` value contained by the object.

equals

`public boolean equals(Object obj)`

Parameters

> `obj`
>
> > The object to be compared with this object.

Returns

> `true` if the objects are equal; `false` if they are not.

Overrides

> `Object.equals()`

Description

> This method returns `true` if `obj` is an instance of `Boolean`, and it contains the same value as the object this method is associated with.

hashCode

`public int hashCode()`

Returns

A hashcode based on the boolean value of the object.

Overrides

Object.hashCode()

toString

public String toString()

Returns

"true" if the value of the object is true; "false" otherwise.

Overrides

Object.toString()

Description

This method returns a string representation of the Boolean object.

Inherited Methods

Method	Inherited From	Method	Inherited From
clone()	Object	finalize()	Object
getClass()	Object	notify()	Object
notifyAll()	Object	wait()	Object
wait(long)	Object	wait(long, int)	Object

6.5 Reading Applet Parameters

Example 6.4 shows an extension to our `Scribble` applet. The `ColorScribble` class is a subclass of `Scribble` that adds the ability to scribble in a configurable foreground color over a configurable background color. (The `ColorScribble` applet looks a lot like the `Scribble` applet of Figure 6.3 and is not pictured here.)

`ColorScribble` has an `init()` method that reads the value of two "applet parameters" that can be optionally specified with the `<PARAM>` tag in the applet's HTML file. The returned string values are converted to colors and specified as the default foreground and background colors for the applet. Note that the `init()` method invokes its superclass's `init()` method, just in case a future version of `Scribble` defines that method to perform initialization.

This example also introduces the `getAppletInfo()` and `getParameterInfo()` methods. These methods provide textual information about the applet (its author, its version, its copyright, etc.) and the parameters that it can accept (the parameter names, their types, and their meanings). An applet should generally define these methods, although the current generation of Web browsers do not actually ever make use of them. (The `appletviewer` application in the JDK does call these methods, however.)

Example 6.4: Reading Applet Parameters

```
import java.applet.*;
import java.awt.*;
public class ColorScribble extends Scribble {
  // Read in two color parameters and set the colors.
  public void init() {
    super.init();
    Color foreground = getColorParameter("foreground");
    Color background = getColorParameter("background");
    if (foreground != null) this.setForeground(foreground);
    if (background != null) this.setBackground(background);
  }
  // Read the specified parameter.  Interpret it as a hexadecimal
  // number of the form RRGGBB and convert it to a color.
  protected Color getColorParameter(String name) {
    String value = this.getParameter(name);
    try { return new Color(Integer.parseInt(value, 16)); }
    catch (Exception e) { return null; }
  }
  // Return information suitable for display in an About dialog box.
  public String getAppletInfo() {
    return "ColorScribble v. 0.02.  Written by David Flanagan.";
  }
  // Return info about the supported parameters.  Web browsers and applet
  // viewers should display this information, and may also allow users to
  // set the parameter values.
  public String[][] getParameterInfo() { return info; }
  // Here's the information that getParameterInfo() returns.
  // It is an array of arrays of strings describing each parameter.
  // Format: parameter name, parameter type, parameter description
  private String[][] info = {
    {"foreground", "hexadecimal color value", "foreground color"},
    {"background", "hexadecimal color value", "background color"}
  };
}
```

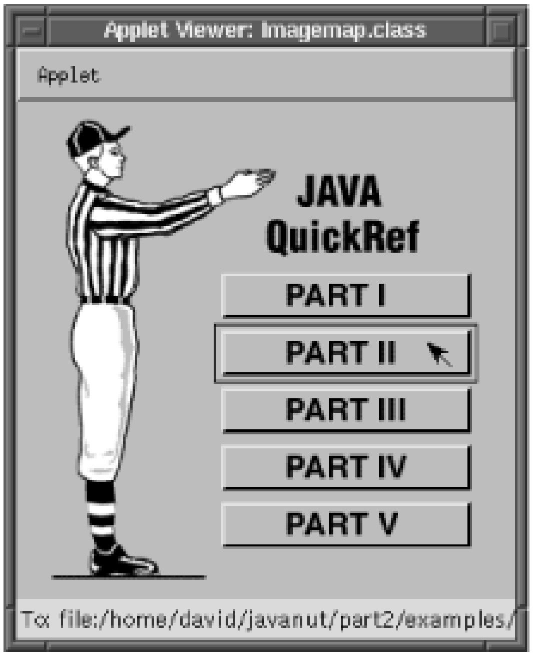
The following HTML fragment references the applet, and demonstrates how parameter values can be set with the <PARAM> tag:

```
<APPLET code="ColorScribble.class" width=300 height=300>
<PARAM name="foreground" value="0000FF">
<PARAM name="background" value="FFCCCC">
</APPLET>
```

6.6 Images and Sounds

Example 6.5 shows a Java applet that implements a simple client-side imagemap, which has the capability to highlight the "hot spots" in the image and play a sound clip when the user clicks on the image. Figure 6.4 shows what this applet might look like, when configured with an appropriate image.

Figure 6.4: An imagemap applet



Applet Viewer: Imagemap.class
Applet
JAVA
QuickRef
PART I
PART II
PART III
PART IV
PART V
To: file:/home/david/javanut/part2/examples/

This applet demonstrates quite a few important applet techniques:

- `getParameter()` looks up the name of the image to display and the audio clip to play when the user clicks, and it also reads a list of rectangles and URLs that define the hot spots and hyperlinks of the imagemap.
- The `getImage()` and `getDocumentBase()` methods load the image in the `init()` method, and `Graphics.drawImage()` displays the image in the `paint()` method.
- `getAudioClip()` loads a sound file in the `init()` method, and `AudioClip.play()` plays the sound in the `mousePressed()` method.

- Events are handled by an "event listener" object, which is defined by an inner class (see Chapter 5, *Inner Classes and Other New Language Features*). This is an example of the Java 1.1 event handling model (see Chapter 7, *Events*). Therefore, this applet only runs in Web browsers that support Java 1.1.

- The `showStatus()` method displays the destination URL when the user presses the mouse button over a hot spot, while the `AppletContext.showDocument()` method makes the browser display that URL when the user releases the mouse button.

- The applet uses "XOR mode" of the `Graphics` class to highlight an area of the image in a way that can be easily "un-highlighted" by redrawing.

- The individual hot spots are represented by instances of a nested top-level class. The `java.util.Vector` class stores the list of hot spot objects, and `java.util.StringTokenizer` parses the descriptions of those hot spots.

The following HTML fragment shows an example of the properties read by this applet:

```
<APPLET code="Soundmap.class" width=288 height=288>
<PARAM name="image" value="image.gif">
<PARAM name="sound" value="sound.au">
<PARAM name="rect0" value="114,95,151,33,#part1">
<PARAM name="rect1" value="114,128,151,33,#part2">
<PARAM name="rect2" value="114,161,151,33,#part3">
<PARAM name="rect3" value="114,194,151,33,#part4">
<PARAM name="rect4" value="114,227,151,33,#part5">
</APPLET>
```

Example 6.5: An Imagemap Applet

 * Note the use of a nested top-level class for neatness.
 */
static class ImagemapRectangle extends Rectangle {
  URL url;
  public ImagemapRectangle(int x, int y, int w, int h, URL url) {
    super(x, y, w, h);
```

```
      this.url = url;
    }
  }
}
```

6.7 JAR Files

The Soundmap applet defined in the previous section requires five files to operate: the class file for the applet itself, the class files for the two nested classes it contains, the image file, and the sound clip file. It can be loaded using an <APPLET> tag like this:

```
<APPLET code="Soundmap.class" width=288 height=288>
   ...
</APPLET>
```

When the applet is loaded in this manner, however, each of the five files is transferred in uncompressed form using a separate HTML request. As you might imagine, this is quite inefficient.

In Java 1.1, you can instead combine the five files into a single JAR (Java ARchive) file. This single, compressed file (it is a ZIP file) can be transferred from Web server to browser much more efficiently. To create a JAR file, use the *jar* tool, which has a syntax reminiscent of the UNIX *tar* command:

```
% jar cf soundmap.jar *.class image.gif sound.au
```

This command creates a new file, *soundmap.jar*, that contains all the *.class* files in the current directory, and also contains the files *image.gif* and *sound.au*. *jar* can also be used to list and extract the contents of a JAR file. See Chapter 16, *JDK Tools* for complete documentation.

To use a JAR file, you specify it as the value of the archive attribute of the <APPLET> tag:

```
<APPLET archive="soundmap.jar" code="Soundmap.class" width=288 height=288>
   ...
</APPLET>
```

Note that the archive attribute does not replace the code attribute. archive specifies where to look for files, but code is still required to tell the browser which of the files in the archive is the applet class file to be executed. The archive attribute may actually specify a comma-separated list of JAR files. The Web browser or applet viewer searches these archives for any files the applet requires. If a file is not found in an archive, however, the browser falls back upon its old behavior and attempts to load the file from the Web server using a new HTTP request.

7. Events

Contents:

The heart of any applet or graphical user interface is the event processing code. Graphical applications are event-driven: they do nothing until the user moves the mouse or clicks a button or types a key. An event-driven program is structured around its event-processing model, so a solid understanding of event handling mechanisms is crucial for good programming.

Unfortunately, the Java event handling model has changed between Java 1.0 and Java 1.1. The Java 1.0 model is a simple one, well suited to writing basic applets. It has a number of shortcomings, however, and does not scale well to complicated interfaces. Although the 1.0 event model is deprecated in Java 1.1, you'll still need to use it for any applets that you want to run on Web browsers based on Java 1.0. The Java 1.1 event model solves many of the shortcomings of the 1.0 model it replaces, but would be quite cumbersome to use if it were not for the new inner class features also introduced in Java 1.1. This chapter covers both event models and provides examples of each.

7.1 The Java 1.0 Event Model

In Java 1.0, all events are represented by the `Event` class. This class has a number of instance variables that describe the event. One of these variables, `id`, specifies the type of the event. `Event` defines a number of constants that are the possible values for the `id` field. The `target` field specifies the object (typically a `Component`) that generated the event, or on which the event occurred (i.e., the source of the event). The other fields may or may not be used, depending on the type of the event. For example, the `x` and `y` fields are defined when `id` is `BUTTON_EVENT`, but not when it is `ACTION_EVENT`. The `arg` field can provide additional type-dependent data.

Java 1.0 events are dispatched first to the `handleEvent()` method of the `Component` on which they occurred. The default implementation of this method checks the `id` field of the `Event` object and dispatches the most commonly used types of events to various type-specific methods, listed in Table 7.1.

Table 7.1: Java 1.0 Event Processing Methods of Component

`action()`	`lostFocus()`	`mouseExit()`
`gotFocus()`	`mouseDown()`	`mouseMove()`
`keyDown()`	`mouseDrag()`	`mouseUp()`
`keyUp()`	`mouseEnter()`	

The methods listed in Table 7.1 are defined by the `Component` class. One of the primary characteristics of the Java 1.0 event model is that you must override these methods in order to process events. This means that you must create a subclass to define custom event-handling behavior, which is exactly what we do when we write an applet, for example. Notice, however, that not all of the event types are dispatched by `handleEvent()` to more specific methods. So, if you are interested in `LIST_SELECT` or `WINDOW_ICONIFY` events, for example, you have to override `handleEvent()` itself, rather than one of the more specific methods. If you do this, you should usually invoke `super.handleEvent()` to continue dispatching events of other types in the default way.

The `handleEvent()` method, and all of the type-specific methods, return `boolean` values. If an event-handling method returns `false`, as they all do by default, it means that the event was not handled, so it should be passed to the container of the current component to see if that container is interested in processing it. If a method returns `true`, on the other hand, it is a signal that the event *has* been handled and no further processing is needed.

The fact that unhandled events are passed up the containment hierarchy is important. It means that we can override the `action()` method (for example) in an applet in order to handle the `ACTION_EVENT` events that are generated by the buttons within the applet. If they were not propagated up as they are, we would have to create a custom subclass of `Button` for every button we wanted to add to an interface!

In programs that use the Java 1.0 event model, it is typical to handle events at the top-level component. In an applet, for example, you override the `handleEvent()` method, or some of the other type-specific methods, of the `Applet` subclass you create. Or, in a stand-alone program that creates its own window, you subclass `Frame` to provide definitions of the event-handling methods. When a program displays a dialog box, it subclasses `Dialog` to define the methods. With complex interfaces, the event-handling methods of the containers at the top of the hierarchy can become long and somewhat convoluted, so you need to be careful when writing them.

Components and Their Events

In the Java 1.0 model, there is no defacto way to know what types of events are generated by what GUI components. You simply have to look this information up in the documentation. Additionally, different components use different fields of the `Event` object, and pass different values in the `arg` field of that object. Table 7.2 lists each of the AWT components, and for each one, lists the type of events it generates. The first column of the table specifies both the type of the component and the type of the event. The event type is the constant stored in the `id` field of the `Event`.

The second through sixth columns indicate whether the `when` (timestamp), `x` (mouse x coordinate), `y` (mouse y coordinate), `key` (the key that was pressed), and `modifiers` (modifier keys that were down) fields are set for a given event. If a dot appears in this column, the event sets a value for the corresponding field. The seventh column explains what occurred to trigger the event, and what the value of the `arg` field of the `Event` object is.

Events listed for the `Component` component type apply to all `java.awt Component` subclasses. The events listed for the `Window` component type also apply to the `Window` subclasses, `Dialog` and `Frame`.

Table 7.2: AWT Components and the Java 1.0 Events They Generate

Component	**when**	**x**	**y**	**key**	**mods**	**Event Meaning**
Event Type (`id`)						**`arg` (Type: value)**
`Button`						User clicked on the button
`ACTION_EVENT`						`String`: the button label
`Checkbox`						User clicked on checkbox
`ACTION_EVENT`						`Boolean`: new checkbox state
`Choice`						User selected an item
`ACTION_EVENT`						`String`: label of selected item
`Component`						Got input focus
`GOT_FOCUS`						*unused*
`Component`	*	*	*	*	*	User pressed a function key
`KEY_ACTION`						*unused*--`key` contains key
						constant

						key value
Component						Lost input focus
LOST_FOCUS						*unused*
Component	*	*	*			Mouse entered the Component
MOUSE_ENTER						*unused*
Component	*	*	*			Mouse left the Component
MOUSE_EXIT						*unused*
Component	*	*	*		*	User pressed mouse button
MOUSE_DOWN						*unused*
Component	*	*	*		*	User released mouse button
MOUSE_UP						*unused*
Component	*	*	*		*	User moved mouse
MOUSE_MOVE						*unused*
Component	*	*	*		*	User dragged mouse
MOUSE_DRAG						*unused*
List						User double-clicked on an item
ACTION_EVENT						String: label of activated item
List						User selected an item
LIST_SELECT						Integer: index of selected item
List						User deselected an item
LIST_DESELECT						Integer: index of deselected item
MenuItem						User selected an item
ACTION_EVENT						String: label of selected item

Scrollbar						User requested scroll
SCROLL_LINE_UP						Integer: position to scroll to
Scrollbar						User requested scroll
SCROLL_LINE_DOWN						Integer: position to scroll to
Scrollbar						User requested scroll
SCROLL_PAGE_UP						Integer: position to scroll to
Scrollbar						User requested scroll
SCROLL_PAGE_DOWN						Integer: position to scroll to
Scrollbar						User requested scroll
SCROLL_ABSOLUTE						Integer: position to scroll to
TextField						User struck <Return>
ACTION_EVENT						String: user's input text
Window						Window was destroyed
WINDOW_DESTROY						*unused*
Window						Window was iconified
WINDOW_ICONIFY						*unused*
Window						Window was deiconified
WINDOW_DEICONIFY						*unused*
Window		*	*			Window was moved
WINDOW_MOVED						*unused*

Key and Modifier Constants

The java.awt.Event class contains the field key, which is filled in when a keyboard event has occurred, and the field modifiers, which list the keyboard modifier keys currently in effect for key and mouse events.

Four modifier constants are defined by the java.awt.Event class; they are listed in Table 7.3. They are mask values that are ORed into the modifiers field. You can test for them using AND. You can also check a given event for the first three of the modifiers with the Event methods shiftDown(), controlDown(), and metaDown().

Table 7.3: Java Keyboard Modifiers

Modifier Constant	**Meaning**

`Event.SHIFT_MASK`	SHIFT key is held down (or CAPS LOCK on)
`Event.CTRL_MASK`	CONTROL key is held down
`Event.META_MASK`	META key is held down
`Event.ALT_MASK`	ALT key is held down

When a `KEY_PRESS` or `KEY_RELEASE` event occurs, it means that the user pressed a key that is a normal printing character, a control character, or a non-printing character with a standard ASCII value--one of RETURN (ASCII 10 or '`\n`'), TAB (ASCII 9 or '`\t`'), ESCAPE (ASCII 27), BACKSPACE (ASCII 8), or DELETE (ASCII 127). In this case, the value of the `key` field in the event is simply the ASCII value of the key that was pressed or released.

When a `KEY_ACTION` or `KEY_ACTION_RELEASE` event occurs, it means that the user pressed some sort of function key, one which does not have an ASCII representation.

`java.awt.Event` defines constants for each of these function keys, which are listed in Table 7.4.

Table 7.4: Java Function Key Constants

Key Constant	**Meaning**
`Event.HOME`	HOME key
`Event.END`	END key
`Event.PGUP`	PAGE UP key
`Event.PGDN`	PAGE DOWN key
`Event.UP`	UP arrow key
`Event.DOWN`	DOWN arrow key
`Event.LEFT`	LEFT arrow key
`Event.RIGHT`	RIGHT arrow key
`Event.F1 to Event.F12`	Function keys 1 through 12

Mouse Buttons

In order to maintain platform independence, Java only recognizes a single mouse button--the `Event` class does not have any kind of `mouseButton` field to indicate which button has been pressed on a multi-button mouse.

On platforms that support two- or three-button mouses, the right and center buttons generate mouse down, mouse drag, and mouse up events as if the user were holding down modifier keys, as shown in

Table 7.5.

Table 7.5: Mouse Button Modifiers

Mouse Button	Flag Set in Event.modifiers Field
Left button	*none*
Right button	`Event.META_MASK`
Middle button	`Event.ALT_MASK`

Using keyboard modifiers to indicate the mouse button that has been pressed maintains compatibility with platforms that only have one-button mouses, but still allows programs to use the right and middle buttons on platforms that support them. Suppose, for example, you want to write a program that allows the user to draw lines with the mouse using two different colors. You might draw in the primary color if there are no modifier flags set, and draw in the secondary color when the `META_MASK` modifier is set. In this way, users with a two- or three-button mouse can simply use the left and right mouse buttons to draw in the two colors; and users with a one-button mouse can use the META key, in conjunction with the mouse, to draw in the secondary color.

6.8 Applet Security Restrictions

Applets loaded over the network are usually considered to be untrusted code. (The exception, as we'll see in the next section, is when the applet bears the digital signature of an entity that you've specified you trust.) The only way to be sure that an untrusted applet cannot perform any malicious actions (e.g., deleting your files, sending out fake email that looks like it came from you, using your computer as a remote file server) is to run it in a tightly controlled environment. For this reason, Web browsers and applet viewers carefully restrict what an applet is allowed to do. When designing an applet, you must be aware of a fairly long list of things that an applet is not allowed to do. The following list details the security restrictions imposed by the *appletviewer* application in Java 1.1. Different Web browsers and applet viewers may impose somewhat different restrictions on applets, and some (including *appletviewer*) may allow the user to relax or customize the restrictions. In general, however, you should assume that your applets will be restricted in the following ways:

- Untrusted code cannot read from or write to the local filesystem. This means that untrusted code cannot:
    - Read files.
    - List directories.
    - Check for the existence of files.
    - Obtain the size or modification date of files.
    - Obtain the read and write permissions of a file.
    - Test whether a filename is a file or directory.
    - Write files.

    - Delete files.

    - Create directories.

    - Rename files.

    - Read or write from `FileDescriptor` objects.

- *appletviewer* allows a system administrator to set properties that allow applets to read and write files within a specified list of directories.

  Untrusted code cannot perform networking operations, except in certain restricted ways. Untrusted code cannot:

    - Create a network connection to any computer other than the one from which the code was itself loaded.

    - Listen for network connections on any of the privileged ports with numbers less than or equal to 1024.

    - Accept network connections on ports less than or equal to 1024 or from any host other than the one from which the code itself was loaded.

    - Use multicast sockets.

    - Create or register a `SocketImplFactory`, `URLStreamHandlerFactory`, or `ContentHandlerFactory`.

- *appletviewer* uses the "host-of-origin" policy described above by default, but can also be configured to disallow all networking or to allow all networking.

  Untrusted code cannot make use of certain system facilities. It cannot:

    - Exit the Java interpreter by calling `System.exit()` or `Runtime.exit()`.

    - Spawn new processes by calling any of the `Runtime.exec()` methods.

    - Dynamically load native code libraries with the `load()` or `loadLibrary()` methods of `Runtime` or `System`.

- Untrusted code cannot make use of certain AWT facilities. One major restriction is that all windows created by untrusted code will display a prominent visual indication that they have been created by untrusted code and are "insecure." This is to prevent untrusted code from spoofing the on-screen appearance of trusted code. Additionally, untrusted code cannot:

  - Initiate a print job.
  - Access the system clipboard.
  - Access the system event queue.

- Untrusted code has restricted access to system properties. It cannot call `System.getProperties()`, and so cannot modify or insert properties into the system properties list. It can call `System.getProperty()` to read individual properties, but can only read system properties to which it has been explicitly granted access. By default, *appletviewer* grants access to only the following ten properties. Note that `user.home` and `user.dir` are excluded:

  - `java.version`
  - `java.class.version`
  - `java.vendor`
  - `java.vendor.url`
  - `os.name`
  - `os.version`
  - `os.arch`
  - `file.separator`
  - `path.separator`
  - `line.separator`

- Untrusted code cannot create or access threads or thread groups outside of the thread group in which the untrusted code is running.

- Untrusted code has restrictions on the classes it can load and define. It cannot:

    - Explicitly load classes from the `sun.*` packages.
    - Define classes in any of the `java.*` or `sun.*` packages.
    - Create a `ClassLoader` object or call any `ClassLoader` methods.

- Untrusted code cannot use the `java.lang.Class` reflection methods to obtain information about non-public members of a class, unless the class was loaded from the same host as the untrusted code.
- Untrusted code has restrictions on its use of the `java.security` package. It cannot:
    - Manipulate security identities in any way.
    - Set or read security properties.
    - List, lookup, insert, or remove security providers.
    - Finally, to prevent untrusted code from circumventing all of these restrictions, it is not allowed to create or register a `SecurityManager` object.

Local Applet Restrictions

When an applet is loaded from the local file system, instead of through a network protocol, Web browsers and applet viewers may relax some, or even many, of the above restrictions. The reason for this is that local applets are assumed to be more trustworthy than anonymous applets from the network.

Intermediate applet security policies are also possible. For example, an applet viewer could be written that would place fewer restrictions on applets loaded from an internal corporate network than on those loaded from the Internet.

Applet Security Implementation

Implementing the security restrictions described above is the responsibility of the `java.lang.SecurityManager` class. This class defines a number of methods that the system calls to check whether a certain operation (such as reading a file) is permitted in the current environment. Applet viewers create a subclass of `SecurityManager` to implement a particular security policy. A security policy is put in place by instantiating a `SecurityManager` object and registering it with `System.setSecurityManager()`. (One of the obvious security restrictions that must be enforced is that untrusted code may not register its own `SecurityManager` object!)

Loading Classes Securely

Another component of Java security is the way Java classes are loaded over the network. The `java.lang.ClassLoader` class defines how this is done. Applet viewers and Web browsers create subclasses of this class that implement security policies and define how class files are loaded via various protocols.

One important function of the class loader is to ensure that loaded classes reside in a separate namespace than classes loaded from the local system. This prevents naming conflicts, and also prevents a malicious applet from replacing standard Java classes with its own versions.

Byte-Code Verification

Another important function of the class loader is to ensure that all untrusted Java code (generally code loaded over the network) is passed through the Java byte-code verification process. This process ensures that the loaded code does not violate Java namespace restrictions or type conversion restrictions. It also checks that the code:

- Is valid Java Virtual Machine code.
- Does not overflow or underflow the stack.
- Does not use registers incorrectly.
- Does not convert data types illegally.

The purpose of these checks is to verify that the loaded code cannot forge pointers or do memory arithmetic, which could give it access to the underlying machine. The checks also ensure that the code cannot crash the Java interpreter or leave it in an undefined state, which might allow malicious code to take advantage of security flaws that could exist in some interpreter implementations. Essentially, the byte-code verification process protects against code from an "untrusted" Java compiler.

Denial of Service Attacks

The one "security hole" that remains when running an untrusted applet is that the applet can perform a "denial of service attack" on your computer. For example, it could frivolously allocate lots of memory, run many threads, or download lots of data. This sort of attack consumes system resources and can slow your computer (or your network connection) considerably. While this sort of attack by an applet is inconvenient, fortunately it cannot usually do any significant damage.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

16. JDK Tools

Contents:

appletviewer

Name

appletviewer---The Java Applet Viewer

Availability

JDK 1.0 and later.

Synopsis

```
appletviewer [-debug]  [-Jjavaoption] [-encoding enc] url|file...
```

Description

appletviewer reads or downloads one or more HTML documents specified by filename or URL on the command line. It reads or downloads all the applets referenced in each document and displays them, each in their own window. If none of the named documents has an `<APPLET>` tag, *appletviewer* does nothing.

Options

`-debug`

> If this option is specified, the *appletviewer* is started within *jdb* (the Java debugger). This allows you to debug the applets referenced by the document or documents.

`-J`*`javaoption`*

> This option passes the following *`javaoption`* as a command-line argument to the Java interpreter. The specified *`javaoption`* should not contain spaces. If a multi-word option must be passed to the Java interpreter, multiple `-J` options should be used. See *java* for a list of valid Java interpreter options. Available in JDK 1.1 and later.

`-encoding`*`enc`*

> This option specifies the character encoding that *appletviewer* should use when reading the contents of the specified files or URLs. It is used in the conversion of applet parameter values to Unicode. Available in JDK 1.1 and later.

Commands

The window displayed by *appletviewer* contains a single **Applet** menu, with the following commands available:

Restart

> Stops and destroys the current applet, then re-initializes and restarts it.

Reload

Stops, destroys, and unloads the applet, then reloads, reinitializes, and restarts it.

Stop

Stops the current applet. Available in Java 1.1 and later.

Save

Serializes the applet and saves the serialized applet in the file *Applet.ser* in the user's home directory. The applet should be stopped before selecting this option. Available in Java 1.1 and later.

Start

Restarts a stopped applet. Available in Java 1.1 and later.

Clone

Creates a new copy of the applet in a new *appletviewer* window.

Tag

Pops up a dialog box that displays the `<APPLET>` tag and all associated `<PARAM>` tags that created the current applet.

Info

Pops up a dialog box that contains information about the applet. This information is provided by the `getAppletInfo()` and `getParameterInfo()` methods implemented by the applet.

Edit

This command is not implemented. The **Edit** menu item is disabled.

Character Encoding

Displays the current character encoding in the status line. Available in Java 1.1 and later.

Print

Prints the applet. Available in Java 1.1 and later.

Properties

Displays a dialog that allows the user to set *appletviewer* preferences, including settings for firewall and caching proxy servers.

Close

Closes the current *appletviewer* window.

Quit

Quits *appletviewer*, closing all open windows.

Properties

When it starts up, *appletviewer* reads property definitions from the file *~/.hotjava/properties* (UNIX) or the *.hotjava\properties* file relative to the `HOME` environment variable (Windows). These properties are stored in the system properties list and are used to specify the various error and status messages the applet viewer displays, as well as its security policies and use of proxy servers. The properties that affect security and proxies are described below.

Security

The following properties specify the security restrictions that *appletviewer* places on untrusted applets:

`acl.read`

This is a list of files and directories that an untrusted applet is allowed to read. The elements of the list should be separated with colons on UNIX systems and semicolons on Windows systems. On UNIX systems, the ~ character is replaced with the home directory of the current user. If the plus character appears as an element in the list, it is replaced by the value of the `acl.read.default` property. This provides an easy way to enable read access--by simply setting `acl.read` to "+". By default, untrusted applets are not allowed to read any files or directories.

`acl.read.default`

This is a list of files and directories that are readable by untrusted applets if the `acl.read` property contains a plus character.

acl.write

This is a list of files and directories that an untrusted applet is allowed to write to. The elements of the list should be separated with colons on UNIX systems and semicolons on Windows systems. On UNIX systems, the ~ character is replaced with the home directory of the current user. If the plus character appears as an element in the list, it is replaced by the value of the `acl.write.default` property. This provides an easy way to enable write access--by simply setting `acl.write` to "+". By default, untrusted applets are not allowed to write to any files or directories.

acl.write.default

This is a list of files and directories that are writable by untrusted applets if the `acl.write` property contains a plus character.

appletviewer.security.mode

This property specifies the types of network access an untrusted applet is allowed to perform. If it is set to "none", then the applet can perform no networking at all. The value "host" is the default, and specifies that the applet can connect only to the host from which it was loaded. The value "unrestricted" specifies that an applet may connect to any host without restrictions.

package.restrict.access.package-prefix

Properties of this form may be set to `true` to prevent untrusted applets from using classes in any package that has the specified package name prefix as the first component of its name. For example, to prevent applets from using any of the Sun classes (such as the Java compiler and the appletviewer itself) that are shipped with the JDK, you could specify the following property:

```
package.restrict.access.sun=true
```

appletviewer sets this property to `true` by default for the `sun.*` and `netscape.*` packages.

package.restrict.definition.package-prefix

Properties of this form may be set to `true` to prevent untrusted applets from defining classes in a package that has the specified package name prefix as the first component of its name. For example, to prevent an applet from defining classes in any of the standard Java packages, you could specify the following property:

```
package.restrict.definition.java=true
```

appletviewer sets this property to `true` by default for the `java.*`, `sun.*`, and `netscape.*` packages.

`property.applet`

When a property of this form is set to `true` in Java 1.1, it specifies that an applet should be allowed to read the property named `property` from the system properties list. By default, applets are only allowed to read ten standard system properties (see Chapter 14, *System Properties*, for a list). For example, to allow an applet to read the `user.home` property, specify a property of the form

```
user.home.applet=true
```

Proxies

appletviewer uses the following properties to configure its use of firewall and caching proxy servers:

`firewallHost`

This is the firewall proxy host to connect to if the `firewallSet` property is `true`.

`firewallPort`

This is the port of the firewall proxy host to connect to if the `firewallSet` property is `true`.

`firewallSet`

This tells you whether the applet viewer should use a firewall proxy. Values are `true` or `false`.

`proxyHost`

This is the caching proxy host to connect to if the `proxySet` property is `true`.

`proxyPort`

This is the port of the caching proxy host to connect to if the `proxySet` property is `true`.

`proxySet`

This tells you whether the applet viewer should use a caching proxy. Values are `true` or `false`.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *appletviewer* should look for class definitions. When a path is specified with this environment variable, *appletviewer* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, the default path is the current directory and the system classes. Note that *appletviewer* does not support the `-classpath` command-line argument, except indirectly through the `-J` option.

java, *javac*, *jdb*

6.9 Signed Applets

In Java 1.1 it is possible to circumvent these applet security restrictions by attaching a digital signature to a JAR file. When a Web browser or applet viewer loads a JAR file that has been signed by a trusted entity (the user specifies whom she trusts), the browser may grant the applet contained in the JAR file special privileges, such as the ability to read and write local files, that are not available to untrusted applets.

Signing an applet with the *javakey* tool provided by the JDK is a somewhat cumbersome task. First, of course, you must have a security database set up. The database must contain the certificate and the public and private keys that you want to use to sign the applet. See the *javakey* documentation in Chapter 16, *JDK Tools* for details on this process.

Once you have a properly configured security database, you must create a simple "directive file" that gives *javakey* the information it needs to sign your JAR file. A directive file might look like this:

```
# The entity doing the signing
signer=david
# The certificate number to use
cert=1
# Currently unused
chain=0
# The base name of the signature files to be added to the JAR manifest
signature.file=DAVIDSIG
```

Having created a directive file named *mysig*, for example, you could then sign a JAR file like this:

```
% javakey -gs mysig soundmap.jar
```

This command creates a new JAR file named *soundmap.jar.sig* that you can use in an HTML `archive` attribute just as you would use an unsigned JAR file.

The *javakey* tool is used for all aspects of administering the Java system security database. One of the other things you can do with it is to declare which entities are trusted. You do this with the `-t` option. For example, you might declare your trust for the author as follows:

```
% javakey -t DavidFlanagan true
```

Or you could revoke your trust like this:

```
% javakey -t DavidFlanagan false
```

The *appletviewer* program makes use of any trust values declared in this way. Note that *javakey* and *appletviewer* support only untrusted entities and fully-trusted entities, without any gradations in between. We may see additional levels of trust in the future.

Bear in mind that the *javakey* techniques described here apply only to the JDK. Other vendors may provide other mechanisms for signing applets, and Web browsers may provide other ways of declaring trusted entities.

7.2 Scribbling in Java 1.0

Example 7.1 shows a simple applet that uses the Java 1.0 event model. It overrides the `mouseDown()` and `mouseDrag()` methods to allow the user to scribble with the mouse. It overrides the `keyDown()` method and clears the screen when it detects the "C" key. And it overrides the `action()` method to clear the screen when the user clicks on a **Clear** button. We've seen applets much like this elsewhere in the book; this one is not pictured here.

Example 7.1: Scribble: Using the 1.0 Event Model

```
import java.applet.*;
import java.awt.*;
/** A simple applet using the Java 1.0 event handling model */
public class Scribble1 extends Applet {
  private int lastx, lasty;    // Remember last mouse coordinates.
  Button clear_button;         // The Clear button.
  Graphics g;                  // A Graphics object for drawing.
  /** Initialize the button and the Graphics object. */
  public void init() {
    clear_button = new Button("Clear");
    this.add(clear_button);
    g = this.getGraphics();
  }
  /** Respond to mouse clicks. */
  public boolean mouseDown(Event e, int x, int y) {
    lastx = x; lasty = y;
    return true;
  }
  /** Respond to mouse drags. */
  public boolean mouseDrag(Event e, int x, int y) {
    g.setColor(Color.black);
    g.drawLine(lastx, lasty, x, y);
    lastx = x; lasty = y;
    return true;
  }
  /** Respond to key presses. */
  public boolean keyDown(Event e, int key) {
    if ((e.id == Event.KEY_PRESS) && (key == 'c')) {
      clear();
      return true;
    }
    else return false;
  }
  /** Respond to Button clicks. */
  public boolean action(Event e, Object arg) {
    if (e.target == clear_button) {
      clear();
      return true;
    }
    else return false;
  }
  /** convenience method to erase the scribble */
  public void clear() {
    g.setColor(this.getBackground());
    g.fillRect(0, 0, bounds().width, bounds().height);
  }
}
```

The Java 1.0 Event Model | BOOK INDEX | The Java 1.1 Event Model

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.3 The Java 1.1 Event Model

The Java 1.1 event model is used by both the AWT and by Java Beans. In this model, different classes of events are represented by different Java classes. Every event is a subclass of `java.util.EventObject`. AWT events, which is what we are concerned with here, are subclasses of `java.awt.AWTEvent`. For convenience, the various types of AWT events, such as `MouseEvent` and `ActionEvent`, are placed in the new `java.awt.event` package.

Every event has a source object, which can be obtained with `getSource()`, and every AWT event has a type value, which can be obtained with `getID()`. This value is used to distinguish the various types of events that are represented by the same event class. For example, the `FocusEvent` has two possible types: `FocusEvent.FOCUS_GAINED` and `FocusEvent.FOCUS_LOST`. Event subclasses contain whatever data values are pertinent to the particular event type. For example, `MouseEvent` has `getX()`, `getY()`, and `getClickCount()` methods; it also inherits the `getModifiers()` and `getWhen()` methods, among others.

The 1.1 event handling model is based on the concept of an "event listener." An object interested in receiving events is an *event listener*. An object that generates events (an *event source*) maintains a list of listeners that are interested in being notified when events occur, and provides methods that allow listeners to add themselves and remove themselves from this list of interested objects. When the event source object generates an event (or when a user input event occurs on the event source object), the event source notifies all the listener objects that the event has occurred.

An event source notifies an event listener object by invoking a method on it and passing it an event object (an instance of a subclass of `EventObject`). In order for a source to invoke a method on a listener, all listeners must implement the required method. This is ensured by requiring that all event listeners for a particular type of event implement a corresponding interface. For example, event listener objects for `ActionEvent` events must implement the `ActionListener` interface. The `java.awt.event` package defines an event listener interface for each of the event types it defines. (Actually, for `MouseEvent` events, it defines two listener interfaces: `MouseListener` and `MouseMotionListener`.) All event listener interfaces themselves extend `java.util.EventListener`. This interface does not define any methods, but instead acts as a marker interface, clearly identifying all event listeners as such.

An event listener interface may define more than one method. For example, an event class like `MouseEvent` represents several different types of mouse events, such as a button press event and a button release event, and these different event types cause different methods in the corresponding event listener to be invoked. By convention, the methods of an event listener are passed a single argument, which is an event object of the type that corresponds to the listener. This event object should contain all the information a program needs to respond to the event. Table 7.6 lists the event types defined in `java.awt.event`, the corresponding listener (or listeners), and the methods defined by each listener interface.

Table 7.6: Java 1.1 Event Types, Listeners, and Listener Methods

Event Class	**Listener Interface**	**Listener Methods**
`ActionEvent`	`ActionListener`	`actionPerformed()`
`AdjustmentEvent`	`AdjustmentListener`	`adjustmentValueChanged()`
`ComponentEvent`	`ComponentListener`	`componentHidden()`
		`componentMoved()`
		`componentResized()`
		`componentShown()`
`ContainerEvent`	`ContainerListener`	`componentAdded()`
		`componentRemoved()`
`FocusEvent`	`FocusListener`	`focusGained()`
		`focusLost()`
`ItemEvent`	`ItemListener`	`itemStateChanged()`
`KeyEvent`	`KeyListener`	`keyPressed()`
		`keyReleased()`
		`keyTyped()`
`MouseEvent`	`MouseListener`	`mouseClicked()`
		`mouseEntered()`
		`mouseExited()`
		`mousePressed()`
		`mouseReleased()`
	_	_
	`MouseMotionListener`	`mouseDragged()`

		`mouseMoved()`
`TextEvent`	`TextListener`	`textValueChanged()`
`WindowEvent`	`WindowListener`	`windowActivated()`
		`windowClosed()`
		`windowClosing()`
		`windowDeactivated()`
		`windowDeiconified()`
		`windowIconified()`
		`windowOpened()`

For each of the event listener interfaces that contains more than one method, `java.awt.event` defines a simple "adapter" class that provides an empty body for each of the methods in the interface. When you are only interested in one or two of the defined methods, it is sometimes easier to subclass the adapter class than it is to implement the interface. If you subclass the adapter, you only have to override the methods of interest, but if you implement the interface directly you have to define all of the methods, which means you must provide empty bodies for all the methods that are not of interest. These pre-defined no-op adapter classes bear the same name as the interfaces they implement, with "Listener" changed to "Adapter": `MouseAdapter`, `WindowAdapter`, etc.

Once you have implemented a listener interface, or subclassed a adapter class, you must instantiate your new class to define an individual event listener object. You then register that listener with the appropriate event source. In AWT programs, an event source is always some sort of AWT component. Event listener registration methods follow a standard naming convention: if an event source generates events of type `X`, it has a method named `addXListener()` to add an event listener, and a method `removeXListener()` to remove a listener. One of the nice features of the 1.1 event model is that it is easy to determine the types of events a component can generate--just look for the event listener registration methods. For example, by inspecting the API of the `Button` object, you can determine that it generates `ActionEvent` events. Table 7.7 lists AWT components and the events they generate.

Table 7.7: AWT Components and the Java 1.1 Events They Generate

Component	**Events Generated**	**Meaning**
Button	ActionEvent	User clicked on the button
Checkbox	ItemEvent	User selected or deselected an item
CheckboxMenuItem	ItemEvent	User selected or deselected an item
Choice	ItemEvent	User selected or deselected an item
Component	ComponentEvent	Component moved, resized, hidden, or shown

	FocusEvent	Component gained or lost focus
	KeyEvent	User pressed or released a key
	MouseEvent	User pressed or released mouse button, mouse entered or exited component, or user moved or dragged mouse. Note: `MouseEvent` has two corresponding listeners, `MouseListener` and `MouseMotionListener`.
Container	ContainerEvent	Component added to or removed from container
List	ActionEvent	User double-clicked on list item
	ItemEvent	User selected or deselected an item
MenuItem	ActionEvent	User selected a menu item
Scrollbar	AdjustmentEvent	User moved the scrollbar
TextComponent	TextEvent	User changed text
TextField	ActionEvent	User finished editing text
Window	WindowEvent	Window opened, closed, iconified, deiconified, or close requested

Scribbling in Java 1.0 | BOOK INDEX | Scribbling in Java 1.1

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.4 Scribbling in Java 1.1

The Java 1.1 event model is quite flexible, and, as we'll see, there are several different ways you can use it to structure your event-handling code. Example 7.2 shows the first technique. Once again, this is our basic `Scribble` applet, this time using the Java 1.1 event model. This version of the applet implements the `MouseListener` and `MouseMotionListener` interfaces itself, and registers itself with its own `addMouseListener()` and `addMouseMotionListener()` methods.

Example 7.2: Scribble: Implementing the Listener Interfaces Directly

```
import java.applet.*;
import java.awt.*;
import java.awt.event.*;
public class Scribble2 extends Applet
                      implements MouseListener,  MouseMotionListener {
  private int last_x, last_y;
  public void init() {
    // Tell this applet what MouseListener and MouseMotionListener
    // objects to notify when mouse and mouse motion events occur.
    // Since we implement the interfaces ourself, our own methods are called.
    this.addMouseListener(this);
    this.addMouseMotionListener(this);
  }
  // A method from the MouseListener interface.  Invoked when the
  // user presses a mouse button.
  public void mousePressed(MouseEvent e) {
    last_x = e.getX();
    last_y = e.getY();
  }
  // A method from the MouseMotionListener interface.  Invoked when the
  // user drags the mouse with a button pressed.
  public void mouseDragged(MouseEvent e) {
    Graphics g = this.getGraphics();
    int x = e.getX(), y = e.getY();
    g.drawLine(last_x, last_y, x, y);
    last_x = x; last_y = y;
  }
  // The other, unused methods of the MouseListener interface.
  public void mouseReleased(MouseEvent e) {;}
  public void mouseClicked(MouseEvent e) {;}
  public void mouseEntered(MouseEvent e) {;}
  public void mouseExited(MouseEvent e) {;}
  // The other method of the MouseMotionListener interface.
  public void mouseMoved(MouseEvent e) {;}
}
```

The Java 1.1 Event Model | BOOK INDEX | Scribbling with Inner Classes

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.5 Scribbling with Inner Classes

The Java 1.1 event model was designed to work well with another new Java 1.1 feature: inner classes. Example 7.3 shows what the applet looks like when the event listeners are implemented as anonymous inner classes. Note how succinct this representation is. This is perhaps the most common way to use the Java 1.1 event model, so you'll probably see a lot of code that looks like this. In this case, our simple applet is nothing but event-handling code, so this version of it consists almost entirely of anonymous class definitions.

Note that we've added a feature to the applet. It now includes a **Clear** button. An `ActionListener` object is registered with the button; it clears the scribble when the appropriate event occurs.

Example 7.3: Scribble: Using Inner Classes

```
import java.applet.*;
import java.awt.*;
import java.awt.event.*;
public class Scribble3 extends Applet {
  int last_x, last_y;
  public void init() {
    // Define, instantiate, and register a MouseListener object.
    this.addMouseListener(new MouseAdapter() {
      public void mousePressed(MouseEvent e) {
        last_x = e.getX();
        last_y = e.getY();
      }
    });
    // Define, instantiate, and register a MouseMotionListener object.
    this.addMouseMotionListener(new MouseMotionAdapter() {
      public void mouseDragged(MouseEvent e) {
        Graphics g = getGraphics();
        int x = e.getX(), y = e.getY();
        g.setColor(Color.black);
        g.drawLine(last_x, last_y, x, y);
        last_x = x; last_y = y;
      }
    });
    // Create a clear button.
    Button b = new Button("Clear");
    // Define, instantiate, and register a listener to handle button presses.
    b.addActionListener(new ActionListener() {
      public void actionPerformed(ActionEvent e) {  // clear the scribble
        Graphics g = getGraphics();
        g.setColor(getBackground());
        g.fillRect(0, 0, getSize().width, getSize().height);
      }
    });
    // And add the button to the applet.
    this.add(b);
  }
}
```

Scribbling in Java 1.1	BOOK INDEX	Inside the Java 1.1 Event Model

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.6 Inside the Java 1.1 Event Model

The listener-based event model we've seen in the sections above is ideal for creating a GUI out of pre-defined AWT components or out of Java Beans. It becomes a little cumbersome, however, when developing custom AWT components. AWT components (but not beans) provide a lower-level interface to this event model that is sometimes more convenient to use.

When an AWTEvent is delivered to a component, there is some default processing that goes on before the event is dispatched to the appropriate event listeners. When you define a custom component (by subclassing), you have the opportunity to override methods and intercept the event before it is sent to listener objects. When an AWTEvent is delivered to a component, it is passed to the processEvent() method.

By default, processEvent() simply checks the class of the event object and dispatches the event to a class-specific method. For example, if the event object is an instance of FocusEvent, it dispatches it to a method named processFocusEvent(). Or, if the event is of type ActionEvent, it is dispatched to processActionEvent(). In other words, any event type *X*Event is dispatched to a corresponding process*X*Event() method. The exception is for MouseEvent events, which are dispatched either to processMouseEvent() or processMouseMotionEvent(), depending on the type of the mouse event that occurred. For any given component, it is the individual process*X*Event() methods that are responsible for invoking the appropriate methods of all registered event listener objects. The processMouseEvent() method, for example, invokes the appropriate method for each registered MouseListener object. There is a one-to-one mapping between these methods and the event listener interfaces defined in java.awt.event. Each process*X*Event() method corresponds to an *X*Listener interface.

As you can see, there is a clear analogy between the Java 1.0 event model and this Java 1.1 low-level event model. processEvent() is analogous to the Java 1.0 handleEvent() method, and methods like processKeyEvent() are analogous to the Java 1.0 keyDown() and keyUp() methods. As with the Java 1.0 model, there are two levels at which you can intercept events: you can override processEvent() itself or you can rely on the default version of processEvent() to dispatch the events based on their class and instead override the individual event methods, such as processFocusEvent() and processActionEvent().

There is one additional requirement to make this low-level Java 1.1 event model work. In order to receive events of a particular type for a component, you must tell the component that you are interested in receiving that type of event. If you do not do this, for efficiency, the component does not bother to deliver that type of event. When using event listeners, the act of registering a listener is enough to notify the component that you are interested in receiving events of that type. But when you use the low-level model, you must register your interest explicitly. You do this by calling the enableEvents() method of the component and passing a bit mask that specifies each of the event types you are interested in. The bit mask is formed by ORing together various EVENT_MASK constants defined by the AWTEvent class.

Scribbling with Low-Level Event Handling

Example 7.4 is another variation on the Scribble applet. This one uses the Java 1.1 low-level event-handling model. It overrides the event-specific methods processMouseEvent(), processMouseMotionEvent(), and processKeyEvent(). Note how it calls enableEvents() in its init() method to register interest in events of that type. Furthermore, it calls requestFocus() to ask that it be given the keyboard focus, so that it can receive key events. Notice also that it passes events it is not interested in to the superclass event-processing method. In this case, the superclass is not going to use those events, but this is still a good practice.

Example 7.4: Scribble: Using the Low-Level Event Model

```
import java.applet.*;
import java.awt.*;
import java.awt.event.*;
public class Scribble4 extends Applet {
  private int lastx, lasty;
  /** Tell the system we're interested in mouse events, mouse motion events,
   *  and keyboard events.  This is required or events won't be sent.
   */
  public void init() {
    this.enableEvents(AWTEvent.MOUSE_EVENT_MASK |
                      AWTEvent.MOUSE_MOTION_EVENT_MASK |
                      AWTEvent.KEY_EVENT_MASK);
    this.requestFocus();  // Ask for keyboard focus so we get key events.
  }
  /** Invoked when a mouse event of some type occurs */
  public void processMouseEvent(MouseEvent e) {
    if (e.getID() == MouseEvent.MOUSE_PRESSED) {  // Check the event type.
      lastx = e.getX(); lasty = e.getY();
    }
    else super.processMouseEvent(e); // Pass unhandled events to superclass.
  }
  /** Invoked when a mouse motion event occurs */
  public void processMouseMotionEvent(MouseEvent e) {
    if (e.getID() == MouseEvent.MOUSE_DRAGGED) {  // check type
      int x = e.getX(), y = e.getY();
      Graphics g = this.getGraphics();
      g.drawLine(lastx, lasty, x, y);
      lastx = x; lasty = y;
    }
    else super.processMouseMotionEvent(e);
  }
  /** Called on key events:  clear the screen when 'c' is typed. */
  public void processKeyEvent(KeyEvent e) {
    if ((e.getID() == KeyEvent.KEY_TYPED) && (e.getKeyChar() == 'c')) {
      Graphics g = this.getGraphics();
      g.setColor(this.getBackground());
      g.fillRect(0, 0, this.getSize().width, this.getSize().height);
    }
    else super.processKeyEvent(e);  // Pass unhandled events to our superclass.
  }
}
```

Another way to implement this example would be to override `processEvent()` directly instead of overriding the various methods that it invokes. If we did this, we'd end up with a large `switch` statement that separated events by type. When overriding `processEvent()`, it is particularly important to remember to pass unhandled events to `super.processEvent()` so that they can be dispatched correctly.

Scribbling with Inner Classes | BOOK INDEX | New AWT Features

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

jar

Name

jar---Java Archive Tool

Availability

JDK 1.1 and later.

Synopsis

```
jar c|t|x[f][m][v] [jar-file] [manifest-file] [files]
```

Description

jar is a tool that can be used to create and manipulate Java Archive (JAR) files. A JAR file is a compressed ZIP file with an additional "manifest" file. The syntax of the *jar* command is reminiscent of the Unix *tar* (tape archive) command.

Options to *jar* are specified as a block of concatenated letters passed as a single argument, rather than as individual command-line arguments. The first letter of this option argument specifies what action *jar* is to perform and is required. Other option letters are optional. The various file arguments depend on which option letters are specified.

Options

The first argument to *jar* is a set of letters that specifies the operation it is to perform. The first letter specifies the basic action and is required. The three possible values are the following:

`c`

Create a new JAR archive. A list of input files and/or directories must be specified as the final arguments to *jar*.

`t`

List the contents of a JAR archive. If a JAR file is specified with the `f` option, its contents are listed. Otherwise, the JAR file to be listed is read from standard input.

`x`

Extract the contents of a JAR archive. If a JAR file is specified with the `f` option, its contents are extracted. Otherwise, the JAR file to be extracted is read from standard input. If the command is followed by a list of files and/or directories, only those files or directories are extracted from the JAR archive. Otherwise, all files in the archive are extracted.

This action specifier can be followed by optional command letters:

`f`

This option indicates that the JAR file to create, list, or extract from is specified on the command line. When `f` is used with `c`, `t`, or `x`, the JAR filename must be the second command-line argument to *jar* (i.e., it must follow the block of option letters). If this option is not specified, *jar* writes the JAR file it creates to standard output, or reads a JAR file from standard input.

`m`

This option is only used with the `c` action. It indicates that *jar* should read the manifest file (partial or complete) specified on the command line and use that file as the basis for the manifest it includes in the JAR file. When this argument is specified after the `f` option, the manifest filename should follow the destination filename. If `m` precedes the `f` option, the manifest filename should precede the destination filename.

`v`

Verbose. If this letter is specified with a `c` action, *jar* lists each file it adds to the archive with compression statistics. If it is used with a `t` action, *jar* lists the size and modification date for each file in the archive, instead of simply listing the filename. If `v` is used with `x`, *jar* displays the name of each file it extracts from the archive.

Examples

To create a simple JAR file:

```
% jar cvf my.jar *.java images
```

To list the contents of a file:

```
% jar tvf your.jar
```

To extract the manifest file from a JAR file:

```
% jar xf the.jar META-INF/MANIFEST.MF
```

To create a JAR file with a partial manifest specified:

```
% jar cfmv YesNoDialog.jar manifest.stub oreilly/beans/yesno
```

appletviewer | BOOK INDEX | java

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

java

Name

java---The Java Interpreter

Availability

JDK 1.0 and later.

Synopsis

```
java [ interpreter options ] classname [ program arguments ]
java_g [ interpreter options ] classname [ program arguments ]
```

Description

java is the Java byte-code interpreter--it runs Java programs. *java_g* is a debugging version of the interpreter. It is unoptimized, and has some additional options for tracing the execution of a program.

The program to be run is the class specified by `classname`. This must be a fully qualified name, it must include the package name of the class, but not the *.class* file extension. Note that you specify the package and class name, with components separated by '.', not the directory and filename of the class, which has its components separated by '/' or '/'. If a Java class has no `package` statement, then it is not in any package, and the class name is specified alone. Examples:

```
% java david.games.Checkers
% java test
```

See the description of the `-classpath` option and the `CLASSPATH` environment variable below for information on specifying where *java* should look for classes.

The class specified by `classname` must contain a method `main()` with exactly the following signature:

```
public static void main(String argv[])
```

Any arguments following the `classname` on the *java* command line are placed into an array and passed to the `main()` method when *java* starts up.

If `main()` creates any threads, *java* runs until the last thread exits. Otherwise, the interpreter executes the body of `main()` and exits.

Although only a single class name is specified when invoking *java*, the interpreter automatically loads any additional classes required by the program. These classes are located relative to the Java class path, described under the `-classpath` option below.

By default, *java* runs a byte-code verifier on all classes loaded over the network. This verifier performs a number of tests on the byte-code of the loaded class to ensure, for example, that it does not corrupt the internal operand stack and that it performs appropriate run-time checks on such things as array references. The `-verify`, `-noverify`, and `-verifyremote` options control the byte-code verification process.

Options

`-classpath` *path*

> The path that *java* uses to look up the specified `classname` and all other classes that it loads. Specifying this option overrides the default path and the `CLASSPATH` environment variable. The class path is an ordered list of directories and ZIP files within and below which *java* searches for named classes. On UNIX systems, a path is specified as a colon-separated list of directories and ZIP files. On Windows systems, directories and ZIP files (which may have drive specifiers that use colons) are separated from each other with semicolons. For example, a UNIX `-classpath` specification might look like this:
>
> ```
> -classpath /usr/lib/java/classes:.:~/java/classes
> ```
>
> On a Windows system, the specification might be:

```
-classpath C:\tools\java\classes.zip;.;D:\users\david\classes
```

A period by itself in the path indicates that the current working directory is searched. Directories and ZIP files are searched in the order they appear. Place the standard Java classes first in the path if you do not want them to be accidentally or maliciously overridden by classes with the same name in other directories.

java expects to find class files in a directory hierarchy (or with a directory name within a ZIP file) that maps to the fully qualified name of the class. Thus, on a UNIX system, Java would load the class `java.lang.String` by looking for the file *java/lang/String.class* beneath one of the directories specified in the class path. Similarly, on a Windows 95 or Windows NT system (which support long filenames), *java* would look for the file *java\lang\String.class* beneath a specified directory or within a specified ZIP file.

If you do not specify `-classpath` or the `CLASSPATH` environment variable, the default class path is:

```
.:$JAVA/classes:$JAVA/lib/classes.zip       UNIX systems
.;$JAVA\classes;$JAVA\lib\classes.zip       Windows systems
```

Where `$JAVA` is JDK installation directory.

`-cs`, `-checksource`

Both of these options tell *java* to check the modification times on the specified class file and its corresponding source file. If the class file cannot be found or if it is out of date, it is automatically recompiled from the source.

`-D`*propertyname=value*

Defines `propertyname` to equal `value` in the system properties list. Your Java program can then look up the specified value by its property name. You may specify any number of `-D` options. For example:

```
% java -Dawt.button.color=gray -Dmy.class.pointsize=14 my.class
```

`-debug`

Causes *java* to display a password as it starts up. This password can be used to allow the *jdb* debugger to attach itself to this interpreter session. Note that this password should not be considered cryptographically secure.

`-help`

Print a usage message and exit.

`-l`*digit*

Sets the logging level for trace output. *java_g* only.

`-ms` *initmem*`[k|m]`

Specifies how much memory is allocated for the heap when the interpreter starts up. By default, `initmem` is specified in bytes. You can specify it in kilobytes by appending the letter `k` or in megabytes by appending the letter `m`. The default is 1 MB. For large or memory intensive applications (such as the Java compiler), you can improve run-time performance by starting the interpreter with a larger amount of memory. You must specify an initial heap size of at least 1000 bytes.

`-mx` *maxmem*`[k|m]`

Specifies the maximum heap size the interpreter will use for dynamically allocated objects and arrays. `maxmem` is specified in bytes by default. You can specify `maxmem` in kilobytes by appending the letter `k` and in megabytes by appending the letter `m`. The default is 16 MB. You must not specify a heap size less than 1000 bytes.

`-noasyncgc`

Do not do garbage collection asynchronously. With this option specified, *java* only performs garbage collection when it runs out of memory or when the garbage collector is explicitly invoked. Without this option, *java* runs the garbage collector as a separate, low-priority thread.

`-noclassgc`

Do not garbage collect loaded classes that are no longer in use. This option is only available in JDK 1.1 and later.

`-noverify`

Never run the byte-code verifier.

`-oss` *stacksize*`[k|m]`

Sets the size of each thread's Java code stack. By default, `stacksize` is specified in bytes. You can specify it in kilobytes by appending the letter `k` or in megabytes by appending the letter `m`. The default value is 400 KB. You must specify at least 1000 bytes.

`-prof[:`*file*`]`

Output profiling information to the specified `file` or to the file *java.prof* in the current directory. The format of this profiling information is not well documented. Prior to JDK 1.1, no `file` can be specified; profiling information is always output to *./java.prof*.

`-ss` *stacksize*`[k|m]`

Sets the size of each thread's native code stack. By default, `stacksize` is specified in bytes. You can specify it in kilobytes by appending the letter `k` or in megabytes by appending the letter `m`. The default value is 128 KB. You must specify at least 1000 bytes.

`-t`

Output a trace of all bytecodes executed. *java_g* only.

`-tm`

Output a trace of all methods executed. *java_g* only.

`-v`, `-verbose`

Print a terminal message each time *java* loads a class.

`-verbosegc`

Print a message whenever the garbage collector frees memory.

`-verify`

Run the byte-code verifier on all classes that are loaded.

`-verifyremote`

Run the byte-code verifier on all classes that are loaded through a class loader. (This generally means classes that are dynamically loaded from an untrusted location.) This is the default behavior for *java*.

`-version`

Print the version of the Java interpreter and exit.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *java* should look for class definitions. When a path is specified with this environment variable, *java* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, the default path is the current directory and the system classes. This variable is overridden by the `-classpath` option. See `-classpath` above for more information on specifying paths.

javac, *jdb*

javac

Name

javac---The Java Compiler

Availability

JDK 1.0 and later.

Synopsis

```
javac [ options ] files
```

Description

javac is the Java compiler--it compiles Java source code (in *.java* files) into Java byte-codes (in *.class* files). The Java compiler is itself written in Java.

javac may be passed any number of Java source files, whose names must all end with the *.java* extension. *javac* produces a separate *.class* class file for each class defined in the source files, regardless of how many source files there are. In other words, there need not be a one-to-one mapping between Java source files and Java class files. Note also that the compiler requires that there be only a single public class defined in any one source file, and that the name of the file (minus the *.java* extension) be the same as the name of the class (minus its package name, of course).

By default, *javac* places the class files it generates in the same directory as the corresponding source file. You can override this behavior with the `-d` option.

When a source file references a class that is not defined in another source file on the command line, *javac* searches for the definition of that class using the class path. The default class path contains only the current directory and the system classes. You may specify additional classes and packages to be searched with the `-classpath` option or the `CLASSPATH` environment variable.

If *javac* compiles a source file that relies on a class that is out of date (i.e., if the source file for that class is newer than the class file), it automatically recompiles that file.

Options

`-classpath` *path*

> The path that *javac* uses to look up classes referenced in the specified source code. This option overrides the default path and any path specified by the `CLASSPATH` environment variable. The `path` specified is an ordered list of directories and ZIP files, separated by colons on UNIX systems or semicolons on Windows systems.
>
> To specify additional directories or ZIP files to be searched, without overriding the default system class path, use the `CLASSPATH` environment variable. See the *java* reference page for more information on specifying paths.

`-d` *directory*

> The directory in which (or beneath which) class files should be stored. By default, *javac* stores the *.class* files it generates in the same directory as the *.java* file that those classes were defined in. If the `-d` flag is specified, however, the specified `directory` is treated as the root of the class hierarchy and *.class* files are placed in this directory, or in the appropriate subdirectory below it, depending on the package name of the class. Thus, the following command:

```
% javac -d java/classes java/src/Checkers.java
```

> places the file *Checkers.class* in the directory *java/classes* if the *Checkers.java* file has no `package` statement. On the other hand, if the source file specifies that it is in a package:

```
package david.games;
```

> then the *.class* file is stored in *java/classes/david/games*. When the `-d` option is specified, *javac* automatically creates any directories it needs to store its class files in the appropriate place.

`-depend`

Tells *javac* to recompile any out-of-date class files it encounters, not just those that are referenced from one of the specified source files.

`-deprecation`

Tells *javac* to issue a warning for every use of a deprecated API. By default, *javac* issues only a single warning if a program uses deprecated APIs. Available in JDK 1.1 and later.

`-g`

This option tells *javac* to add line numbers and local variable information to the output class files, for use by debuggers. By default, *javac* only generates the line numbers. With the `-O` option, *javac* does not generate even that information.

`-J`*javaoption*

Pass the argument `javaoption` directly through to the Java interpreter. `javaoption` should not contain spaces; if multiple arguments must be passed to the interpreter, use multiple `-J` options. Available in JDK 1.1 and later.

`-nowarn`

Tells *javac* not to print warning messages. Errors are still reported as usual.

`-nowrite`

Tells *javac* not to create any class files. Source files are parsed as usual, but no output is written. This option is useful when you want to check that a file will compile without actually compiling it.

`-O`

Enable optimization of class files. This option may cause *javac* to compile `static`, `final`, and `private` methods inline, so that they execute faster. The trade-off is that the class files will be larger. This option also prevents *javac* from adding line number debugging information to the class files.

`-verbose`

Tells the compiler to display messages about what it is doing.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *javac* should look for class definitions. When a path is specified with this environment variable, *javac* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, the default path is the current directory and the system classes. This variable is overridden by the `-classpath` option.

javadoc

Name

javadoc---The Java Documentation Generator

Availability

JDK 1.0 and later.

Synopsis

```
javadoc [ options ] packagename
javadoc [ options ] filenames
```

Description

javadoc generates API documentation, in HTML format, for the specified package, or for the individual Java source files specified on the command line.

When a package name is specified on the command line, *javadoc* looks for a corresponding package directory relative to the class path. It then parses all of the *.java* source files in that directory and generates an HTML documentation file for each class and an HTML index of the classes in the package. By default, the HTML files are placed in the current directory. The `-d` option allows you to override this default.

Note that the `packagename` argument to *javadoc* is the name of the package (components separated by periods) and not the name of the package directory. You may need to specify the `-sourcepath` option so that *javadoc* can find your package source code correctly, if it is not stored in the same location as the package class files.

javadoc may also be invoked with any number of Java source files specified on the command line. Note that these are filenames, not class names, and are specified with any necessary directory components, and with the *.java* extension. When *javadoc* is invoked in this way, it reads the specified source files and generates HTML files (in the current directory, by default) that describe each public class defined in the specified source files.

The class documentation files that *javadoc* generates describe the class (or interface) and its inheritance hierarchy, and index and describe each of the `public` and `protected` members of the class. The generated file also contains any "doc comments" that are associated with the class and with its methods, constructors, and variables. A "doc comment," or documentation comment, is a Java comment that begins with `/**` and ends with `*/`. A doc comment may include any HTML markup tags (although it should not include structuring tags like <H1> or <HR>), and may also include tag values that are treated specially by *javadoc*. These special tags and their syntax are documented fully in Chapter 13, *Java Syntax*.

Options

`-author` *path*

> Specifies that author information specified with the `@author` tag should be output. This information is not output by default.

`-classpath` *path*

> This option specifies a path that *javadoc* uses to look up both class files and source files for the specified package. If you specify this option to tell *javadoc* to look for your source files, you must also be sure to include the standard system classpath as well, or *javadoc* will not be able to find the classes it needs. This option overrides the default path and any path specified by the `CLASSPATH` environment variable. The `path` specified is an ordered list of directories and ZIP files, separated by colons on UNIX systems or semicolons on Windows systems. To specify additional directories or ZIP files to search without overriding the default system class path, use the `CLASSPATH` environment variable. See the *java* reference page for more information on specifying paths.

`-d` *directory*

> The directory in which *javadoc* should store the HTML files it generates. The default is the current directory.

`-docencoding` *encoding-name*

Specifies the character encoding to be used for the output documents generated by *javadoc*. Available in JDK 1.1 and later.

`-encoding` *encoding-name*

Specifies the character encoding to be used to read the input source files and the documentation comments they contain. Available in JDK 1.1 and later.

`-J`*javaoption*

Pass the argument `javaoption` directly through to the Java interpreter. `javaoption` should not contain spaces; if multiple arguments must be passed to the interpreter, use multiple `-J` options. Available in JDK 1.1 and later.

`-nodeprecated`

Specifies that *javadoc* should not include `@deprecated` tags in its output, as it does by default. Available in JDK 1.1 and later.

`-noindex`

Specifies that *javadoc* should not generate the *AllNames.html* index file that it creates by default.

`-notree`

Specifies that `javadoc` should not generate the *tree.html* class hierarchy file that it creates by default.

`-sourcepath` *path*

A synonym for `-classpath`. Note that any specified "sourcepath" must include the system classpath.

`-verbose`

Tells *javadoc* to print additional messages about what it is doing.

`-version` *path*

Specifies that version information specified with the `@version` tag should be output. This information is not output by default. Note that this option does *not* tell *javadoc* to print its own version number.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *javadoc* should look for class definitions. When a path is specified with this environment variable, *javadoc* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, then the default path is the current directory and the system classes. This variable is overridden by the `-classpath` option.

Bugs

When *javadoc* cannot find a specified package, it produces a stub HTML file and does not warn you that the package was not found.

javac BOOK INDEX javah

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

javah

Name

javah---Native Method C File Generator

Availability

JDK 1.0 and later.

Synopsis

```
javah [ options ] classnames
```

Description

javah generates C header and source files (*.h* and *.c* files) that describe the specified classes. Note that classes are specified by classname, not filename. These generated C files provide the information necessary for implementing native methods for the specified classes in C. By default, *javah* produces output files suitable for the native interface used in JDK 1.0. If the `-jni` option is specified, it generates output files for use with the Java 1.1 Java Native Interface (JNI).

By default, *javah* generates a header file for the specified class or classes. This header file declares a C `struct` that contains fields that correspond to the instance fields of the Java class. The header also declares a procedure that you must implement for each of the native methods that the Java class contains. (A full description of how to implement Java native methods in C is beyond the scope of this reference page.)

If *javah* is run with the `-stubs` option, it generates a *.c* file that contains additional stub procedures necessary for linking the native method into the Java environment. Note that you should not put your native method implementation in this generated stub file.

With the `-jni` option specified, *javah* generates C header files that declare function prototypes each of the native methods of the specified classes. No structure definitions are required using this new native interface. The JNI does not require stub files, either, so `-stubs` should not be specified with `-jni`.

By default, *javah* creates C files in the current directory and bases their name on the name of the class. If the name of the class includes a package name, then the C files include all the components of the fully qualified class name, with periods replaced by underscores. You can override this default behavior with the `-d` and `-o` options.

Options

`-classpath` *path*

> The path that *javah* uses to look up the classes named on the command line. This option overrides the default path, and any path specified by the `CLASSPATH` environment variable. The `path` specified is an ordered list of directories and ZIP files, separated by colons on UNIX systems or semicolons on Windows systems.
>
> To specify additional directories or ZIP files for *javah* to search without overriding the default system class path, use the `CLASSPATH` environment variable. See the *java* reference page for more information on specifying paths.

`-d` *directory*

> Specifies a directory where *javah* should store the files it generates. By default it stores them in the current directory. This option does not work with `-o`; you must specify any desired directory within the `-o` filename.

`-help`

> Causes *javah* to display a simple usage message and exit.

`-jni`

> Specifies that *javah* should output a header file for use with the new JNI (Java Native Interface), rather than using the old JDK 1.0 native interface. Available in JDK 1.1 and later.

`-o` *outputfile*

Combine all *.h* or *.c* file output into a single file, `outputfile`. This is a convenience when you want to implement native methods for a number of classes in a single package. It allows you to avoid having many short *.h* and *.c* files that must be manipulated separately.

`-stubs`

Generate *.c* stub files for the class or classes, and do not generate the *.h* header files. Without this option, *javah* generates header files.

`-td` *directory*

The directory where *javah* should store temporary files. The default is */tmp*.

`-trace`

Specifies that *javah* should include tracing output commands in the stub files it generates.

`-v`

Verbose. Causes *javah* to print messages about what it is doing.

`-version`

Causes *javah* to display its version number.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *javah* should look for class definitions. When a path is specified with this environment variable, *javah* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, the default path is the current directory and the system classes. This variable is overridden by the `-classpath` option.

java, *javac*

javakey

Name

javakey---Key Management and Digital Signatures

Availability

JDK 1.1 and later.

Synopsis

```
javakey options
```

Description

javakey provides a command-line interface to a number of complex key and certificate generation and management tasks, including the generation of digital signatures. There are quite a few options that perform a number of distinct operations. *javakey* manages a system database of entities. Each entity may have public and private keys and/or certificates associated with it, and in addition, each entity may be declared to be trusted or not. Any entity in the database may be an "identity" or a "signer." Identities have only a public key associated with them, while signers have both a public and private key, and thus may sign files.

The different *javakey* operations are specified with the various options described below.

Options

`-c` *identity-name* `[true|false]`

Create. Create and add a new identity to the database, using the specified name. If the identity name is followed by `true`, declare the identity to be trusted. Otherwise make it untrusted.

`-cs` *signer-name* `[true|false]`

Create signer. Create and add a new signer entity to the database, using the specified name. If the name is followed by `true`, declare the signer to be trusted. Otherwise make it untrusted.

`-t` *entity-name* `true|false`

Assign trust. Specify whether the named entity is trusted (`true`) or not (`false`).

`-l`

List. List the names of all entities in the security database.

`-ld`

List details. List the names and other details about all entities in the security database.

`-li` *entity-name*

List information. List detailed information about the named entity from the security database.

`-r` *entity-name*

Remove. Remove the named entity from the security database.

`-ik` *identity-name keyfile*

Import key. Read a public key from the specified file and associate it with the named identity. The key must be in X.509 format.

`-ikp` *signer-name pubkeyfile privkeyfile*

Import key pair. Read the specified public key and private key files and associate them with the named signer entity. The keys must be in X.509 format.

`-ic` *entity-name certificate-file*

Import certificate. Read a certificate from the named certificate file and associate it with the named entity. If the entity already has a public key, compare it to the key in the certificate and issue a warning if they do not match. If the entity has not had a public key assigned, use the public key from the certificate.

`-ii` *entity-name*

Import information. This command allows you to enter arbitrary textual information about an entity into the database.

`-gk` *signer algorithm size [pubfile [privfile]]*

Generate key. Generate a public and private key and associate them with the named signer. Use the specified algorithm. Currently, the only supported algorithm is "DSA." Generates keys of the specified number of bits, which must be between 512 and 1024. If `pubfile` is specified, write the public key to the specified file. If `privfile` is specified, write the private key to the specified file.

`-g` *signer algorithm size [pubfile [privfile]]*

A synonym for the `-gk` command.

`-gc` *directivefile*

Generate certificate. Generate a certificate according to the parameters specified in the directive file. The directive file is a `Properties` file that must provide values for the following named properties:

- `issuer.name`. The name of the entity issuing the certificate.
- `issuer.cert`. The issuer's certificate number to be used to sign the generated certificate (unless the certificate will be self-signed.)
- `subject.name`. The database name of the entity that the certificate is being issued to.
- `subject.real.name`. The real name of the entity that the certificate is being issued to.
- `subject.country`. The country that the subject entity is in.

- `subject.org`. The organization that the subject entity is affiliated with.
- `subject.org.unit`. A division within the subject's organization.
- `start.date`. The starting date (and time) of the certificate.
- `end.date`. The ending date (and time) of the certificate.
- `serial.number`. A serial number for the certificate. This number must be unique among all certificates generated by the issuer.
- `out.file`. An optional filename that specifies what file the certificate should be written to.

`-dc` *certfile*

Display certificate. Display the contents of the certificate stored in `certfile`.

`-ec` *entity certificate-number file*

Export certificate. Output the numbered certificate of the specified entity into the specified file. Use the `-li` command to inspect the certificate numbers for a given entity.

`-ek` *entity pubfile [privfile]*

Export key. Output the public key of the specified entity into the specified file. If the entity is a signer, and the `privfile` is specified, additionally export the private key of the entity to that file.

`-gs` *directivefile jarfile*

Generate signature. Apply a digital signature to the specified JAR file using the directives in the specified directive file. The directive file is a `Properties` file that must provide values for the following named properties:

- `signer`. The entity name of the signer.
- `cert`. The certificate number to use for the signature.
- `chain`. The length of a chain of certificates to include. This is not currently supported; specify 0.

    - `signature.file`. The basename of the signature file and signature block to be inserted into the JAR file. It must be 8 characters or less. This name should not conflict with any other digital signatures that may be inserted into the JAR file.
    - `out.file`. This optional property specifies the name that should be used for the signed JAR file that is generated.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

javap

Name

javap---The Java Class Disassembler

Availability

JDK 1.0 and later.

Synopsis

```
javap [ options ] classnames
```

Description

javap disassembles the class files specified by the class names on the command line and prints a human-readable version of those classes.

By default, *javap* prints declarations of the non-`private` members of each of the classes specified on the command line. The `-l`, `-p`, and `-c` options specify additional information to be printed, including a complete disassembly of the byte-codes in each of the specified classes. *javap* can also be used to run the class verifier on Java classes.

Options

`-c`

Print the Java Virtual Machine instructions for each of the methods in each of the specified classes. This option disassembles all methods, including `private` methods.

`-classpath` *path*

The path that *javap* uses to look up the classes named on the command line. This option overrides the default path and any path specified by the `CLASSPATH` environment variable. The `path` specified is an ordered list of directories and ZIP files, separated by colons on UNIX systems or semicolons on Windows systems.

To specify additional directories or ZIP files for *javap* to search without overriding the default system class path, use the `CLASSPATH` environment variable. See the *java* reference page for more information on specifying paths.

`-h`

Outputs the class in a form suitable for inclusion in a C header file.

`-l`

Prints line numbers and local variable tables in addition to the public fields of the class. Note that line numbers and local variable information is included for use with debuggers. Local variable information is available only if a class was compiled with the `-g` option to *javac*; line number information is available only if a class was compiled *without* the `-O` option.

`-p`

Prints `private` methods and variables of the specified class in addition to the `public` ones. Note that some compilers (though not *javac*) may allow this `private` field information to be "obfuscated" in such a way that `private` fields and method arguments no longer have meaningful names. This makes Java classes harder to disassemble or reverse engineer.

`-s`

Outputs the class member declarations using the internal Virtual Machine format.

`-v`

Verbose. Outputs additional information (in the form of Java comments) about each member of each specified class.

`-verify`

Causes *javap* to run the class verifier on the specified classes and display the results of verification.

`-version`

Causes *javap* to display its version number.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *javap* should look for class definitions. When a path is specified with this environment variable, *javap* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, the default path is the current directory and the system classes. This variable is overridden by the `-classpath` option.

javakey BOOK INDEX jdb

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

jdb

Name

jdb---The Java Debugger

Availability

JDK 1.0 and later.

Synopsis

```
jdb [ java options ] class
jdb [ -host hostname ] -password password
```

Description

jdb is a debugger for Java classes. It is text-based, command-line oriented, and has a command syntax like that of the UNIX *dbx* or *gdb* debuggers.

When *jdb* is invoked with the name of a Java class, it starts another copy of the *java* interpreter, passing any specified *java* options to the interpreter. *jdb* is itself a Java program, running in its own copy of the interpreter. This new interpreter loads the specified class file and stops for debugging before executing the first Java byte-code.

jdb may also be started with the `-password` and optional `-host` arguments. Invoked in this way, *jdb* "attaches itself" to an already running copy of the interpreter. In order for this to work, the Java interpreter running the program to be debugged must have been started with the `-debug` option. When the interpreter is started with this option, it prints a password that must be used with the *jdb* `-password` option.

Once a debugging session is started, you may issue any of the commands described below.

Options

When invoking *jdb* with a specified class file, any of the *java* interpreter options may be specified. See the *java* reference page for an explanation of these options.

When attaching *jdb* to an already running Java interpreter, the following options are available:

`-host` *hostname*

> Specifies the name of the host upon which the desired interpreter session is running.

`-password` *password*

> This option is required to attach to a running interpreter. The interpreter must have been started with the `-debug` option, and this `-password` option specifies the password that the interpreter generated. Only a debugger that knows this password is allowed to attach to the interpreter. Note that the passwords generated by *java* should not be considered cryptologically secure.

Commands

jdb understands the following debugging commands:

`!!`

> This is a shorthand command that is replaced with the text of the last command entered. It may be followed with additional text that is appended to that previous command.

`catch` [*exception class*]

> Cause a breakpoint whenever the specified exception is thrown. If no exception is specified, the command lists the exceptions currently being caught. Use `ignore` to stop these breakpoints from occurring.

`classes`

List all classes that have been loaded.

`clear` [*class*:*line*]

Remove the breakpoint set at the specified line of the specified class. Typing `clear` or `stop` with no arguments displays a list of current breakpoints and the line numbers that they are set at.

`cont`

Resume execution. This command should be used when the current thread is stopped at a breakpoint.

`down` [*n*]

Move down `n` frames in the call stack of the current thread. If `n` is not specified, move down one frame.

`dump` *id(s)*

Print the value of all fields of the specified object or objects. If you specify the name of a class, `dump` displays all class (static) methods and variables of the class, and also displays the superclass and list of implemented interfaces. Objects and classes may be specified by name or by their eight-digit hexadecimal ID number. Threads may also be specified with the shorthand `t@`*thread-number*.

`exit (or quit)`

Quit *jdb*.

`gc`

Run the garbage collector to force unused objects to be reclaimed.

`help (or ?)`

Display a list of all *jdb* commands.

`ignore` *exception class*

Do not treat the specified exception as a breakpoint. This command turns off a `catch` command.

`list` [*line number*]

List the specified line of source code as well as several lines that appear before and after it. If no line number is specified, use the line number of the current stack frame of the current thread. The lines listed are from the source file of the current stack frame of the current thread. Use the `use` command to tell *jdb* where to find source files.

`load` *classname*

Load the specified class into *jdb*.

`locals`

Display a list of local variables for the current stack frame. Java code must be compiled with the `-g` option in order to contain local variable information.

`memory`

Display a summary of memory usage for the Java program being debugged.

`methods` *class*

List all methods of the specified class. Use `dump` to list the instance variables or an object or the class (static) variables of a class.

`print` *id(s)*

Print the value of the specified item or items. Each item may be a class, object, field, or local variable, and may be specified by name or by eight-digit hexadecimal ID number. You may also refer to threads with the special syntax `t@`*thread-number*. The `print` command displays an object's value by invoking its `toString()` method.

`resume` [*thread(s)*]

Resume execution of the specified thread or threads. If no threads are specified, all suspended threads are resumed. See also `suspend`.

`run` [*class*] [*args*]

Run the `main()` method of the specified class, passing the specified arguments to it. If no class or arguments are specified, use the class and arguments specified on the *jdb* command line.

`step`

Run the current line of the current thread and stop again.

`stop [ at` *class*:*line*]
`stop [ in` *class*.*method*]

Set a breakpoint at the specified line of the specified class or at the beginning of the specified method of the specified class. Program execution stops when it reaches this line or enters the method. If `stop` is executed with no arguments, then it lists the current breakpoints.

`suspend` [*thread(s)*]

Suspend the specified thread or threads. If no threads are specified, suspend all running threads. Use `resume` to restart them.

`thread` *thread*

Set the current thread to the specified thread. This thread is used implicitly by a number of other *jdb* commands. The thread may be specified by name or number.

`threadgroup` *name*

Set the current thread group to the named thread group.

`threadgroups`

List all thread groups running in the Java interpreter session being debugged.

`threads` [*threadgroups*]

List all threads in the named thread group. If no thread group is specified, list all threads in the current thread group (specified by `threadgroup`).

`up` [*n*]

Move up `n` frames in the call stack of the current thread. If `n` is not specified, move up one frame.

`use` [*source-file-path*]

Set the path used by *jdb* to look up source files for the classes being debugged. If no path is specified, display the current source path being used.

`where [` *thread* `] [ all ]`

Display a stack trace for the specified thread. If no thread is specified, display a stack trace for the current thread. If `all` is specified, display a stack trace for all threads.

Environment

`CLASSPATH`

Specifies an ordered list (colon-separated on UNIX, semicolon-separated on Windows systems) of directories and ZIP files in which *jdb* should look for class definitions. When a path is specified with this environment variable, *jdb* always implicitly appends the location of the system classes to the end of the path. If this environment variable is not specified, the default path is the current directory and the system classes. This variable is overridden by the `-classpath` option.

See Also

java

native2ascii

Name

native2ascii---Convert Java source code to ASCII

Availability

JDK 1.1 and later.

Synopsis

```
native2ascii [ options ] [ inputfile [ outputfile ]]
```

Description

javac can only process files encoded in ASCII, with any other characters encoded using the `\u`*xxxx* Unicode notation. *native2ascii* is a simple program that reads a Java source file encoded using a local encoding and converts it to the ASCII-plus-encoded-Unicode form required by *javac*.

The `inputfile` and `outputfile` are optional. If unspecified, standard input and standard output are used, making *native2ascii* suitable for use in pipes.

Options

`-encoding` *encoding-name*

Specifies the encoding used by source files. If this option is not specified, the encoding is taken from the `file.encoding` system property.

`-reverse`

Specifies that the conversion should be done in reverse--from encoded `\u`*xxxx* characters to characters in the native encoding.

jdb BOOK INDEX serialver

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

serialver

Name

serialver---Class Version Number Generator

Availability

JDK 1.1 and later.

Synopsis

```
serialver [-show] classname...
```

Description

serialver displays the version number, or serialization-unique identifier, for a named class or classes. If the class declares a `long serialVersionUID` constant, the value of that field is displayed. Otherwise, a unique version number is computed by applying the Secure Hash Algorithm (SHA) to the API defined by the class. This program is primarily useful for computing an initial unique version number for a class, which is then declared as a constant in the class. The output of *serialver* is a line of legal Java code, suitable for pasting into a class definition.

Options

`-show`

When the `-show` option is specified, *serialver* displays a simple graphical interface that allows the user to type in a single classname at a time and obtain its serialization UID. When using `-show`, no class names may be specified on the command-line.

Environment

`CLASSPATH`

serialver is written in Java, and so it is sensitive to the `CLASSPATH` environment variable in the same way that the *java* interpreter is. The specified classes are looked up relative to this class path.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

14. System Properties

Contents:

Java programs cannot read environment variables the way that native programs can. The reason is that environment variables are platform dependent. Similar mechanisms exist, however, that allow applications to read the value of a named resource. These resource values allow customization of an application's behavior based on site-specific parameters, such as the type of host, or based on user preferences.

These named resource values are specified for applications in the "system properties" list. Applications can read these "system properties" with the `System.getProperty()` method, or can read the entire list of properties with `System.getProperties()`. `System.getProperty()` returns the property value as a string. Applications can also read properties in parsed form using methods that are based on `System.getProperty()`, such as `Font.getFont()`, `Color.getColor()`, `Integer.getInteger()`, and `Boolean.getBoolean()`.

14.1 Standard System Properties

When the Java interpreter starts, it inserts a number of standard properties into the system properties list. These properties, and the meaning of their values, are listed in Table 14.1. The table also specifies whether untrusted applets are allowed (at least by default) to read the value of these properties. For reasons of security, untrusted code is only allowed to read the values of properties to which it has explicitly been granted access. (Untrusted applets are not allowed to set the value of system properties, nor are they allowed to call `System.getProperties()` to obtain the entire list of properties.)

Table 14.1: Standard System Properties

Name	Value	Applet Access

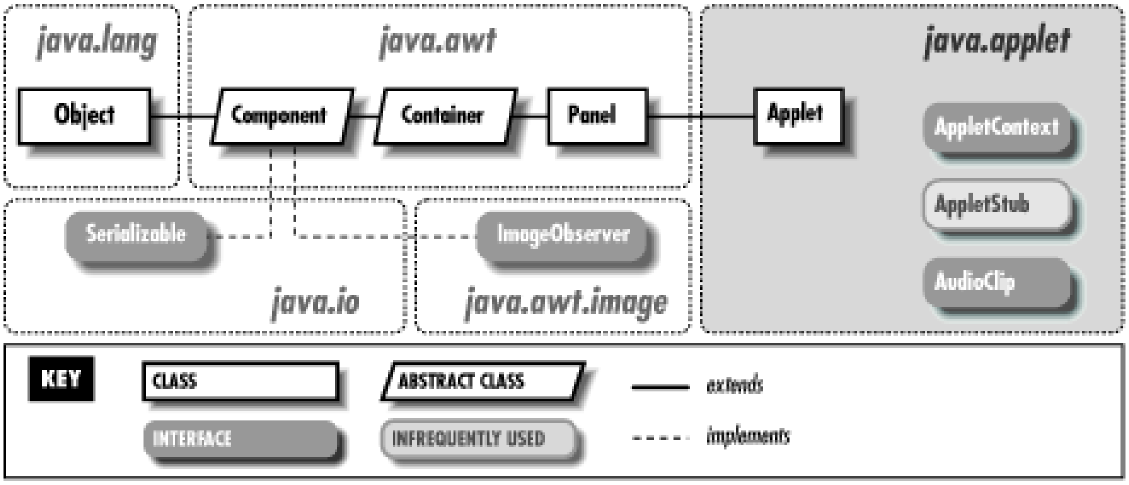
java.version	Version of the Java interpreter	yes
java.vendor	Vendor-specific identifier string	yes
java.vendor.url	Vendor's URL	yes
java.class.version	The version of the Java API	yes
java.class.path	The classpath value	no
java.home	The directory Java is installed in	no
java.compiler	The JIT compiler to use, if any (Java 1.1)	no
os.name	The name of the operating system	yes
os.arch	The host hardware architecture	yes
os.version	Version of the host operating system	yes
file.separator	Platform-dependent file separator (e.g., `/` or #)	yes
path.separator	Platform-dependent path separator (e.g., `:` or `;`)	yes
line.separator	Platform-dependent line separator (e.g., `#n` or `#r#n`)	yes
user.name	The username of the current user	no
user.home	The home directory of the current user	no
user.dir	The current working directory	no
user.language	The 2-letter language code of the default locale (Java 1.1)	no
user.region	The 2-letter country code of the default locale (Java 1.1)	no
user.timezone	The default time zone (Java 1.1)	no
file.encoding	The character encoding for the default locale (Java 1.1)	no
file.encoding.pkg	The package that contains converters between local encodings and Unicode (Java 1.1)	no

17. The java.applet Package

Contents:

An *applet* is a small, embeddable Java program. The `java.applet` package is a small one. It contains the `Applet` class, which is the superclass of all applets, and three related interfaces. Figure 17.1 shows the class hierarchy of this package. See Chapter 6, *Applets*, for more information about this package.

Figure 17.1: The java.applet package



17.1 java.applet.Applet (JDK 1.0)

This class implements an applet. To create your own applet, you should create a subclass of this class and override some or all of the following methods. Note that you never need to call these methods--they are called when appropriate by a Web browser or other applet viewer.

`init()` should perform any initialization for the applet; it is called when the applet first starts. `destroy()` should free up any resources that the applet is holding; it is called when the applet is about to be permanently stopped. `start()` is called to make the applet start doing whatever it is that it does. Often, it starts a thread to perform an animation or similar task. `stop()` should temporarily stop the applet from executing. It is called when the applet temporarily becomes hidden or non-visible.

`getAppletInfo()` should return text suitable for display in an **About** dialog posted by the Web browser or applet viewer. `getParameterInfo()` should return an arbitrary-length array of three-element arrays of strings where each element describes one of the parameters that this applet understands. The three elements of each parameter description are strings that specify, respectively, the parameter's name, type, and description.

In addition to these methods, an applet also typically overrides several of the methods of `java.awt.Component`, notably the `paint()` method to draw the applet on the screen. There are also several `Applet` methods that you do not override but may call from applet code: `showStatus()` displays text in the Web browser or applet viewer's status line. `getImage()` and `getAudioClip()` read image (GIF and JPEG formats) and audio files (AU format) over the network and return corresponding Java objects. `getParameter()` looks up the value of a parameter specified with a `<PARAM>` tag within an `<APPLET>...</APPLET>` pair. `getCodeBase()` returns the base URL from which the applet's code was loaded, and `getDocumentBase()` returns the base URL from which the HTML document containing the applet was loaded. `getAppletContext()` returns an `AppletContext` object, which also has useful methods.

```
public class Applet extends Panel {
    // Default Constructor: public Applet()
    // Public Instance Methods
            public void destroy();
            public AppletContext getAppletContext();
            public String getAppletInfo();
            public AudioClip getAudioClip(URL url);
            public AudioClip getAudioClip(URL url, String name);
            public URL getCodeBase();
            public URL getDocumentBase();
            public Image getImage(URL url);
            public Image getImage(URL url, String name);
            public Locale getLocale();  // Overrides Component
            public String getParameter(String name);
            public String[][] getParameterInfo();
            public void init();
            public boolean isActive();
            public void play(URL url);
            public void play(URL url, String name);
            public void resize(int width, int height);  // Overrides Component
            public void resize(Dimension d);  // Overrides Component
            public final void setStub(AppletStub stub);
            public void showStatus(String msg);
            public void start();
            public void stop();
}
```

Hierarchy:

```
Object->Component(ImageObserver, MenuContainer, Serializable)->Container->Panel->Applet
```

Returned By:

```
AppletContext.getApplet()
```

Reading a Quick Reference Entry | BOOK INDEX | java.applet.AppletContext (JDK 1.0)

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.2 Reading a Quick Reference Entry

Each class and interface has its own entry in this quick reference. These quick-reference entries document the class or interface as described below. Because the information in each entry is quite dense, the descriptions of it that follow are somewhat complicated. I recommend that you flip through the following chapters as you read to find examples of each of the features described.

Name and Availability

Each quick reference entry has a title that is the name of the class or interface it documents. To the right of that title, you'll find availability information that indicates when the class or interface was added to the Java API. The string "JDK 1.0" indicates that the class or interface has been around since the original release of Java. The string "JDK 1.1" indicates that it has been added in the Java 1.1 release, and is therefore not backwards compatible with Java 1.0 environments. If the availability string is followed by the word "Deprecated," it means that the class or interface has been deprecated and its use is discouraged. There are two such deprecated classes in Java 1.1.

Description

The class name is followed by a short description of the most important features of the class. This description may be anywhere from a couple of sentences to several paragraphs long.

Synopsis

The description is always followed by a synopsis of the class or interface. This is a listing that looks like a Java class definition, except that method bodies and field initializers are omitted. This synopsis contains the following information:

Class Modifiers

The synopsis begins with a list of class modifiers. All classes and interfaces in this quick reference are `public`; some are also declared `abstract` or `final`

Class or Interface

If the modifiers are followed by the `class` keyword, it is a class that is being documented. If they are followed by the `interface` keyword, it is an interface that is being documented.

Class Name

The name of the class or interface follows the `class` or `interface` keyword. It is highlighted in bold.

Superclass

The superclass of the class follows the `extends` keywords.

Interfaces

The list of interfaces that the class implements, if any, follows the `implements` keyword.

Members

The constructors, fields, and methods defined by the class or interface form the bulk of the synopsis. All `public` and `protected` members are listed. They are divided into the following categories, and listed alphabetically by name within each category. Each category begins with a comment to break the synopsis listing into logical sections. The categories, in the order listed, are:

1. Public constructors
2. Protected constructors
3. Constants
4. Class variables
5. Public instance variables
6. Protected instance variables

7. Class methods

8. Public instance methods

9. Protected instance methods

Availability

If a member synopsis begins with the string "1.1", it indicates that the constructor, field, or method has been added to the class or interface in Java 1.1. Note that this indication only appears in classes and interfaces that are not themselves new in Java 1.1. If a member synopsis begins with "#", it means that the constructor, field, or method has been deprecated in Java 1.1, and that its use is discouraged.

Member Modifiers

The modifiers for each member are listed. These provide important information about how the members are used. The modifiers you may find listed are: `public`, `protected`, `static`, `abstract`, `final`, `synchronized`, `native`, and `transient`.

Member Type

The listing for a member may include a type. The types of fields and constants are shown, as are the return types of methods. Constructors do not have return types in Java.

Member Name

The name of each class member is in bold, for easy scanning.

Parameters

The synopsis for a method or constructor includes the type and name of each parameter that it takes. The parameter names are shown in italic to indicate that they are not to be used literally.

Exceptions

The exceptions that may be thrown by a method or constructor follow the `throws` keyword in the synopsis.

Inheritance

The synopsis for a method may be followed by a comment that includes a class or interface name. If a method is followed by a `//Overrides` comment, the method overrides a method by the same name in the specified superclass. If a method synopsis is followed by a `//Defines` comment, the method provides the definition of an `abstract` method of the specified superclass. Finally, if a method synopsis is followed by a `//From` comment, the method implements a method from the named interface (which is implemented by the class or a superclass).

Cross References

The synopsis section is followed by a number of optional "cross reference" sections that indicate other, related classes that may be of interest. In the first edition of this book, this information was available in separate index chapters. We think it should be even more useful when associated directly with each class and interface entry. The cross reference sections are the following:

Hierarchy

This section lists all of the superclasses of the class, as well as any interfaces implemented by those superclasses. It may also list any interfaces extended by an interface. This section only appears when it provides information that is not available from the `extends` and `implements` clauses of the class synopsis. In the hierarchy listing, arrows indicate superclass to subclass relationships, while the interfaces implemented by a class follow the class name in parentheses. This information can be useful, for example, to determine whether a class implements `Serializable` or `Cloneable` somewhere up its superclass hierarchy.

Extended By

This section lists all direct subclasses of this class, or any interfaces that extend this interface, which tells you that there are more specific classes or interfaces to look at.

Implemented By

This section lists all of the classes that directly implement this interface, which is useful when you know that you want to use the interface but you don't know what implementations of it are available.

Passed To

This section lists all of the methods and constructors that are passed an object of this type as an argument, which is useful when you have an object of a given type and want to figure out what you can do with it.

Returned By

This section lists all of the methods (but not constructors) that return an object of this type, which is useful when you know that you want to work with an object of this type, but don't know how to obtain one.

Type Of

This section lists all of the fields and constants that are of this type, which can help you figure out how to obtain an object of this type.

Thrown By

For exception and error classes, this section lists all of the methods and constructors that throw exceptions of this type. This material helps you figure out when a given exception or error may be thrown. Note, however, that this section is based on the exception types listed in the `throws` clauses of methods and constructors. Subclasses of `RuntimeException` do not have to be listed in `throws` clauses, so it is not possible to generate a complete cross reference of methods that throw these types of "unchecked" exceptions.

Finding a Quick Reference Entry | BOOK INDEX | The java.applet Package

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5. How To Use This Quick Reference

Contents:

The quick-reference section that follows packs a lot of information into a small space. This introduction explains how to get the most out of that information. It explains how the quick reference is organized and how to read the individual quick-ref entries.

5.1 Finding a Quick Reference Entry

The following chapters each document one package of the Java API. The packages are listed alphabetically, beginning with `java.applet` and ending with `java.util.zip`. Each chapter begins with an overview of the package, including a hierarchy diagram for the classes and interfaces in the package. Within each chapter, the classes and interfaces of a package are themselves listed alphabetically.

If you know the name of a class, but not of the package that it is a part of, or if you know the name of a method or field, but do not know what class defines it, use the index in Chapter 32, *Class, Method, and Field Index* to find the information you need.

17.2 java.applet.AppletContext (JDK 1.0)

This interface defines the methods that allow an applet to interact with the context in which it runs (which is usually a Web browser or an applet viewer). The object that implements the `AppletContext` interface is returned by `Applet.getAppletContext()`. You can use it to take advantage of a Web browser's cache, or to display a message to the user in the Web browser's or applet viewer's message area.

The `getAudioClip()` and `getImage()` methods may make use of a Web browser's caching mechanism. `showDocument()` and `showStatus()` give an applet a small measure of control over the appearance of the browser or applet viewer. The `getApplet()` and `getApplets()` methods allow an applet to find out what other applets are running at the same time.

```
public abstract interface AppletContext {
    // Public Instance Methods
            public abstract Applet getApplet(String name);
            public abstract Enumeration getApplets();
            public abstract AudioClip getAudioClip(URL url);
            public abstract Image getImage(URL url);
            public abstract void showDocument(URL url);
            public abstract void showDocument(URL url, String target);
            public abstract void showStatus(String status);
}
```

Returned By:

`Applet.getAppletContext(), AppletStub.getAppletContext()`

17.3 java.applet.AppletStub (JDK 1.0)

This is an internal interface used when implementing an applet viewer.

```
public abstract interface AppletStub {
    // Public Instance Methods
            public abstract void appletResize(int width, int height);
            public abstract AppletContext getAppletContext();
            public abstract URL getCodeBase();
            public abstract URL getDocumentBase();
            public abstract String getParameter(String name);
            public abstract boolean isActive();
}
```

Passed To:

```
Applet.setStub()
```

17.4 java.applet.AudioClip (JDK 1.0)

This interface describes the essential methods that an audio clip must have. `AppletContext.getAudioClip()` and `Applet.getAudioClip()` both return an object that implements this interface. The current JDK implementations of this interface only work with sounds encoded in AU format. The `AudioClip` interface is in the `java.applet` package only because there is not a better place for it.

```
public abstract interface AudioClip {
    // Public Instance Methods
            public abstract void loop();
            public abstract void play();
            public abstract void stop();
}
```

Returned By:

`Applet.getAudioClip(), AppletContext.getAudioClip()`

18. The java.awt Package

Contents:

The `java.awt` package is the Abstract Windowing Toolkit. The classes of this package may be roughly divided into three categories (see Figure 18.1 and Figure 18.2).

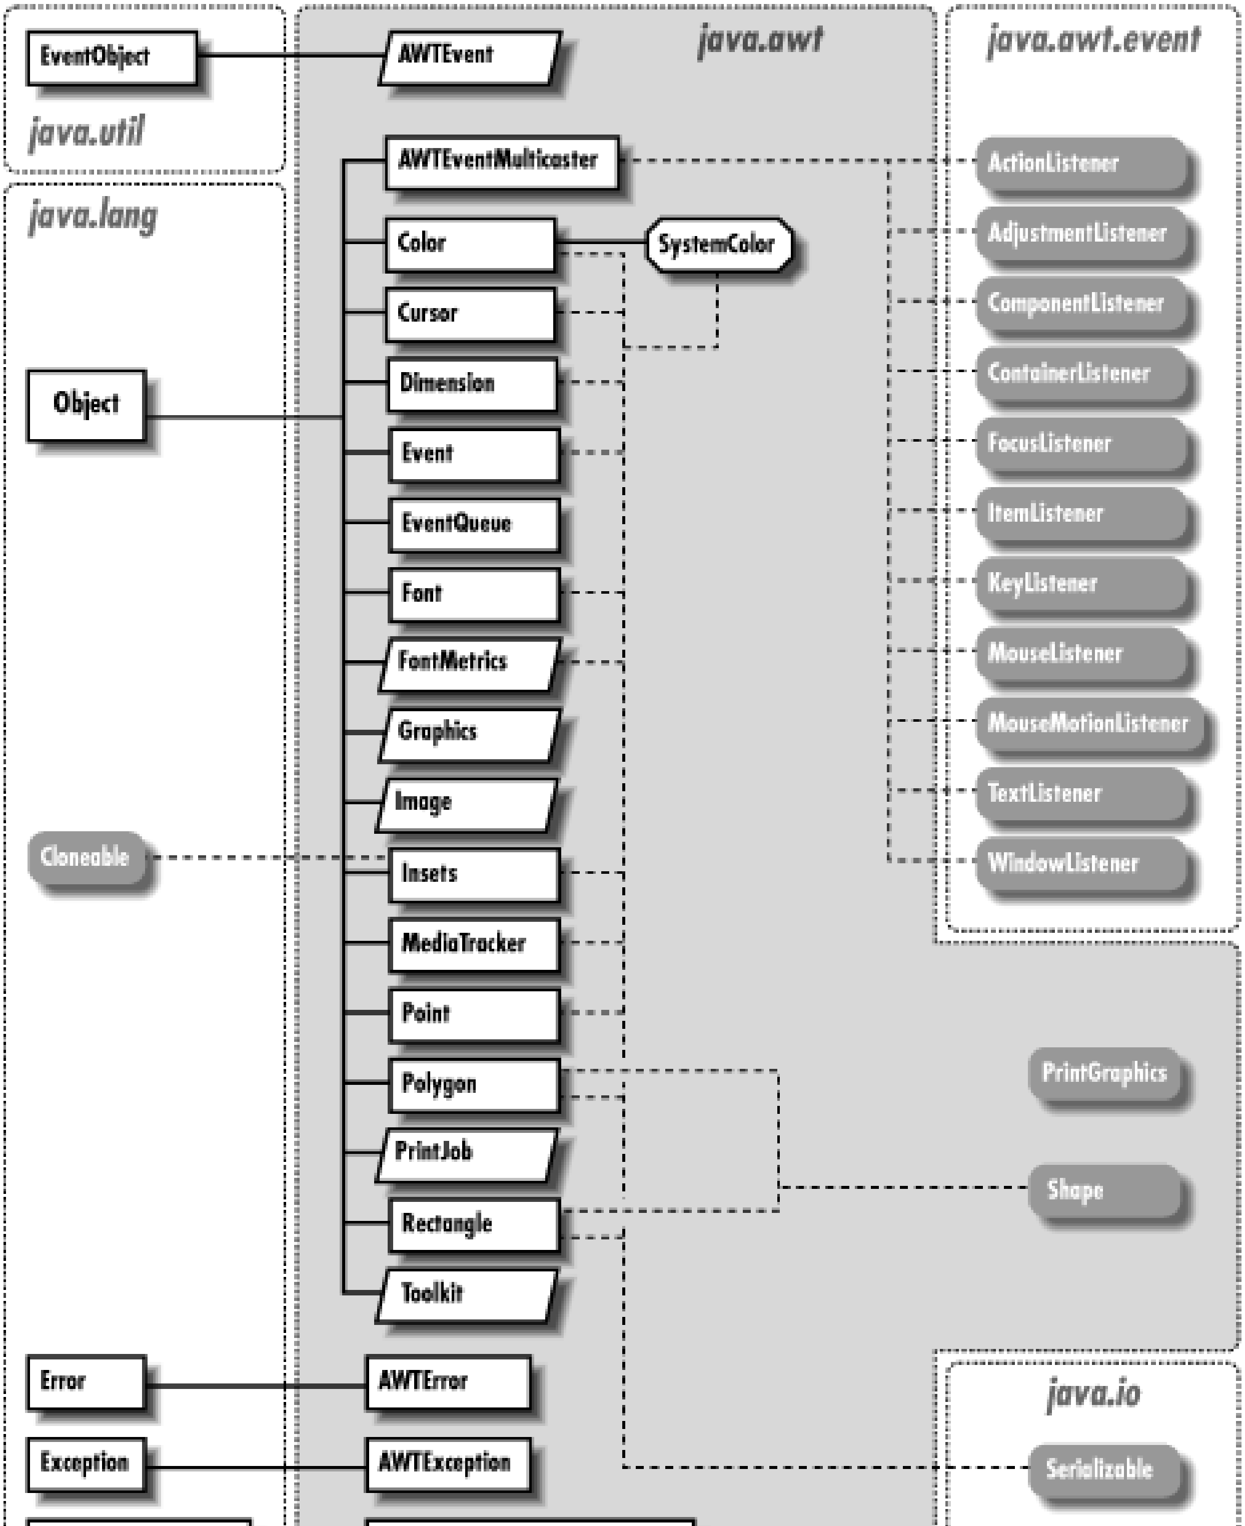
- Graphics: These classes define colors, fonts, images, polygons, and so forth.

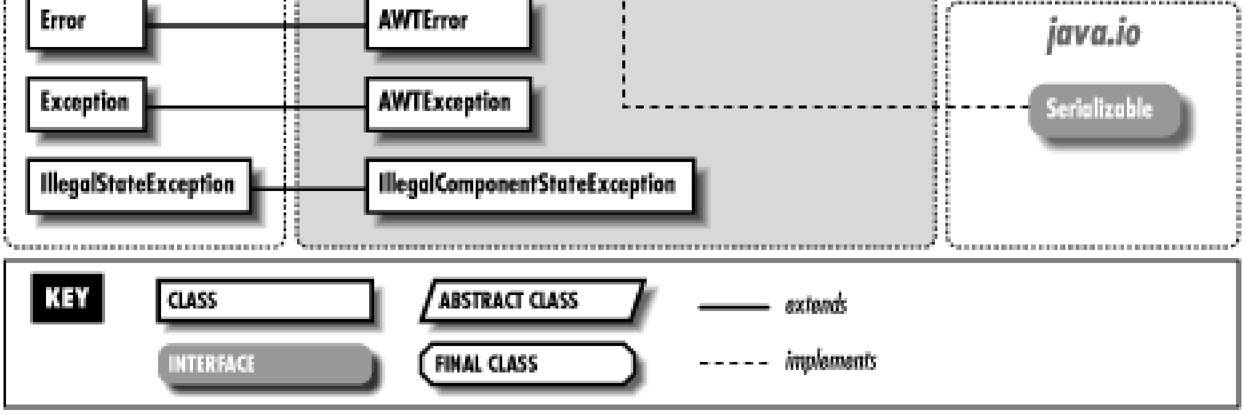
- Components: These classes are GUI (graphical user interface) components such as buttons, menus, lists, and dialog boxes.

- Layout Managers: These classes control the layout of components within their container objects.

Note that separate packages, `java.awt.datatransfer`, `java.awt.event`, and `java.awt.image`, contain classes for cut-and-paste, event handling, and image manipulation.

Figure 18.1: Graphics, event, and exception classes of the java.awt package





In the first category of classes, `Graphics` is probably the most important. This class defines methods for doing line and text drawing and image painting. It relies on other classes such as `Color`, `Font`, `Image`, and `Polygon`. `Image` is itself an important class, used in many places in `java.awt` and throughout the related package `java.awt.image`. `Event` is another important class that describes a user or window system event that has occurred. In Java 1.1, `Event` is superseded by the `AWTEvent` class.

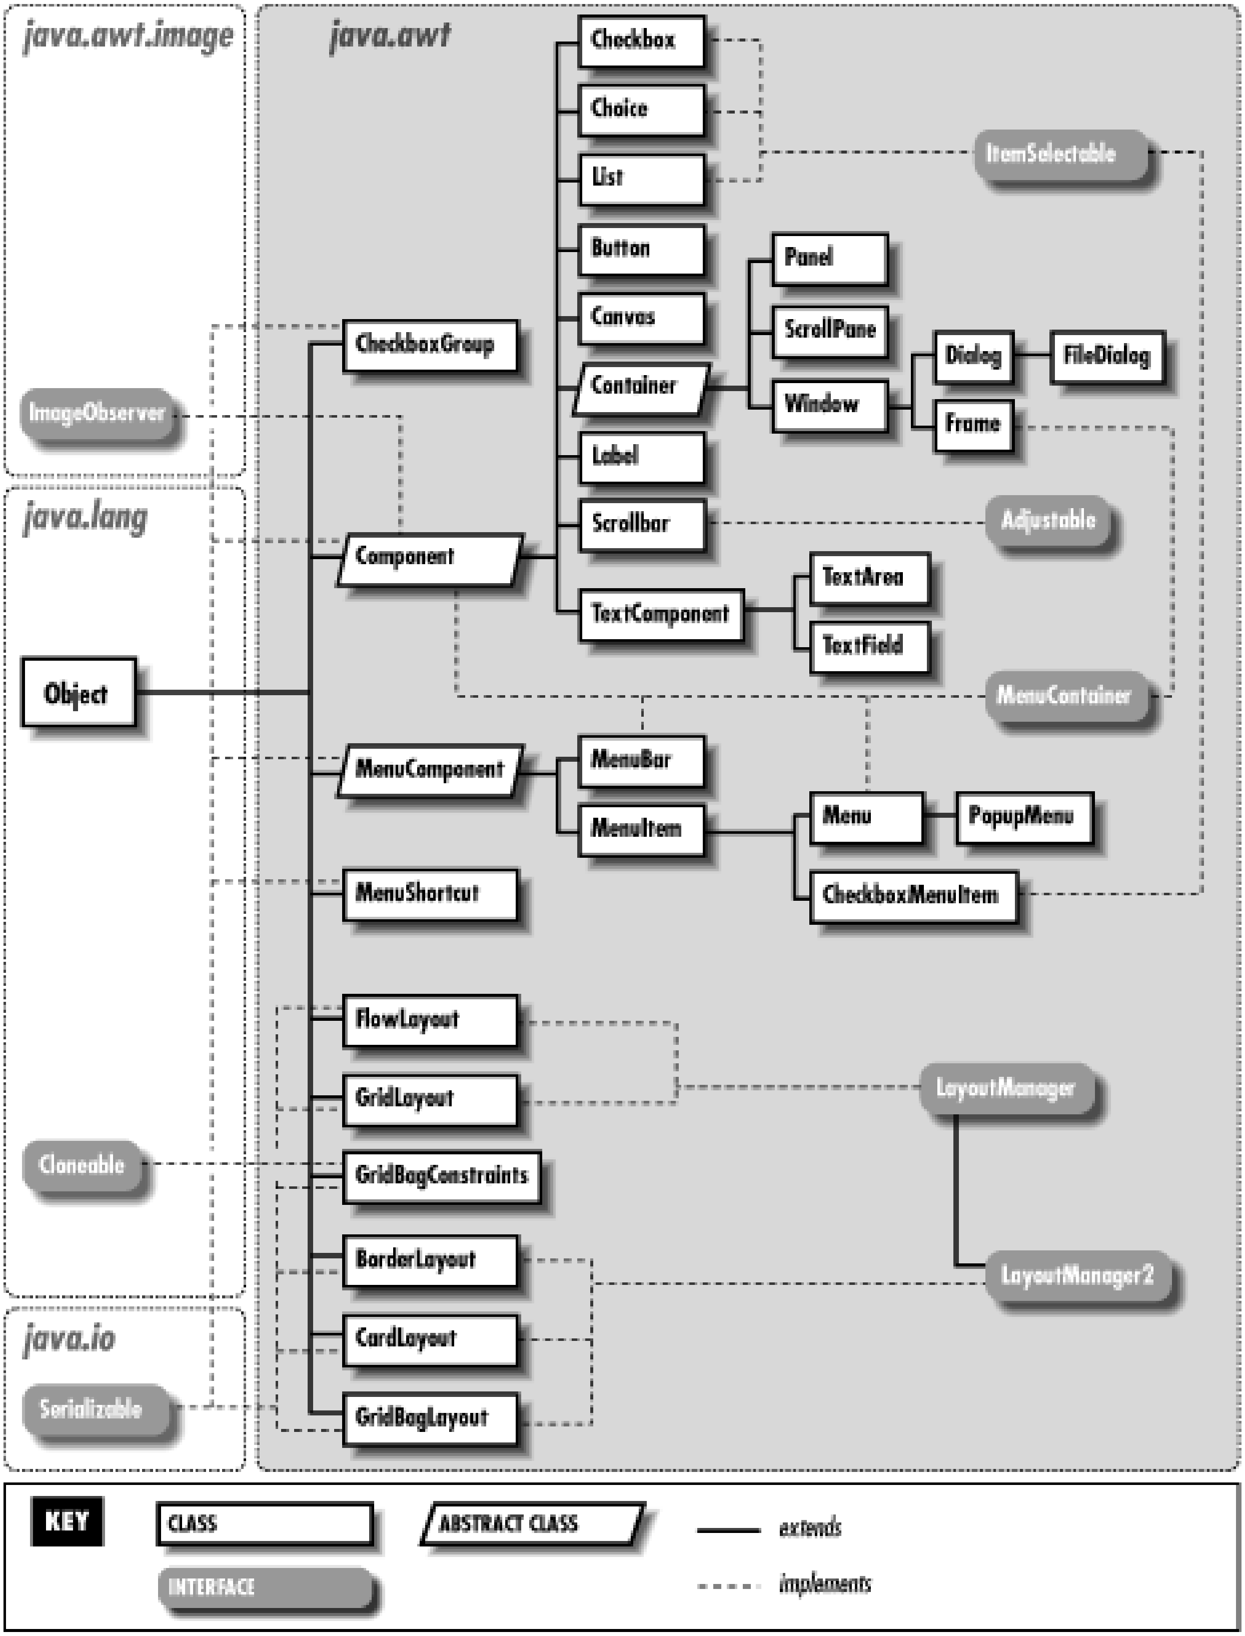
`Component` and `MenuComponent` are root classes in the second category of `java.awt` classes. Their subclasses are GUI components that can appear in interfaces and menus. The `Container` class is one that contains components and arranges them visually. You add components to a container with the `add()` method and specify a layout manager for the container with the `setLayout()` method.

There are three commonly used `Container` subclasses. `Frame` is a toplevel window that can contain a menu bar and have a custom cursor and an icon. `Dialog` is a dialog window. `Panel` is a container that does not have its own window--it is contained within some other container.

The third category of `java.awt` classes is the layout managers. The subclasses of `LayoutManager` are responsible for arranging the `Component` objects contained within a specified `Container`. `GridBagLayout`, `BorderLayout`, and `GridLayout` are probably the most useful of these layout managers.

See Chapter 8, *New AWT Features*, for examples of using some of the new Java 1.1 features of this package.

Figure 18.2: Component and layout classes of the java.awt package



18.1 java.awt.AWTError (JDK 1.0)

Signals that an error has occurred in the `java.awt` package.

```
public class AWTError extends Error {
    // Public Constructor
            public AWTError(String msg);
}
```

Hierarchy:

```
Object->Throwable(Serializable)->Error->AWTError
```

8. New AWT Features

Contents:

In addition to the new AWT event model that we saw in Chapter 7, *Events*, there are a number of important new AWT features in Java 1.1. These new features were outlined in Chapter 4, *What's New in Java 1.1*. This chapter details many of those new features and demonstrates them in a single extended example application at the end of the chapter. The major features of the example are:

- The new `ScrollPane` component
- Popup menus and menu shortcuts
- Printing
- Data transfer through cut-and-paste

In addition, the example also demonstrates the use of object serialization to save and load application state. This functionality is described in Chapter 9, *Object Serialization*.

8.1 The ScrollPane Container

The new `ScrollPane` container holds a single child component that is usually larger than the `ScrollPane` itself. The `ScrollPane` displays a fixed-size area of the child and provides horizontal and vertical scrollbars so the user can scroll the child component within the "viewport" of the `ScrollPane`. Figure 8.1 shows a top-level window created by the application listed in Example 8.1 at the end of this chapter. As you can see, the application creates a `ScrollPane` container to hold the larger `Scribble` component that supports free-hand drawing.

Figure 8.1: New AWT features demo application

[Graphic: Figure 8-1]

The ScrollPane is quite easy to use. Simply create it and add a child component as you would with any other container. Note, however, that ScrollPane only supports a single child and it cannot have a LayoutManager specified. The ScrollPane is created in the ScribbleFrame() constructor of the example. The important thing to note is that the ScrollPane does not have any preferred or natural size of its own, so you should use setSize() to specify the size you want it to be. The ScrollPane class defines three constants that are legal values of its "scrollbar display policy." Because the example does not specify one of these constants, the policy defaults to SCROLLBARS_AS_NEEDED, which indicates that scrollbars are displayed for any dimension in which the contained child is larger than the available "viewport" space of the ScrollPane container.

Here is an excerpt of the ScribbleFrame() constructor that shows the creation of the ScrollPane:

```
ScrollPane pane = new ScrollPane();      // Create a ScrollPane.
pane.setSize(300, 300);                  // Specify its size.
this.add(pane, "Center");                // Add it to the frame.
Scribble scribble;
scribble = new Scribble(this, 500, 500); // Create a bigger scribble area.
pane.add(scribble);                      // Add it to the ScrollPane.
```

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

28.23 java.net.URLConnection (JDK 1.0)

This abstract class defines a network connection to an object specified by a URL. `URL.openConnection()` returns a `URLConnection` instance. You would use a `URLConnection` object when you want more control over the downloading of data than is available through the simpler `URL` methods.

`connect()` actually performs the network connection. Other methods that depend on being connected will call this method. `getContent()` returns the data referred to by the `URL`, parsed into an appropriate type of `Object`. If the URL protocol supports read and write operations, then `getInputStream()` and `getOutputStream()` respectively return input and output streams to the object referred to by the URL.

`getContentLength()`, `getContentType()`, `getContentEncoding()`, `getExpiration()`, `getDate()`, and `getLastModified()` return the appropriate information about the object referred to by the URL, if that information can be determined (e.g., from HTTP header fields). `getHeaderField()` returns an HTTP header field specified by name or by number. `getHeaderFieldInt()` and `getHeaderFieldDate()` return the value of a named header field parsed as an integer or a date.

There are a number of options that you may specify to control how the `URLConnection` behaves. These options are set with the various `set()` methods, and may be queried with corresponding `get()` methods. The options must be set before the `connect()` method is called. `setDoInput()` and `setDoOutput()` allow you to specify whether you use the `URLConnection` for input and/or output. The default is input-only. `setAllowUserInteraction()` specifies whether user interaction (such as typing a password) is allowed during the data transfer. The initial default is `false`. `setDefaultAllowUserInteraction()` is a class method that allows you to change the default value for user interaction. `setUseCaches()` allows you to specify whether a cached version of the URL may be used. You can set this to `false` to force a URL to be reloaded. `setDefaultUseCaches()` sets the default value for `setUseCaches()`. `setIfModifiedSince()` allows you to specify that a URL should not be fetched (if it is possible to determine its modification date) unless it has been modified since a specified time.

```
public abstract class URLConnection extends Object {
    // Protected Constructor
            protected URLConnection(URL url);

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

28.25 java.net.URLStreamHandler (JDK 1.0)

This abstract class defines the `openConnection()` method that creates a `URLConnection` for a given `URL`. A separate subclass of this class may be defined for various URL protocol types. A `URLStreamHandler` is created by a `URLStreamHandlerFactory`.

Normal applications never need to use or subclass this class.

```
public abstract class URLStreamHandler extends Object {
    // Default Constructor: public URLStreamHandler()
    // Protected Instance Methods
            protected abstract URLConnection openConnection(URL u) throws 
IOException;
            protected void parseURL(URL u, String spec, int start, int limit);
            protected void setURL(URL u, String protocol, String host, int port, 
String file, String ref);
            protected String toExternalForm(URL u);
}
```

Returned By:

URLStreamHandlerFactory.createURLStreamHandler()

13.2 Character Escape Sequences

Java uses the escape sequences listed in Table 13.2 to represent certain special character values. These escape sequences may appear in any Java `char` or `String` literal.

Table 13.2: Java Escape Characters

Escape Sequence	**Character Value**
\b	Backspace
\t	Horizontal tab
\n	Newline
\f	Form feed
\r	Carriage return
\"	Double quote
\'	Single quote
\\	Backslash
\xxx	The character corresponding to the octal value `xxx`, where `xxx` is between 000 and 0377.
\uxxxx	The Unicode character with encoding `xxxx`, where `xxxx` is one to four hexidecimal digits. Unicode escapes are distinct from the other escape types listed here; they are described below in more detail.

Java characters, strings, and identifiers (e.g., field, method, and class names) are composed of 16-bit Unicode characters. The Unicode `\u` escape sequence may be used anywhere in a Java program (not only in `char` and `String` literals) to represent a Unicode character.

Unicode `\u` escape sequences are processed before the other escape sequences described in Character Escape Sequences, and thus the two types of escape sequences can have very different semantics. A

Unicode escape is simply an alternative way to represent a character which may not be displayable on non-Unicode systems. The character escapes, however, can represent special characters in a way that prevents the usual interpretation of those characters by the compiler.

13.4 Modifiers

There are quite a few Java keywords that serve as modifiers for Java classes, interfaces, methods, and fields. They are described in Table 13.4.

Table 13.4: Java Modifiers

Modifier	Used On	Meaning
abstract	class	The class contains unimplemented methods and cannot be instantiated.
	interface	All interfaces are `abstract`. The modifier is optional in interface declarations.
	method	No body is provided for the method (it is provided by a subclass). The signature is followed by a semicolon. The enclosing class must also be `abstract`.
final	class	The class may not be subclassed.
	field	The field may not have its value changed (compiler may precompute expressions).
	method	The method may not be overridden (compiler may optimize).
	variable	Java 1.1 and later: the local variable or method or exception parameter may not have its value changed.
native	method	The method is implemented in C, or in some other platform-dependent way. No body is provided; the signature is followed by a semicolon.
none (package)	class	A non-`public` class is accessible only in its package
	interface	A non-`public` interface is accessible only in its package
	member	A member that is not `private`, `protected`, or `public` has package visiblity and is accessible only within its package.
private	member	The member is only accessible within the class that defines it.

protected	member	The member is only accessible within the package in which it is defined, and within subclasses.
public	class	The class is accessible anywhere its package is.
	interface	The interface is accessible anywhere its package is.
	member	The member is accessible anywhere its class is.
static	class	In Java 1.1, a class delared `static` is a toplevel class, not an inner class.
	field	A `static` field is a "class field." There is only one instance of the field, regardless of the number of class instances created. It may be accessed through the class name.
	initializer	The intializer is run when the class is loaded, rather than when an instance is created.
	method	A `static` method is a "class method." It is not passed as an implicit `this` object reference. It may be invoked through the class name.
synchronized	method	The method makes non-atomic modifications to the class or instance, and care must be taken to ensure that two threads cannot modify the class or instance at the same time. For a `static` method, a lock for the class is acquired before executing the method. For a non-`static` method, a lock for the specific object instance is acquired.
transient	field	The field is not part of the persistent state of the object, and should not be serialized with the object.
volatile	field	The field may be accessed by unsynchronized threads, so certain code optimizations must not be performed on it.

Table 13.5 summarizes the visibility modifiers; it shows the circumstances under which class members of the various visibility types are accessible.

Table 13.5: Class Member Accessibility

Accessible to:	**Member Visibility**			
	public	**protected**	**package**	**private**
Same class	yes	yes	yes	yes
Class in same package	yes	yes	yes	no
Subclass in different package	yes	yes	no	no
Non-subclass, different package	yes	no	no	no

PREVIOUS HOME NEXT

13.5 Reserved Words

Table 13.6 lists reserved words in Java. These are keywords or `boolean` literal values. Note that `byvalue`, `cast`, `const`, `future`, `generic`, `goto`, `inner`, `operator`, `outer`, `rest`, and `var` are reserved by Java but currently unused.

Table 13.6: Java Reserved Words

abstract	default	goto	operator	synchronized
boolean	do	if	outer	this
break	double	implements	package	throw
byte	else	import	private	throws
byvalue	extends	inner	protected	transient
case	false	instanceof	public	true
cast	final	int	rest	try
catch	finally	interface	return	var
char	float	long	short	void
class	for	native	static	volatile
const	future	new	super	while
continue	generic	null	switch	

Reserved Method Names

Table 13.7 lists the method names of the `Object` class. Strictly speaking, these method names are not reserved, but since the methods are inherited by every class, they should not be used as the name of a method, except when intentionally overriding an `Object` method.

Table 13.7: Reserved Method Names

clone	getClass	notifyAll
equals	hashCode	toString
finalize	notify	wait

Acknowledgments

Many people contributed to putting this book together under a schedule that became increasingly rushed as time passed. Thanks to their efforts, we gave birth to something we can all be proud of.

Foremost we would like to thank Tim O'Reilly for giving us the opportunity to write this book. Special thanks to Mike Loukides, the series editor, whose endless patience and experience got us through the difficult parts and to Paula Ferguson, whose organizational and editing abilities got the material into its final form. It's due largely to Mike and Paula's tireless efforts that this book has gotten to you as quickly as it has. We could not have asked for a more skillful or responsive team of people with whom to work.

Particular thanks are due to our technical reviewers: Andrew Cohen, Eric Raymond, and Lisa Farley. All of them gave thorough reviews that were invaluable in assembling the final draft. Eric contributed many bits of text that eventually found their way into the book.

Speaking of borrowings, the original version of the glossary came from David Flanagan's book, *Java in a Nutshell*. We also borrowed the class hierarchy diagrams from David's book. These diagrams were based on similar diagrams by Charles L. Perkins. His original diagrams are available at http://rendezvous.com/java/.

Thanks also to Marc Wallace and Steven Burkett for reading the book in progress. As for the crowd in St. Louis: a special thanks to LeeAnn Langdon of the Library Ltd. and Kerri Bonasch. Deepest thanks to Victoria Doerr for her patience and love. Finally, thanks for the support of the "lunch" crowd: Karl "Gooch" Stefvater, Bryan "Butter" O'Connor, Brian "Brian" Gottlieb, and the rest of the clan at Washington University.

Many people in O'Reilly's production and design groups contributed their blood, sweat, and tears to the project. Mary Anne Weeks Mayo was production editor and copy editor, and had the stress-filled job of working under a very tight deadline with chapters arriving asynchronously (which means at random and later than expected). Seth Maislin wrote the index, and Stephen Spainhour adapted David Flanagan's glossary for this book. Chris Reilley converted rough diagrams into professional technical illustrations. Erik Ray, Ellen Siever, and Lenny Muellner converted HTML files into SGML and made sure we could convert electrons into paper without mishap. Lenny also implemented a new design for this book, which was created by Nancy Priest. Hanna Dyer created the back cover; Edie Freedman designed the front cover.

Conventions Used in This Book | BOOK INDEX | Yet Another Language?

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.2 A Virtual Machine

Java is both a compiled and an interpreted language. Java source code is turned into simple binary instructions, much like ordinary microprocessor machine code. However, whereas C or C++ source is refined to native instructions for a particular model of processor, Java source is compiled into a universal format--instructions for a virtual machine.

Compiled Java byte-code, also called J-code, is executed by a Java run-time interpreter. The run-time system performs all the normal activities of a real processor, but it does so in a safe, virtual environment. It executes the stack-based instruction set and manages a storage heap. It creates and manipulates primitive data types, and loads and invokes newly referenced blocks of code. Most importantly, it does all this in accordance with a strictly defined open specification that can be implemented by anyone who wants to produce a Java-compliant virtual machine. Together, the virtual machine and language definition provide a complete specification. There are no features of Java left undefined or implementation dependent. For example, Java specifies the sizes of all its primitive data types, rather than leave it up to each implementation.

The Java interpreter is relatively lightweight and small; it can be implemented in whatever form is desirable for a particular platform. On most systems, the interpreter is written in a fast, natively compiled language like C or C++. The interpreter can be run as a separate application, or it can be embedded in another piece of software, such as a Web browser.

All of this means that Java code is implicitly portable. The same Java application can run on any platform that provides a Java run-time environment, as shown in Figure 1.1. You don't have to produce alternate versions of your application for different platforms, and you never have to distribute source code to end users.

Figure 1.1: Java virtual machine environment

[Graphic: Figure 1-1]

The fundamental unit of Java code is the *class*. As in other object-oriented languages, classes are application components that hold executable code and data. Compiled Java classes are distributed in a universal binary format that contains Java byte-code and other class information. Classes can be maintained discretely and stored in files or archives on a local system or on a network server. Classes are located and loaded dynamically at run-time, as they are needed by an application.

In addition to the platform-specific run-time system, Java has a number of fundamental classes that contain architecture-dependent methods. These *native methods* serve as Java's gateway to the real world. These methods are implemented in a native language on the host platform. They provide access to resources such as the network, the windowing system, and the host filesystem. The rest of Java is written entirely in Java, and is therefore portable. This includes fundamental Java utilities like the Java compiler, which is also a Java application and is therefore immediately available on all Java platforms.

In general, interpreters are slow, but because the Java interpreter runs compiled byte-code, Java is a fast interpreted language. Java has also been designed so that software implementations of the run-time system can optimize their performance by compiling byte-code to native machine code on the fly. This is called "just in time" compilation. Sun claims that with just in time compilation, Java code can execute nearly as fast as native compiled code and maintain its transportability and security. The one performance hit that natively compiled Java code will always suffer is array bounds checking. But on the other hand, some of the basic design features of Java place more information in the hands of the compiler, which allows for certain kinds of optimizations not possible in C or C++.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.3 Java Compared

Java is a new language, but it draws on many years of programming experience with other languages in its choice of features. So a lot can be said in comparing and contrasting Java with other languages. There are at least three pillars necessary to support a universal language for network programming today: portability, speed, and security. Figure 1.2 shows how Java compares to other languages.

Figure 1.2: Programming languages compared

[Graphic: Figure 1-2]

You may have heard that Java is a lot like C or C++, but that's really not true, except at a superficial level. When you first look at Java code, you'll see that the basic syntax looks a lot like C or C++. But that's where the similarities end. Java is by no means a direct descendant of C or a next generation C++. If you compare language features, you'll see that Java actually has more in common with languages like Smalltalk and Lisp. In fact, Java's implementation is about as far from native C as you can imagine.

The surface-level similarities to C and C++ are worth noting, however. Java borrows heavily from C and C++ syntax, so you'll see lots of familiar language constructs, including an abundance of curly braces and semicolons. Java also subscribes to the C philosophy that a good language should be compact; in other words, it should be sufficiently small and regular so that a programmer can hold all the language's capabilities in his or her head at once. As C is extensible with libraries, packages of Java classes can be added to the core language components.

C has been successful because it provides a reasonably featureful programming environment, with high performance and an acceptable degree of portability. Java also tries to balance functionality, speed, and portability, but it does so in a very different way. While C trades functionality to get portability, Java trades speed for portability. Java also addresses security issues, while C doesn't.

Java is an interpreted language, so it won't be as fast as a compiled language like C. But Java is fast enough, especially for interactive, network-based applications, where the application is often idle, waiting for the user to do something or waiting for data from the network. For situations where speed is critical, a Java implementation can optimize performance by compiling byte-code to native machine code on the fly.

Scripting languages, like Tcl, Perl, and Wksh, are becoming quite popular, and for good reason. There's no reason a scripting language could not be suitable for safe, networked applications (e.g., Safe Tcl), but most scripting languages are not designed for serious, large-scale programming. The attraction to scripting languages is that they are dynamic; they are powerful tools for rapid prototyping. Some scripting languages, like awk and Perl, also provide powerful tools for text-processing tasks more general-purpose languages find unwieldy. Scripting languages are also highly portable.

One problem with scripting languages, however, is that they are rather casual about program structure and data typing. Most scripting languages (with a hesitant exception for Perl 5.0) are not object oriented. They also have vastly simplified type systems and generally don't provide for sophisticated scoping of variables and functions. These characteristics make them unsuitable for building large, modular applications. Speed is another problem with scripting languages; the high-level, fully interpreted nature of these languages often makes them quite slow.

Java offers some of the essential advantages of a scripting language, along with the added benefits of a lower-level language.[1] Incremental development with object-oriented components, combined with Java's simplicity, make it possible to develop applications rapidly and change them easily, with a short concept to implementation time. Java also comes with a large base of core classes for common tasks such as building GUIs and doing network communications. But along with these features, Java has the scalability and software-engineering advantages of more static languages. It provides a safe structure on which to build higher-level networked tools and languages.

> [1] Don't confuse Java with JavaScript. JavaScript is an object-based scripting language being developed by Netscape and is designed to create dynamic, interactive Web applications. JavaScript is a very different language from Java in most respects. For more information on JavaScript, check out Netscape's Web site (http://home.netscape.com).

As I've already said, Java is similar in design to languages like Smalltalk and Lisp. However, these languages are used mostly as research vehicles, rather than for developing large-scale systems. One reason is that they never developed a standard portable binding to operating-system services analogous to the C standard library or the Java core classes. Smalltalk is compiled to an interpreted byte-code format, and it can be dynamically compiled to native code on the fly, just like Java. But Java improves on the design by using a byte-code verifier to ensure the correctness of Java code. This verifier gives Java a performance advantage over Smalltalk because Java code requires fewer run-time checks. Java's byte-code verifier also helps with security issues, something that Smalltalk doesn't address. Smalltalk is a mature language though, and Java's designers took lessons from many of its features.

Throughout the rest of this chapter, we'll take a bird's eye view of the Java language. I'll explain what's new and what's not so new about Java; how it differs from other languages, and why.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.4 Safety of Design

You have no doubt heard a lot about the fact that Java is designed to be a safe language. But what do we mean by safe? Safe from what or whom? The security features that attract the most attention for Java are those features that make possible new types of dynamically portable software. Java provides several layers of protection from dangerously flawed code, as well as more mischievous things like viruses and trojan horses. In the next section, we'll take a look at how the Java virtual machine architecture assesses the safety of code before it's run, and how the Java class loader builds a wall around untrusted classes. These features provide the foundation for high-level security policies that allow or disallow various kinds of activities on an application-by-application basis.

In this section though, we'll look at some general features of the Java programming language. What is perhaps more important, although often overlooked in the security din, is the safety that Java provides by addressing common design and programming problems. Java is intended to be as safe as possible from the simple mistakes we make ourselves, as well as those we inherit from contractors and third-party software vendors. The goal with Java has been to keep the language simple, provide tools that have demonstrated their usefulness, and let users build more complicated facilities on top of the language when needed.

Syntactic Sweet 'n Low

Java is parsimonious in its features; simplicity rules. Compared to C, Java uses few automatic type coercions, and the ones that remain are simple and well-defined. Unlike C++, Java doesn't allow programmer-defined operator overloading. The string concatenation operator `+` is the only system-defined, overloaded operator in Java. All methods in Java are like C++ virtual methods, so overridden methods are dynamically selected at run-time.

Java doesn't have a preprocessor, so it doesn't have macros, `#define` statements, or conditional source compilation. These constructs exist in other languages primarily to support platform dependencies, so in that sense they should not be needed in Java. Another common use for conditional compilation is for debugging purposes. Debugging code can be included directly in your Java source code by making it conditional on a constant (i.e., `static` and `final`) variable. The Java compiler is smart enough to remove this code when it determines that it won't be called.

Java provides a well-defined package structure for organizing class files. The package system allows the compiler to handle most of the functionality of *make*. The compiler also works with compiled Java classes because all type information is preserved; there is no need for header files. All of this means that Java code requires little context to read. Indeed, you may sometimes find it faster to look at the Java source code than to refer to class documentation.

Java replaces some features that have been troublesome in other languages. For example, Java supports only a single inheritance class hierarchy, but allows multiple inheritance of interfaces. An interface, like an abstract class in C++, specifies the behavior of an object without defining its implementation, a powerful mechanism borrowed from Objective C. It allows a class to implement the behavior of the interface, without needing to be a subclass of the interface. Interfaces in Java eliminate the need for multiple inheritance of classes, without causing the problems associated with multiple inheritance.

As you'll see in Chapter 4, *The Java Language*, Java is a simple, yet elegant, programming language.

Type Safety and Method Binding

One attribute of a language is the kind of type checking it uses. When we categorize a language as static or dynamic we are referring to the amount of information about variable types that is known at compile time versus what is determined while the application is running.

In a strictly statically typed language like C or C++, data types are etched in stone when the source code is compiled. The compiler benefits from having enough information to enforce usage rules, so that it can catch many kinds of errors before the code is executed. The code doesn't require run-time type checking, which is advantageous because it can be compiled to be small and fast. But statically typed languages are inflexible. They don't support high-level constructs like lists and collections as naturally as languages with dynamic type checking, and they make it impossible for an application to safely import new data types while it's running.

In contrast, a dynamic language like Smalltalk or Lisp has a run-time system that manages the types of objects and performs necessary type checking while an application is executing. These kinds of languages allow for more complex behavior, and are in many respects more powerful. However, they are also generally slower, less safe, and harder to debug.

The differences in languages have been likened to the differences between kinds of automobiles.[2] Statically typed languages like C++ are analogous to a sports car--reasonably safe and fast--but useful only if you're driving on a nicely paved road. Highly dynamic languages like Smalltalk are more like an offroad vehicle: they afford you more freedom, but can be somewhat unwieldy. It can be fun (and sometimes faster) to go roaring through the back woods, but you might also get stuck in a ditch or mauled by bears.

[2] The credit for the car analogy goes to Marshall P. Cline, author of the C++ FAQ.

Another attribute of a language deals with when it binds method calls to their definitions. In an early-binding language like C or C++, the definitions of methods are normally bound at compile-time, unless the programmer specifies otherwise. Smalltalk, on the other hand, is a late-binding language because it locates the definitions of methods dynamically at run-time. Early-binding is important for performance reasons; an application can run without the overhead incurred by searching method tables at run-time. But late-binding is more flexible. It's also necessary in an object-oriented language, where a subclass can override methods in its superclass, and only the run-time system can determine which method to run.

Java provides some of the benefits of both C++ and Smalltalk; it's a statically typed, late-binding language. Every object in Java has a well-defined type that is known at compile time. This means the Java compiler can do the same kind of static type checking and usage analysis as C++. As a result, you can't assign an object to the wrong type of reference or call nonexistent methods within it. The Java compiler goes even further and prevents you from messing up and trying to use uninitialized variables.

However, Java is fully run-time typed as well. The Java run-time system keeps track of all objects and makes it possible to determine their types and relationships during execution. This means you can inspect an object at run-time to determine what it is. Unlike C or C++, casts from one type of object to another are checked by the run-time system, and it's even possible to use completely new kinds of dynamically loaded objects with a level of type safety.

Since Java is a late-binding language, all methods are like virtual methods in C++. This makes it possible for a subclass to override methods in its superclass. But Java also allows you to gain the performance benefits of early-binding by declaring (with the `final` modifier) that certain methods can't be overridden by subclassing, removing the need for run-time lookup.

Incremental Development

Java carries all data-type and method-signature information with it from its source code to its compiled byte-code form. This means that Java classes can be developed incrementally. Your own Java classes can also be used safely with classes from other sources your compiler has never seen. In other words, you can write new code that references binary class files, without losing the type safety you gain from having the source code. The Java run-time system can load new classes while an application is running, thus providing the capabilities of a dynamic linker.

A common irritation with C++ is the "fragile base class" problem. In C++, the implementation of a base class can be effectively frozen by the fact that it has many derived classes; changing the base class may require recompilation of the derived classes. This is an especially difficult problem for developers of class libraries. Java avoids this problem by dynamically locating fields within classes. As long as a class maintains a valid form of its original structure, it can evolve without breaking other classes that are derived from it or that make use of it.

Dynamic Memory Management

Some of the most important differences between Java and C or C++ involve how Java manages memory. Java eliminates ad hoc pointers and adds garbage collection and true arrays to the language. These features eliminate many otherwise insurmountable problems with safety, portability, and optimization.

Garbage collection alone should save countless programmers from the single largest source of programming errors in C or C++: explicit memory allocation and deallocation. In addition to maintaining objects in memory, the Java run-time system keeps track of all references to those objects. When an object is no longer in use, Java automatically removes it from memory. You can simply throw away references to objects you no longer use and have confidence that the system will clean them up at an appropriate time. Sun's current implementation of Java uses a conservative, mark and sweep garbage collector that runs intermittently in the background, which means that most garbage collecting takes place between mouse clicks and keyboard hits. Once you get used to garbage collection, you won't go back. Being able to write air-tight C code that juggles memory without dropping any on the floor is an important skill, but once you become addicted to Java you can "realloc" some of those brain cells to new tasks.

You may hear people say that Java doesn't have pointers. Strictly speaking, this statement is true, but it's also misleading. What Java provides are *references*--a safe kind of pointer--and Java is rife with them. A reference is a strongly typed handle for an object. All objects in Java, with the exception of primitive numeric types, are accessed through references. If necessary, you can use references to build all the normal kinds of data structures you're accustomed to building with pointers, like linked lists, trees, and so forth. The only difference is that with references you have to do so in a type-safe way.

Another important difference between a reference and a pointer is that you can't do pointer arithmetic with references. A reference is an atomic thing; you can't manipulate the value of a reference except by assigning it to an object. References are passed by value, and you can't reference an object through more than a single level of indirection. The protection of references is one of the most fundamental aspects of Java security. It means that Java code has to play by the rules; it can't peek into places it shouldn't.

Unlike C or C++ pointers, Java references can point only to class types. There are no pointers to methods. People often complain about this missing feature, but you will find that most tasks that call for pointers to methods, such as callbacks, can be accomplished using interfaces and anonymous adapter classes instead. [3]

> [3] Java 1.1 does have a `Method` class, which lets you have a reference to a method. You can use a `Method` object to construct a callback, but it's tricky.

Finally, arrays in Java are true, first-class objects. They can be dynamically allocated and assigned like other objects. Arrays know their own size and type, and although you can't directly define array classes or subclass them, they do have a well-defined inheritance relationship based on the relationship of their base types. Having true arrays in the language alleviates much of the need for pointer arithmetic like that in C or C++.

Error Handling

Java's roots are in networked devices and embedded systems. For these applications, it's important to have robust and intelligent error management. Java has a powerful exception-handling mechanism, somewhat like that in newer implementations of C++. Exceptions provide a more natural and elegant way to handle errors. Exceptions allow you to separate error-handling code from normal code, which makes for cleaner, more readable applications.

When an exception occurs, it causes the flow of program execution to be transferred to a predesignated catcher block of code. The exception carries with it an object that contains information about the situation that caused the exception. The Java compiler requires that a method either declare the exceptions it can generate or catch and deal with them itself. This promotes error information to the same level of importance as argument and return typing. As a Java programmer, you know precisely what exceptional conditions you must deal with, and you have help from the compiler in writing correct software that doesn't leave them unhandled.

Multithreading

Applications today require a high degree of parallelism. Even a very single-minded application can have a complex user interface. As machines get faster, users become more sensitive to waiting for unrelated tasks that seize control of their time. Threads provide efficient multiprocessing and distribution of tasks. Java makes threads easy to use because support for them is built into the language.

Concurrency is nice, but there's more to programming with threads than just performing multiple tasks simultaneously. In many cases, threads need to be synchronized, which can be tricky without explicit language support. Java supports synchronization based on the monitor and condition model developed by C.A.R. Hoare--a sort of lock and key system for accessing resources. A keyword, `synchronized`, designates methods for safe, serialized access within an object. Only one synchronized method within the object may run at a given time. There are also simple, primitive methods for explicit waiting and signaling between threads interested in the same object.

Learning to program with threads is an important part of learning to program in Java. See Chapter 6, *Threads* for a discussion of this topic. For complete coverage of threads, see *Java Threads*, by Scott Oaks and Henry Wong (O'Reilly & Associates).

Scalability

At the lowest level, Java programs consist of classes. Classes are intended to be small, modular components. They can be separated physically on different systems, retrieved dynamically, and even cached in various distribution schemes. Over classes, Java provides packages, a layer of structure that groups classes into functional units. Packages provide a naming convention for organizing classes and a second level of organizational control over the visibility of variables and methods in Java applications.

Within a package, a class is either publicly visible or protected from outside access. Packages form another type of scope that is closer to the application level. This lends itself to building reusable components that work together in a system. Packages also help in designing a scalable application that can grow without becoming a bird's nest of tightly coupled code dependency.

Java Compared | BOOK INDEX | Safety of Implementation

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.5 Safety of Implementation

It's one thing to create a language that prevents you from shooting yourself in the foot; it's quite another to create one that prevents others from shooting you in the foot.

Encapsulation is a technique for hiding data and behavior within a class; it's an important part of object-oriented design. It helps you write clean, modular software. In most languages however, the visibility of data items is simply part of the relationship between the programmer and the compiler. It's a matter of semantics, not an assertion about the actual security of the data in the context of the running program's environment.

When Bjarne Stroustrup chose the keyword `private` to designate hidden members of classes in C++, he was probably thinking about shielding you from the messy details of a class developer's code, not the issues of shielding that developer's classes and objects from the onslaught of someone else's viruses and trojan horses. Arbitrary casting and pointer arithmetic in C or C++ make it trivial to violate access permissions on classes without breaking the rules of the language. Consider the following code:

```
// C++

class Finances {
    private:
        char creditCardNumber[16];
        ...
    };

main() {
    Finances finances;

    // Forge a pointer to peek inside the class
    char *cardno = (char *)finances;
    printf("Card Number = %s\n", cardno);
}
```

In this little C++ drama, we have written some code that violates the encapsulation of the `Finances` class and pulls out some secret information. If this example seems unrealistic, consider how important it is to protect the foundation (system) classes of the run-time environment from similar kinds of attacks. If untrusted code can corrupt the components that provide access to real resources, such as the filesystem, the network, or the windowing system, it certainly has a chance at stealing your credit card numbers.

In Visual BASIC, it's also possible to compromise the system by peeking, poking, and, under DOS, installing interrupt handlers. Even some recent languages that have some commonalities with Java lack important security features. For example, the Apple Newton uses an object-oriented language called NewtonScript that is compiled into an interpreted byte-code format. However, NewtonScript has no concept of public and private members, so a Newton application has free reign to access any information it finds. General Magic's Telescript language is another example of a device-independent language that does not fully address security concerns.

If a Java application is to dynamically download code from an untrusted source on the Internet and run it alongside applications that might contain confidential information, protection has to extend very deep. The Java security model wraps three layers of protection around imported classes, as shown in Figure 1.3.

Figure 1.3: The Java security model

[Graphic: Figure 1-3]

At the outside, application-level security decisions are made by a security manager. A security manager controls access to system resources like the filesystem, network ports, and the windowing environment. A security manager relies on the ability of a class loader to protect basic system classes. A class loader handles loading classes from the network. At the inner level, all system security ultimately rests on the Java verifier, which guarantees the integrity of incoming classes.

The Java byte-code verifier is an integral part of the Java run-time system. Class loaders and security managers, however, are implemented by applications that load applets, such as applet viewers and Web browsers. All these pieces need to be functioning properly to ensure security in the Java environment.[4]

[4] You may have seen reports about various security flaws in Java. While these weaknesses are real, it's important to realize that they have been found in the implementations of various components, namely Sun's byte-code verifier and Netscape's class loader and security manager, not in the basic security model itself. One of the reasons Sun has released the source code for Java is to encourage people to search for weaknesses, so they can be removed.

The Verifier

Java's first line of defense is the byte-code *verifier*. The verifier reads byte-code before they are run and makes sure they are well-behaved and obey the basic rules of the Java language. A trusted Java compiler won't produce code that does otherwise. However, it's possible for a mischievous person to deliberately assemble bad code. It's the verifier's job to detect this.

Once code has been verified, it's considered safe from certain inadvertent or malicious errors. For example, verified code can't forge pointers or violate access permissions on objects. It can't perform illegal casts or use objects in ways other than they are intended. It can't even cause certain types of internal errors, such as overflowing or underflowing the operand stack. These fundamental guarantees underlie all of Java's security.

You might be wondering, isn't this kind of safety implicit in lots of interpreted languages? Well, while it's true that you shouldn't be able to corrupt the interpreter with bogus BASIC code, remember that the protection in most interpreted languages happens at a higher level. Those languages are likely to have heavyweight interpreters that do a great deal of run-time work, so they are necessarily slower and more cumbersome.

By comparison, Java byte-code is a relatively light, low-level instruction set. The ability to statically verify the Java byte-code before execution lets the Java interpreter run at full speed with full safety, without expensive run-time checks. Of course, you are always going to pay the price of running an interpreter, but that's not a serious problem with the speed of modern CPUs. Java byte-code can also be compiled on the fly to native machine code, which has even less run-time overhead.

The verifier is a type of theorem prover. It steps through the Java byte-code and applies simple, inductive rules to determine certain aspects of how the byte-code will behave. This kind of analysis is possible because compiled Java byte-code has a lot more type information stored within it than other languages of this kind. The byte-code also has to obey a few extra rules that simplify its behavior. First, most byte-code instructions operate only on individual data types. For example, with stack operations, there are separate instructions for object references and for each of the numeric types in Java. Similarly, there is a different instruction for moving each type of value into and out of a local variable.

Second, the type of object resulting from any operation is always known in advance. There are no byte-code operations that consume values and produce more than one possible type of value as output. As a result, it's always possible to look at the next instruction and its operands, and know the type of value that will result.

Because an operation always produces a known type, by looking at the starting state, it's possible to determine the types of all items on the stack and in local variables at any point in the future. The collection of all this type information at any given time is called the *type state* of the stack; this is what Java tries to analyze before it runs an application. Java doesn't know anything about the actual values of stack and variable items at this time, just what kind of items they are. However, this is enough information to enforce the security rules and to insure that objects are not manipulated illegally.

To make it feasible to analyze the type state of the stack, Java places an additional restriction on how Java byte-code instructions are executed: all paths to the same point in the code have to arrive with exactly the same type state.[5] This restriction makes it possible for the verifier to trace each branch of the code just once and still know the type state at all points. Thus, the verifier can insure that instruction types and stack value types always correspond, without actually following the execution of the code.

> [5] The implications of this rule are mainly of interest to compiler writers. The rule means that Java byte-code can't perform certain types of iterative actions within a single frame of execution. A common example would be looping and pushing values onto the stack. This is not allowed because the path of execution would return to the top of the loop with a potentially different type state on each pass, and there is no way that a static analysis of the code can determine whether it obeys the security rules.

Class Loader

Java adds a second layer of security with a *class loader*. A class loader is responsible for bringing Java binary classes that contain byte-code into the interpreter. Every application that loads classes from the network must use a class loader to handle this task.

After a class has been loaded and passed through the verifier, it remains associated with its class loader. As a result, classes are effectively partitioned into separate namespaces based on their origin. When a class references another class, the request is served by its original class loader. This means that classes retrieved from a specific source can be restricted to interact only with other classes retrieved from that same location. For example, a Java-enabled Web browser can use a class loader to build a separate space for all the classes loaded from a given uniform resource locator (URL).

The search for classes always begins with the built-in Java system classes. These classes are loaded from the locations specified by the Java interpreter's class path (see Chapter 3, *Tools of the Trade*). Classes in the class path are loaded by the system only once and can't be replaced. This means that it's impossible for an applet to replace fundamental system classes with its own versions that change their functionality.

Security Manager

Finally, a security manager is responsible for making application-level security decisions. A security manager is an object that can be installed by an application to restrict access to system resources. The security manager is consulted every time the application tries to access items like the filesystem, network ports, external processes, and the windowing environment, so the security manager can allow or deny the request.

A security manager is most useful for applications that run untrusted code as part of their normal operation. Since a Java-enabled Web browser can run applets that may be retrieved from untrusted sources on the Net, such a browser needs to install a security manager as one of its first actions. This security manager then restricts the kinds of access allowed after that point. This lets the application impose an effective level of trust before running an arbitrary piece of code. And once a security manager is installed, it can't be replaced.

A security manager can be as simple or complex as a particular application warrants. Sometimes it's sufficient simply to deny access to all resources or to general categories of services such as the filesystem or network. But it's also possible to make sophisticated decisions based on high-level information. For example, a Java-enabled Web browser could implement a security manager that lets users specify how much an applet is to be trusted or that allows or denies access to specific resources on a case-by-case basis. Of course, this assumes that the browser can determine which applets it ought to trust. We'll see how this problem is solved shortly.

The integrity of a security manager is based on the protection afforded by the lower levels of the Java security model. Without the guarantees provided by the verifier and the class loader, high-level assertions about the safety of system resources are meaningless. The safety provided by the Java byte-code verifier means that the interpreter can't be corrupted or subverted, and that Java code has to use components as they are intended. This, in turn, means that a class loader can guarantee that an application is using the core Java system classes and that these classes are the only means of accessing basic system resources. With these restrictions in place, it's possible to centralize control over those resources with a security manager.

Safety of Design | BOOK INDEX | Application and User Level Security

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

1.6 Application and User Level Security

There's a fine line between having enough power to do something useful and having all the power to do anything you want. Java provides the foundation for a secure environment in which untrusted code can be quarantined, managed, and safely executed. However, unless you are content with keeping that code in a little black box and running it just for its own benefit, you will have to grant it access to at least some system resources so that it can be useful. Every kind of access carries with it certain risks and benefits. The advantages of granting an untrusted applet access to your windowing system, for example, are that it can display information and let you interact in a useful way. The associated risks are that the applet may instead display something worthless, annoying, or offensive. Since most people can accept that level of risk, graphical applets and the World Wide Web in general are possible.

At one extreme, the simple act of running an application gives it a resource, computation time, that it may put to good use or burn frivolously. It's difficult to prevent an untrusted application from wasting your time, or even attempting a "denial of service" attack. At the other extreme, a powerful, trusted application may justifiably deserve access to all sorts of system resources (e.g., the filesystem, process creation, network interfaces); a malicious application could wreak havoc with these resources. The message here is that important and sometimes complex security issues have to be addressed.

In some situations, it may be acceptable to simply ask the user to "OK" requests. Sun's HotJava Web browser can pop up a dialog box and ask the user's permission for an applet to access an otherwise restricted file. However, we can put only so much burden on our users. An experienced person will quickly grow tired of answering questions; an inexperienced user may not even be able to answer the questions. Is it okay for me to grant an applet access to something if I don't understand what that is?

Making decisions about what is dangerous and what is not can be difficult. Even ostensibly harmless access, like displaying a window can become a threat when paired with the ability for an untrusted application to communicate off of your host. The Java `SecurityManager` provides an option to flag windows created by an untrusted application with a special, recognizable border to prevent it from impersonating another application and perhaps tricking you into revealing your password or your secret recipe collection. There is also a grey area, in which an application can do devious things that aren't quite destructive. An applet that can mail a bug report can also mail-bomb your boss. The Java language provides the tools to implement whatever security policies you want. However, what these policies will be ultimately depends on who you are, what you are doing, and where you are doing it.

To fully exploit the power of Java, we need to have some basis on which to make reasonable decisions about the level of trust an application should have. Web browsers such as HotJava start by defining a few rules and some coarse levels of security that restrict where applets may come from and what system resources they may access. These rules are sufficient to keep the waving Duke applet from clutching your password file, but they aren't sufficient for applications you'd like to trust with sensitive information. What if you want to implement a secure applet to carry a credit card number to the mall, or more likely the credit-card company? How are people to trust that the applet they are using is really secure? If it's named the "Bank of Boofa" applet, how do they know it's legit?

You might think of trusting only certain hosts for these kinds of applications. However, as Java class files begin to fill the Net, the situation will become more complicated. Hosts can be impersonated. If your communications pass through an untrusted network, you can't be sure you're talking to the intended entity. Furthermore, class files may need to be cached or retrieved through complicated distribution mechanisms. For these kinds of applications, what we really need is a mechanism for verifying the authorship and authenticity of an item and making sure that it has not been tampered with by the time that you received it. Fortunately, this is a problem solved a while ago by your friendly neighborhood cryptographers.

Signing Classes

Digital signatures provide a means of authenticating documents. Like their inky analogs, they associate a name with an item in a way that is supposed to be difficult to forge. Unlike pen on paper, though, electronic digital signatures are actually difficult to forge when used properly. By their nature, digital signatures also provide the benefit that, if authenticated, a document is known not to have been altered in transit. In other words, you can't clip out a digital signature and attach it to a new document.

The details of cryptography are a bit beyond the scope of this book but the basics are important and interesting.[6] Digital signatures are one side of the coin of public-key cryptography. Public-key algorithms rely on the fundamental mathematical difficulty of factoring arbitrarily large numbers. In a public-key system, there are two pieces of information: a public key (as you might have guessed) and a private one. These keys have a special asymmetric relationship such that a message encrypted with one key can be decrypted only by knowing the other. This means that by giving you my public key, you can send me messages that only I can read. No one else, including you, has enough information to decrypt the encoded message, so it's safe to send it over untrusted networks. Now, by reversing this process, I can encrypt something with my private key so that anyone can use my public key to read the message. The important thing in this case is that the task of creating such a message without the private key is just as difficult as decoding the message in the first scenario. Since no one else knows my private key, only the real me could have sent the message. This is the basis for digital signatures. For Java, this means that we can tell a browser "I trust applets signed by John Doe"; if the browser succeeds in decoding an applet using John Doe's public key, it knows that the applet really came from John Doe, and therefore can be allowed greater privileges.

This process can be used to authenticate Java class files and other types of objects sent over the network. The author of a class signs the code with a digital signature, and we authenticate it when we retrieve it. Now we know that we have the authentic class, or do we? There is one problem that a digital signature alone doesn't solve: at some point we still have to assume we have the author's authentic public key. This is where a key-certification agency comes into play.

A key-certification agency validates a key by issuing a certificate that lists a name and an official public key. The certificate is signed with the agency's own digital signature. The agency presumably has a well-known public key to verify the certificate. Of course, this doesn't solve the problem entirely, but it reduces the number of people you have to trust and the amount of information you have to transport reliably. Presumably the agency is a reputable organization, its private keys are well guarded, and it certifies keys only after some kind of real-world validation such as person-to-person contact.

The most recent Java release (1.1) contains the tools you need to work with signed classes. You can sign Java classes; you can tell the HotJava browser whose classes you trust (and how much you trust them). Other browsers, like Netscape Navigator, should support signed classes in the future. You can also use the security API in your own Java programs to handle sensitive data safely. The important thing is, as always, to know who you are dealing with and what kind of software and security you have in place before sending any kind of confidential information over the Net. Don't become paranoid, just keep yourself informed so that you can weigh the risks and the benefits.

1.7 Java and the World Wide Web

> Alice was beginning to get very tired of sitting by her sister on the bank, and of having nothing to do: once or twice she had peeped into the book her sister was reading, but it had no pictures or conversations in it, "and what is the use of a book," thought Alice, "without pictures or conversations?"
>
> --*Alice in Wonderland*

The application-level safety features of Java make it possible to develop new kinds of applications not necessarily feasible before now. A Web browser that implements the Java run-time system can incorporate Java applets as executable content inside of documents. This means that Web pages can contain not only static hypertext information but also full-fledged interactive applications. The added potential for use of the WWW is enormous. A user can retrieve and use software simply by navigating with a Web browser. Formerly static information can be paired with portable software for interpreting and using the information. Instead of just providing some data for a spreadsheet, for example, a Web document might contain a fully functional spreadsheet application embedded within it that allows users to view and manipulate the information.

Applets

The term *applet* is used to mean a small, subordinate, or embeddable application. By embeddable, I mean it's designed to be run and used within the context of a larger system. In that sense, most programs are embedded within a computer's operating system. An operating system manages its native applications in a variety of ways: it starts, stops, suspends, and synchronizes applications; it provides them with certain standard resources; and it protects them from one another by partitioning their environments.

In this book, I'll be describing Java applets, which are Java applications meant to be embedded in and controlled by a larger application, such as a Java-enabled Web browser or an applet viewer. To include an applet as executable content in a Web document, you use a special HTML tag. The `<applet>` tag points to an applet and provides configuration information about the applet.

As far as the Web browser model is concerned, an applet is just another type of object to display. Browsers make a distinction between items presented inline and items anchored via hypertext links and made available by external means, such as a viewer or helper application. If you download an MPEG video clip, for instance, and your browser doesn't natively understand MPEG, it will look for a helper application (an MPEG player) to pass the information to. Java-enabled Web browsers generally execute applets inline, in the context of a particular document, as shown in Figure 1.4. However, less capable browsers could initially provide some support for Java applets through an external viewer.

Figure 1.4: Applets in a Web document

[Graphic: Figure 1-4]

A Java applet is a compiled Java program, composed of classes just like any Java program. While a simple applet may consist of only a single class, most large applets should be broken into many classes. Each class is stored in a separate class file. The class files for an applet are retrieved from the network as they are needed. A large applet doesn't need to retrieve all its parts or all its data before beginning to interact with the user. Well-designed applets can take advantage of multithreading to wait for certain resources in the background, while performing other activities.

An applet has a four-part life cycle. When an applet is initially loaded by a Web browser, it's asked to initialize itself. The applet is then informed each time it's displayed and each time it's no longer visible to the user. Finally, the applet is told when it's no longer needed, so that it can clean up after itself. During its lifetime, an applet may start and suspend itself, do work, communicate with other applications, and interact with the Web browser.

Applets are autonomous programs, but they are confined within the walls of a Web browser or applet viewer, and have to play by its rules. I'll be discussing the details of what applets can and can't do as we explore features of the Java language. However, under the most conservative security policies, an applet can interact only with the user and can only communicate over the network with the host from which it originated. Other types of activities, like accessing files or interacting directly with outside applications, are typically prevented by the security manager that is part of the Web browser or applet viewer. But aside from these restrictions, there is no fundamental difference between a Java applet and a standalone Java application.

New Kinds of Applications

Sun's HotJava Web browser is written entirely in Java. Because it's a Java application, HotJava is immediately available on any platform with the Java run-time system. This goes a long way towards the goal of a Web browser serving as a universal access point for resources on the Net. And where one Web browser leads the way, more will surely follow.

In addition to displaying Java applets as executable content in Web pages, the HotJava application dynamically extends itself by loading Java code from the Net. HotJava uses *protocol handlers* and *content handlers* to provide this functionality.[7] Protocol handlers and content handlers are classes in the Java API that let an application implement new types of URLs and interpret the objects retrieved from them. A Web browser that supports this functionality can load handlers from a remote location and effectively upgrade itself on the fly to use new protocols and access new kinds of information.

[7] Downloadable content and protocol handlers are not supported in HotJava 1.0, but will be supported in a future release.

Like applets, content handlers and protocol handlers can be served by a Web site, along with the information they interpret. As an example, consider the new Portable Network Graphics (PNG) format, a freely distributable alternative to GIF. By supplying a PNG content handler along with PNG images on our server, we give users the ability to use the new image format, just as they would a built-in format. We don't have to create a new standard and force every Web browser to support the new format. Instead, the first time a user loads a document referencing a PNG image from our site, the Web browser will realize it doesn't understand the object and will ask the server if it has a content handler for it. Since we've provided a content handler, the browser can load it and then use it to interpret and display the image dynamically.

In a similar manner, protocol handlers allow a Web browser to start speaking a new protocol with the server. This is especially useful for things like security protocols. If we invent a revolutionary new cryptographic protocol late one night, all we have to do is implement it in the form of a protocol handler and place it on our server. We can then start using URLs that point through our new protocol at objects on our server, and people can immediately begin using it.

These scenarios describe just a few things that safe, transportable code will allow. We will undoubtedly see many other new breeds of application we can't even begin to anticipate.

New Kinds of Media

When it was first released, Java quickly achieved a reputation for multimedia capabilities. Frankly, this wasn't really deserved. At that point, Java provided facilities for doing simple animations and playing audio. You could even animate and play audio simultaneously, though you couldn't synchronize the two. Still, this was a significant advance for the Web, and people thought it was pretty impressive.

JavaSoft is now working on real media features, which go far beyond anything that has yet been seen on the Web. This includes CD quality sound, 3D animation, media players that synchronize audio and video, speech synthesis and recognition, and more. These new features aren't yet in Java 1.1, but will make their way into Java over the next eighteen months. In short, if you were impressed by Java 1.0, you haven't seen anything yet. Java's multimedia capabilities will be taking shape over the next two years.

New Software Development Models

For some time now, people have been using visual development environments to develop user interfaces. These environments let you generate applications by moving components around on the screen, connecting components to each other, and so on. In short, designing a user interface is a lot more like drawing a picture than like writing code.

For visual development environments to work well, you need to be able to create reusable software components. That's what Java Beans are all about. The JavaBeans architecture defines a way to package software as reusable building blocks. A graphical development tool can figure out a component's capabilities, customize the component, and connect it to other components to build applications. JavaBeans takes the idea of graphical development a step further. Beans aren't limited to visible, user interface components: you can have Beans that are entirely invisible, and whose job is purely computational. For example, you could have a Bean that did database access; you could connect this to a Bean that let the user request information from the database; and you could use another Bean to display the result. Or you could have a set of Beans that implemented the functions in a mathematical library; you could then do numerical analysis by connecting different functions to each other. In either case, you could "write" programs without writing a single line of code. Granted, someone would have to write the Beans in the first place; but that's a much smaller task, and we expect markets to develop for "off the shelf" Bean collections.

Before it can use a Bean, an application builder must find out the Bean's capabilities. There are a few ways it can do this; the simplest is called "reflection". To write a Bean that uses reflection, all you need to do is follow some simple design patterns. Let's say that you're writing a Bean that is capable of changing its color. Then you would write two methods that report the current color and change its value:

```
...
private Color c;
public Color getMyColor() { return c; }
public void setMyColor( Color c) { this.c = c; }
```

These methods follow some well defined conventions (design patterns) that let the graphical interface builder (or any other tool that wants to do the work) analyze the Bean, and discover that it has a property called `MyColor`, that the value of this property is a `Color` object, and that the methods `getMyColor()` and `setMyColor()` should be used to change its value.

If they need to, Beans can provide additional information using a process called "introspection". But even without introspection, you can see that a graphical development tool can easily analyze a Bean, figure out what it can do, and let a user change the Bean's properties without writing any code.

Of course, once a development tool has customized a Bean and connected it to other Beans, it needs a way to save the result. A process called "serialization" lets a tool save the Bean's current state, along with any extra code it has written to stitch Beans together in an application.

Visual development tools that support Java Beans include Borland's JBuilder (http://www.borland.com), Symantec's Visual Cafe (http://www.symantec.com), and SunSoft's Java Workshop. By using a "bridge", Java Beans will be able to interact with other component environments, including ActiveX, OpenDoc, and LiveConnect. A beta version of the ActiveX bridge is currently available.

1.8 Java as a General Application Language

The Java applet API is a framework that allows Java-enabled Web browsers to manage and display embedded Java applications within WWW documents. However, Java is more than just a tool for building transportable multimedia applications. Java is a powerful, general-purpose programming language that just happens to be safe and architecture independent. Standalone Java applications are not subject to the restrictions placed on applets; they can do all activities that software written in a language like C does.

Any software that implements the Java run-time system can run Java applications. Applications written in Java can be large or small, standalone or component-like, as in other languages. Java applets are different from other Java applications only in that they expect to be managed by a larger application. In this book, we will build examples of both applets and standalone Java applications. With the exception of the few things applets can't do, such as access files, all of the tools we examine in this book apply to both applets and standalone Java applications.

1.9 A Java Road Map

With everything that's going on, it's hard to keep track of what's available now, what's promised, and what has been around for some time. Here's a road map that tries to impose some order on Java's past, present, and future.

The Past: Java 1.0

Java 1.0 provided the basic framework for Java development: the language itself, plus packages that let you write applets and simple applications. Java 1.0 is officially obsolete, though it will be some time before vendors catch up with the new release.

The Present: Java 1.1

Java 1.1 is the current version of Java. It incorporates major improvements in the AWT package (Java's windowing facility). It also adds many completely new features, including:

JDBC

> A general facility for interacting with databases.

RMI

> Remote Method Invocation: a facility that lets you call methods that are provided by a server running somewhere else on the network.

JavaBeans

> Java's component architecture, which we discussed earlier.

Security

A facility for cryptography; this is the basis for signed classes, which we discussed earlier.

Internationalization

The ability to write programs that adapt themselves to the language the user wants to use; the program automatically displays text in the appropriate language.

Java 1.1 incorporates many other improvements and new features, but these are the most important. As of May, 1997, most Web browsers haven't yet incorporated Java 1.1, but they will as soon as possible. In this book, we'll try to give you a taste of as many features as possible; unfortunately for us, the Java environment has become so rich that it's impossible to cover everything in a single book.

The Future

We've mentioned a few of the things that are in the pipeline, including high quality audio, advanced 3D rendering, and speech synthesis. Other things to look forward to are class libraries for advanced 2D graphics (Java 2D), electronic commerce (JECF), managing network devices (Java Management), naming and directory services (JNDI), telephony (JTAPI), and writing network servers (Java Server). Beta versions of some of these facilities are available now.

We're also starting to see new kinds of computing devices that incorporate Java. Network computers that are based on Java and use the HotJava browser as their user interface are already available, as are "smart cards": credit card-like devices with a Java processor built in. You can expect to see Java incorporated into PDAs, telephones, and many other devices.

Java as a General Application Language | BOOK INDEX | Availability

1.10 Availability

By the time you read this book, you should have several choices for Java development environments and run-time systems. As this book goes to press, Sun's Java Development Kit (JDK) 1.1 is available for Solaris, Windows NT, and Windows 95. The JDK provides an interpreter and a compiler for building general-purpose Java applications. A beta version of JDK 1.1 for the Macintosh will be available later in 1997. Visit Sun's Java Web site, http://www.javasoft.com/ for more information about the JDK. There are also a number of JDK ports for various platforms. Some of the most significant platforms are Novell, HP-UX, OSF/1 (including Digital UNIX), Silicon Graphics' IRIX, and Linux. For more information, see the Web pages maintained by the vendor you're interested in. JavaSoft maintains a Web page summarizing porting efforts at http://www.javasoft.com/products/jdk/jdk-ports.html. Another good source for current information is the Java FAQ from the comp.lang.java newsgroup.

There are efforts under way to produce a free clone of Java, redistributable in source form. The Java Open Language Toolkit (JOLT) Project is working to assemble a high-quality Java implementation that will pass Sun's validation tests and earn a Java stamp. The JOLT Project Web page is accessible from http://www.redhat.com/.

The Netscape Navigator Web browser comes with its own implementation of the Java run-time system that runs Java applets. Netscape also provides a `-java` switch that lets you execute Java applications (including the Java compiler) and applets and run nongraphical applications. Netscape's Web site is located at http://home.netscape.com/. Check there for information on the latest version of Netscape Navigator.

2.2 Hello Web! II: The Sequel

Let's make our applet a little more interactive, shall we? The following improvement, `HelloWeb2`, allows us to drag the message around with the mouse. `HelloWeb2` is also customizable. It takes the text of its message from a parameter of the `<applet>` tag of the HTML document.

`HelloWeb2` is a new applet--another subclass of the `Applet` class. In that sense, it's a sibling of `HelloWeb`. Having just seen inheritance at work, you might wonder why we aren't creating a subclass of `HelloWeb` and exploiting inheritance to build upon our previous example and extend its functionality. Well, in this case, that would not necessarily be an advantage, and for clarity we simply start over.[2] Here is `HelloWeb2`:

[2] You are left to consider whether such a subclassing would even make sense. Should `HelloWeb2` really be a kind of `HelloWeb`? Are we looking for refinement or just code reuse?

```
import java.applet.Applet;
import java.awt.*;
import java.awt.event.*;
public class HelloWeb2 extends Applet implements MouseMotionListener {
    int messageX = 125, messageY = 95;
    String theMessage;

    public void init() {
        theMessage = getParameter("message");
        addMouseMotionListener(this);
    }

    public void paint( Graphics graphics ) {
        graphics.drawString( theMessage, messageX, messageY );
    }
    public void mouseDragged( MouseEvent e ) {
        messageX = e.getX();
        messageY = e.getY();
        repaint();
    }
    public void mouseMoved( MouseEvent e ) { }
}
```

Place the text of this example in a file called *HelloWeb2.java* and compile it as before. You should get a new class file, *HelloWeb2.class*, as a result. We need to create a new `<applet>` tag for `HelloWeb2`. You can either create another HTML document (copy *HelloWeb.html* and modify it) or simply add a second `<applet>` tag to the existing *HelloWeb.html* file. The `<applet>` tag for `HelloWeb2` has to use a parameter; it should look like:

```
<applet code=HelloWeb2 width=300 height=200>
<param name="message" value="Hello Web!" >
</applet>
```

Feel free to substitute your own salacious comment for the value of `message`.

Run this applet in your Java-enabled Web browser, and enjoy many hours of fun, dragging the text around with your mouse.

Import

So, what have we added? First you may notice that a few lines are now hovering above our class:

```
import java.applet.Applet;
import java.awt.*;
import java.awt.event.*;
public class HelloWeb2 extends Applet implements MouseMotionListener {
...
```

The `import` statement lists external classes to use in this file and tells the compiler where to look for them. In our first `HellowWeb` example, we designated the `Applet` class as the superclass of `HelloWeb`. `Applet` was not defined by us and the compiler therefore had to look elsewhere for it. In that case, we referred to `Applet` by its fully qualified name, `java.applet.Applet`, which told the compiler that `Applet` belongs to the `java.applet` package so it knew where to find it.

The `import` statement is really just a convenience; by importing `java.applet.Applet` in our newer example, we tell the compiler up front we are using this class and, thereafter in this file, we can simply refer to it as `Applet`. The second import statement makes use of the wildcard "*" to tell the compiler to import all of the classes in the `java.awt` package. But don't worry, the compiled code doesn't contain any excess baggage. Java doesn't do things like that. In fact, compiled Java classes don't contain other classes at all; they simply note their relationships. Our current example uses only the `java.awt.Graphics` class. However, we are anticipating using several more classes from this package in the upcoming examples. We also import all the classes from the package `java.awt.event`; these classes provide the `Event` objects that we use to communicate with the user. By listening for events, we find out when the user moved the mouse, clicked a button, and so on. Notice that importing `java.awt.*` doesn't automatically import the event package. The star only imports the classes in a particular package, not other packages.

The `import` statement may seem a bit like the C or C++ preprocessor `#include` statement, which injects header files into programs at the appropriate places. This is not true; there are no header files in Java. Unlike compiled C or C++ libraries, Java binary class files contain all necessary type information about the classes, methods, and variables they contain, obviating the need for prototyping.

Instance Variables

We have added some variables to our example:

```
public class HelloWeb2 extends Applet {
    int messageX = 125, messageY = 95;
    String theMessage;
...
```

`messageX` and `messageY` are integers that hold the current coordinates of our movable message. They are initialized to default values, which should place a message of our length somewhere near the center of the applet. Java integers are always 32-bit signed numbers. There is no fretting about what architecture your code is running on; numeric types in Java are precisely defined. The variable `theMessage` is of type `String` and can hold instances of the `String` class.

You should note that these three variables are declared inside the braces of the class definition, but not inside any particular method in that class. These variables are called *instance variables* because they belong to the entire class, and copies of them appear in each separate instance of the class. Instance variables are always visible (usable) in any of the methods inside their class. Depending on their modifiers, they may also be accessible from outside the class.

Unless otherwise initialized, instance variables are set to a default value of `0` (zero), `false`, or `null`. Numeric types are set to zero, `boolean` variables are set to `false`, and class type variables always have their value set to `null`, which means "no value." Attempting to use an object with a `null` value results in a run-time error.

Instance variables differ from method arguments and other variables that are declared inside of a single method. The latter are called *local variables*. They are effectively private variables that can be seen only by code inside the method. Java doesn't initialize local variables, so you must assign values yourself. If you try to use a local variable that has not yet been assigned a value, your code will generate a compile-time error. Local variables live only as long as the method is executing and then disappear (which is fine since nothing outside of the method can see them anyway). Each time the method is invoked, its local variables are recreated and must be assigned values.

Methods

We have made some changes to our previously stodgy `paint()` method. All of the arguments in the call to `drawString()` are now variables.

Several new methods have appeared in our class. Like `paint()`, these are methods of the base `Applet` class we override to add our own functionality. `init()` is an important method of the `Applet` class. It's called once, when our applet is created, to give us an opportunity to do any work needed to set up shop. `init()` is a good place to allocate resources and perform other activities that need happen only once in the lifetime of the applet. A Java-enabled Web browser calls `init()` when it prepares to place the `Applet` on a page.

Our overridden `init()` method does two things; it sets the text of the `theMessage` instance variable, and it tells the system "Hey, I'm interested in anything that happens involving the mouse":

```
public void init() {
    theMessage = getParameter("message");
    addMouseMotionListener(this);
}
```

When an applet is instantiated, the parameters given in the `<applet>` tag of the HTML document are stored in a table and made available through the `getParameter()` method. Given the name of a parameter, this method returns the value as a `String` object. If the name is not found, it returns a `null` value.

So what, you may ask, is the type of the argument to the `getParameter()` method? It, too, is a `String`. With a little magic from the Java compiler, quoted strings in Java source code are turned into `String` objects. A bit of funny-business is going on here, but it's simply for convenience. (See Chapter 7, *Basic Utility Classes* for a complete discussion of the `String` class.)

`getParameter()` is a public method we inherited from the `Applet` class. We can use it from any of our methods. Note that the `getParameter()` method is invoked directly by name; there is no object name prepended to it with a dot. If a method exists in our class, or is inherited from a superclass, we can call it directly by name.

In addition, we can use a special read-only variable, called `this`, to explicitly refer to our object. A method can use `this` to refer to the instance of the object that holds it. The following two statements are therefore equivalent:

```
theMessage = getParameter("message");
```

or

```
theMessage = this.getParameter("message");
```

I'll always use the shorter form. We will need the `this` variable later when we have to pass a reference to our object to a method in another class. We often do this so that methods in another class can give us a call back later or can watch our public variables.

The other method that we call in `init()` is `addMouseMotionListener()`. This method is part of the event mechanism, which we discuss next.

Events

The last two methods of `HelloWeb2` let us get information from the mouse. Each time the user performs an action, such as hitting a key on the keyboard, moving the mouse, or perhaps banging his or her head against a touch-sensitive screen, Java generates an *event*. An event represents an action that has occurred; it contains information about the action, such as its time and location. Most events are associated with a particular graphical user interface (GUI) component in an application. A keystroke, for instance, could correspond to a character being typed into a particular text entry field. Pressing a mouse button could cause a certain graphical button on the screen to activate. Even just moving the mouse within a certain area of the screen could be intended to trigger effects such as highlighting or changing the cursor to a special mouse cursor.

The way events work is one of the biggest changes between Java 1.0 and Java 1.1. We're going to talk about the Java 1.1 events only; they're a big improvement, and there's no sense in learning yesterday's news. In Java 1.1, there are many different event classes: `MouseEvent`, `KeyEvent`, `ActionEvent`, and many others. For the most part, the meaning of these events is fairly intuitive. A `MouseEvent` occurs when the user does something with the mouse, a `KeyEvent` occurs when the user types a key, and so on. `ActionEvent` is a little special; we'll see it at work in our third applet. For now, we'll focus on dealing with a `MouseEvent`.

The various GUI components in Java generate events. For example, if you click the mouse inside an applet, the applet generates a mouse event. (In the future, we will probably see events as a general purpose way to communicate between Java objects; for the moment, let's limit ourselves to the simplest case.) In Java 1.1, any object can ask to receive the events generated by some other component. We call the object that wants to receive events a "listener." To declare that it wants to receive some component's mouse motion events, you call that component's `addMouseMotionListener()` method. That's what our applet is doing in `init()`. In this case, the applet is calling its own `addMouseMotionListener()` method, with the argument `this`, meaning "I want to receive my own mouse motion events." (For the time being, we're ignoring a minor distinction between "mouse events" and "mouse motion events." Suffice it to say that in this example, we only care about mouse motions.)

That's how we register to receive events. But how do we actually get them? That's what the two remaining methods in our applet are for. The `mouseDragged()` method is called automatically whenever the user drags the mouse--that is, moves the mouse with any button pressed. The `mouseMoved()` method is called whenever the user moves the mouse without pressing a button. Our `mouseMoved()` method is simple: it doesn't do anything. We're ignoring simple mouse motions.

`mouseDragged()` has a bit more meat to it. It is called repeatedly to give us updates on the position of the mouse. Here it is:

```
    public void mouseDragged( MouseEvent e ) {
        messageX = e.getX();
        messageY = e.getY();
        repaint();
    }
```

The first argument to `mouseDragged()` is a `MouseEvent` object, `e`, that contains all the information we need to know about this event. We ask the `MouseEvent` to tell us the `x` and `y` coordinates of the mouse's current position by calling its `getX()` and `getY()` methods. These are saved in the `messageX` and `messageY` instance variables. Now, having changed the coordinates for the message, we would like `HelloWeb2` to redraw itself. We do this by calling `repaint()`, which asks the system to redraw the screen at a later time. We can't call `paint()` directly because we don't have a graphics context to pass to it.

The real beauty of this event model is that you only have to handle the kinds of events you want. If you don't care about keyboard events, you just don't register a listener for them; the user can type all he or she wants, and you won't be bothered. Java doesn't go around asking potential recipients whether they might be interested in some event, as it did in older versions. If there are no listeners for a particular kind of event, Java won't even generate it. The result is that event handling in Java 1.1 is quite efficient.

I've danced around one question that should be bothering you by now: how does the system know to call `mouseDragged()` and `mouseMoved()`? And why do we have to supply a `mouseMoved()` method that doesn't do anything? The answer to these questions has to do with "interfaces." We'll discuss interfaces after clearing up some unfinished business with `repaint()`.

The repaint() Method

We can use the `repaint()` method of the `Applet` class to request our applet be redrawn. `repaint()` causes the Java windowing system to schedule a call to our `paint()` method at the next possible time; Java supplies the necessary `Graphics` object, as shown in Figure 2.5.

Figure 2.5: Invoking the repaint() method

[Graphic: Figure 2-5]

This mode of operation isn't just an inconvenience brought about by not having the right graphics context handy at the moment. The foremost advantage to this mode of operation is that the repainting is handled by someone else, while we are free to go about our business. The Java system has a separate, dedicated thread of execution that handles all `repaint()` requests. It can schedule and consolidate `repaint()` requests as necessary, which helps to prevent the windowing system from being overwhelmed during painting-intensive situations like scrolling. Another advantage is that all of the painting functionality can be kept in our `paint()` method; we aren't tempted to spread it throughout the application.

Interfaces

Now it's time to face up to the question I avoided earlier: how does the system know to call `mouseDragged()` when a mouse event occurs? Is it simply a matter of knowing that `mouseDragged()` is some magic name that our event handling method must have? No; the answer to the question lies in the discussion of interfaces, which are one of the most important features of the Java language.

The first sign of an interface comes on the line of code that introduces the `HelloWeb2` applet: we say that the applet implements `MouseMotionListener`. `MouseMotionListener` is an interface that the applet implements. Essentially, it's a list of methods that the applet must have; this particular interface requires our applet to have methods called `mouseDragged()` and `mouseMoved()`. The interface doesn't say what these methods have to do--and indeed, `mouseMoved()` doesn't do anything. It does say that the methods must take a `MouseEvent` as an argument and return `void` (i.e., no return value).

Another way of looking at an interface is as a contract between you, the code developer, and the compiler. By saying that your applet implements the `MouseMotionListener` interface, you're saying that these methods will be available for other parts of the system to call. If you don't provide them, the compiler will notice and give you an error message.

But that's not the only impact interfaces have on this program. An interface also acts like a class. For example, a method could return a `MouseMotionListener`, or take a `MouseMotionListener` as an argument. This means that you don't care about the object's class; the only requirement is that the object implement the given interface. In fact, that's exactly what the method `addMouseMotionListener()` does. If you look up the documentation for this method, you'll find that it takes a `MouseMotionListener` as an argument. The argument we pass is `this`, the applet itself. The fact that it's an applet is irrelevant, it could be a `Cookie`, an `Aardvark`, or any other class we dream up. What is important is that it implements `MouseMotionListener`, and thus declares that it will have the two named methods. That's why we need a `mouseMoved()` method, even though the one we supplied doesn't do anything: the `MouseMotionListener` interface says we have to have one.

In other languages, you'd handle this problem by passing a function pointer; for example, in C, the argument to `addMouseMotionListener()` might be a pointer to the function you want to have called when an event occurs. This technique is called a "callback." For security reasons, the Java language has eliminated function pointers. Instead, we use interfaces to make contracts between classes and the compiler. (Some new features of the language make it easier to do something similar to a callback, but that's beyond the present discussion.)

The Java distribution comes with many interfaces that define what classes have to do in various situations. Furthermore, in Chapter 5, *Objects in Java*, you'll see how to define your own interfaces. It turns out that this idea of a contract between the compiler and a class is very important. There are many situations like the one we just saw, where you don't care what class something is, you just care that it has some capability, like listening for mouse events. Interfaces give you a way of acting on objects based on their capabilities, without knowing or caring about their actual type.

Furthermore, interfaces provide an important escape clause to the rule that any new class can only extend a single class (formally called "single inheritance"). They provide most of the advantages of multiple inheritance (a feature of languages like C++) without the confusion. A class in Java can only extend one class, but can implement as many interfaces as it wants; our next applet will implement two interfaces, and the final example in this chapter will implement three. In many ways, interfaces are almost like classes, but not quite. They can be used as data types, they can even extend other interfaces (but not classes), and can be inherited by classes (if class A implements interface B, subclasses of A also implement B). The crucial difference is that applets don't actually inherit methods from interfaces; the interfaces only specify the methods the applet must have.

2.3 Hello Web! III: The Button Strikes!

Well, now that we have those concepts under control, we can move on to some fun stuff. `HelloWeb3` brings us a new graphical interface component: the `Button`. We add a `Button` component to our applet that changes the color of our text each time the button is pressed. Our new example is shown below.

```
import java.applet.Applet;
import java.awt.*;
import java.awt.event.*;
public class HelloWeb3 extends Applet
    implements MouseMotionListener, ActionListener {
    int messageX = 125, messageY = 95;
    String theMessage;
    Button theButton;
    int colorIndex = 0;
    static Color[] someColors = {
        Color.black, Color.red, Color.green, Color.blue, Color.magenta };

    public void init() {
        theMessage = getParameter("message");
        theButton = new Button("Change Color");
        add(theButton);
        addMouseMotionListener(this);
        theButton.addActionListener(this);
    }

    public void paint( Graphics gc ) {
        gc.drawString( theMessage, messageX, messageY );
    }
    public void mouseDragged( MouseEvent e ) {
        messageX = e.getX();
        messageY = e.getY();
        repaint();
    }
    public void mouseMoved( MouseEvent e ) { }
    public void actionPerformed( ActionEvent e ) {
        if ( e.getSource() == theButton ) {
            changeColor();
        }
    }
    synchronized private void changeColor() {
        if ( ++colorIndex == someColors.length )
            colorIndex = 0;
        setForeground( currentColor() );
        repaint();
    }
    synchronized private Color currentColor() {
        return someColors[ colorIndex ];
    }
}
```

Create `HelloWeb3` just as the other applets and put an `<applet>` tag referencing it in an HTML document. An `<applet>` tag just like the one for `HelloWeb2` will do nicely. Run the example, and you should see the display shown in Figure 2.6. Drag the text. Each time you press the button the color should change. Call your friends! They should be duly impressed.

Figure 2.6: Hello Web! III

[Graphic: Figure 2-6]

The New Operator

So what have we added this time? Well, for starters we have a new variable:

```
Button theButton;
```

The `theButton` variable is of type `Button` and is going to hold an instance of the `java.awt.Button` class. The `Button` class, as you might expect, represents a graphical button, which should look like other buttons in your windowing system.

Two additional lines in `init()` actually create the button and cause it to be displayed in our applet:

```
theButton = new Button("Change Color");
add(theButton);
```

The first line brings us to something new. The `new` keyword is used to create an instance of a class. Recall that the variable we have declared is just an empty reference and doesn't yet point to a real object--in this case, an instance of the `Button` class. This is a fundamental and important concept. We have dealt with objects previously in our examples. We have assigned them to variables, and we have called methods in them. So far, however, these objects have always been handed to us ready to go, and we have not had to explicitly create them ourselves. In the case of our `paint()` method, we were given a `Graphics` object with which to draw. The system created this instance of the `Graphics` class for our area of the screen and passed it to us in the parameter variable `gc`. Our `theMessage` variable is of type `String`, and we used it to hold a `String` that was returned by the `getParameter()` method. In each case, some other method instantiated (created a new instance of) the class for us.

The closest we came to actually instantiating an object was when we passed the name of the HTML `<applet>` parameter as an argument to the `getParameter()` method. In that case, we created a `String` object and passed it as the argument, but we did it in a rather sneaky fashion. As I mentioned previously, `String` objects have special status in the Java language. Because strings are used so frequently, the Java compiler creates an instance of the `String` class for us whenever it comes across quoted text in our source code. `String` objects are, in all other respects, normal objects. (See Chapter 7, *Basic Utility Classes*.)

The `new` operator provides the general mechanism for instantiating objects. It's the feature of the Java language that creates a new instance of a specified class. It arranges for Java to allocate storage for the object and then calls the constructor method of the objects' class to initialize it.

Constructors

A *constructor* is a special method that is called to set up a new instance of a class. When a new object is created, Java allocates storage for it, sets variables to their default values, and then calls the constructor method for the class to do whatever application-level setup is required.

A constructor method looks like a method with the same name as its class. For example, the constructor for the `Button` class is called `Button()`. Constructors don't have a return type; by definition they return an object of that class. But like other methods, constructors can take arguments. Their sole mission in life is to configure and initialize newly born class instances, possibly using whatever information is passed to them in parameters.

It's important to understand the difference between a constructor and a method like our `init()` method. Constructors are special methods of a class that help set up and initialize an instance of a class when it's first created. The `init()` method of the `Applet` class serves a very similar purpose; however, it's quite different. Constructors are a feature of the Java language. Every class, including `Applet`, has constructors. `init()`, however, is just a method of the `Applet` class like any other. It's an application-level phenomenon that happens to perform initialization.

An object is created by using the `new` operator with the constructor for the class and any necessary arguments. The resulting object instance is returned as a value. In our example, we create a new instance of `Button` and assign it to our `theButton` variable:

```
theButton = new Button("Change Color");
```

This `Button` constructor takes a `String` as an argument and, as it turns out, uses it to set the label of the button on the screen. A class could also, of course, provide methods that allow us to configure an object manually after it's created or to change its configuration at a later time. Many classes do both; the constructor simply takes its arguments and passes them to the appropriate methods. The `Button` class, for example, has a public method, `setLabel()`, that allows us to set a `Button`'s label at any time. Constructors with parameters are therefore a convenience that allows a sort of short hand to set up a new object.

Method Overloading

I said this `Button` constructor because there could be more than one. A class can have multiple constructors, each taking different parameters and possibly using them to do different kinds of setup. When there are multiple constructors for a class, Java chooses the correct one based on the types of arguments that are passed to it. We call the `Button` constructor and pass it a `String` argument, so Java locates the constructor method of the `Button` class that takes a single `String` argument and uses it to set up the object. This is called *method overloading*. All methods in Java, not just constructors, can be overloaded; this is one aspect of the object-oriented programming principle of polymorphism.

A constructor method that takes no arguments is called the *default constructor*. As you'll see in Chapter 7, *Basic Utility Classes*, default constructors play a special role in the initialization of inherited class members.

Garbage Collection

I've told you how to create a new object with the `new` operator, but I haven't said anything about how to get rid of an object when you are done with it. If you are a C programmer, you're probably wondering why not. The reason is that you don't have to do anything to get rid of objects when you are done with them.

The Java run-time system uses a *garbage collection* mechanism to deal with objects no longer in use. The garbage collector sweeps up objects not referenced by any variables and removes them from memory. Garbage collection is one of the most important features of Java. It frees you from the error-prone task of having to worry about details of memory allocation and deallocation.

Components

I have used the terms *component* and *container* somewhat loosely to describe graphical elements of Java applications. However, you may recall from Figure 2.3 that these terms are the names of actual classes in the `java.awt` package.

`Component` is a base class from which all of Java's GUI components are derived. It contains variables that represent the location, shape, general appearance, and status of the object, as well as methods for basic painting and event handling. The familiar `paint()` method we have been using in our example is actually inherited from the `Component` class. `Applet` is, of course, a kind of `Component` and inherits all of its public members, just as other (perhaps simpler) types of GUI components do.

The `Button` class is also derived from `Component` and therefore shares this functionality. This means that the developer of the `Button` class had methods like `paint()` available with which to implement the behavior of the `Button` object, just as we did when creating our applet. What's exciting is that we are perfectly free to further subclass components like `Button` and override their behavior to create our own special types of user-interface components.

Both `Button` and `Applet` are, in this respect, equivalent types of things. However, the `Applet` class is further derived from a class called `Container`, which gives it the added ability to hold other components and manage them.

Containers

A `Button` object is a simple GUI component. It makes sense only in the context of some larger application. The `Container` class is an extended type of `Component` that maintains a list of child components and helps to group them. The `Container` causes its children to be displayed and arranges them on the screen according to a particular scheme. A `Container` may also receive events related to its child components. As I mentioned earlier, if a component doesn't respond to a particular type of event by overriding the appropriate event-handling method and handling the event, the event is passed to the parent `Container` of the component. This is the default behavior for the standard Java AWT components, which gives us a great deal of flexibility in managing interface components. We could, for example, create a smart button by subclassing the `Button` class and overriding certain methods to deal with the action of being pressed. Alternatively, we could simply have the `Button`'s container note which `Button` is pressed and handle the event appropriately. In the interest of keeping our examples contained in a single class, I am using the gestalt view and letting our `Button`'s container, `HelloWeb3`, deal with its events.

Remember that a `Container` is a `Component` too and, as such, can be placed alongside other `Component` objects in other `Containers`, in a hierarchical fashion, as shown in Figure 2.7. Our `HelloWeb3` applet is a kind of `Container` and can therefore hold and manage other Java AWT components and containers like buttons, sliders, text fields, and panels.

Figure 2.7: A hypothetical layout of Java containers and components

[Graphic: Figure 2-7]

In Figure 2.7, the italicized items are components, and the bold items are containers. The keypad is implemented as a container object that manages a number of keys. The keypad itself is contained in the `GizmoTool` container object.

Layout

After creating the `Button` object, we'd like to stick it in our applet. To do so, we invoke the `add()` method of `Applet`, passing the `Button` object as a parameter:

```
add(theButton);
```

`add()` is a method inherited by our `Applet` from the `Container` class. It appends our `Button` to the list of components `HelloWeb3` manages. Thereafter, `HelloWeb3` is responsible for the `Button`: the applet causes the button to be displayed, it determines where in our part of the screen the button should be placed, and it receives events when the button is pushed.

Java uses an object called a `LayoutManager` to determine the precise location in `HelloWeb3`'s screen area the `Button` is displayed. A `LayoutManager` object embodies a particular scheme for arranging components on the screen and adjusting their sizes. You'll learn more about layout managers in Chapter 12, *Layout Managers*. There are several standard layout managers to choose from, and we can, of course, create new ones. In our case, we have not specified a layout manager, so we get the default one, which means our button appears centered at the top of the applet.

Subclassing and Subtypes

If you look up the add() method of the Container class, you'll see that it takes a Component object as an argument. But in our example we've given it a Button object. What's going on?

Well, if you check the inheritance diagram in Figure 2.3 again, you'll see that Button is a subclass of the Component class. Because a subclass is a kind of its superclass and has, at minimum, the same public methods and variables, we can use an instance of a subclass anywhere we use an instance of its superclass. This is a very important concept, and it's a second aspect of the object-oriented principle of polymorphism. Button is a kind of Component, and any method that expects a Component as an argument will accept a Button.

More Events and Interfaces

Now that we have a Button, we need some way to communicate with it: that is, to get the events it generates. We could just listen for mouse clicks, figure out whether they were close enough to the button, and act accordingly. But that would take a lot of work, and would give up the advantages of using a pre-built component. Buttons generate a special kind of event called an ActionEvent when someone clicks on them. To receive these events, we have added another method to our class:

```
public void actionPerformed( ActionEvent e ) {
    if ( e.getSource() == theButton ) {
        changeColor();
    }
}
```

If you understood the previous applet, you shouldn't be surprised to see that HelloWeb3 now declares that it implements the ActionListener interface, in addition to MouseMotionListener. ActionListener requires us to implement an actionPerformed() method, which is called whenever an ActionEvent occurs. You also shouldn't be surprised to see that we added a line to init(), registering the applet as a listener for the button's action events: this is the call to theButton.addActionListener(this).

The actionPerformed() method takes care of any action events that arise. First, it checks to make sure that the event's source (the component generating the event) is what we think it should be: theButton, the only button we've put in the applet. This may seem superfluous; after all, what else could possibly generate an action event? In this applet, nothing. But it's a good idea to check, because another applet may have several buttons, and you may need to figure out which one is meant. Or you may add a second button to this applet later, and you don't want the applet to break something. To make this check, we call the getSource() method of the ActionEvent object, e. Then we use the "==" operator to make sure that the event source matches theButton. Remember that in Java, == is a test for identity, not equality; it is true if the event source and theButton are the same object. The distinction between equality and identity is important. We would consider two String objects to be equal if they have the same characters in the same sequence. However, they might not be the same object. In Chapter 5, *Objects in Java*, we'll look at the equals() method, which tests for equivalence. Once we establish that the event e comes from the right button, we call our changeColor() method, and we're done.

You may be wondering why we don't have to change mouseDragged() now that we have a Button in our applet. The rationale is that the coordinates of the event are all that matter for this method. We are not particularly concerned if the event happens to fall within an area of the screen occupied by another component. This means that you can drag the text right through the Button and even lose it behind the Button if you aren't careful: try it and see!

Color Commentary

To support HelloWeb3's colorful side we have added a couple of new variables and two helpful methods. We create and initialize an array of Color objects representing the colors through which we cycle when the button is pressed. We also declare an integer variable that serves as an index to this array, specifying the current color:

```
Color[] someColors = {
    Color.black, Color.red, Color.green, Color.blue, Color.magenta };
int colorIndex;
```

A number of things are going on here. First let's look at the Color objects we are putting into the array. Instances of the java.awt.Color class represent colors and are used by all classes in the java.awt package that deal with color graphics. Notice that we are referencing variables such as Color.black and Color.red. These look like normal references to an object's instance variables; however Color is not an object, it's a class. What is the meaning of this?

Static Members

If you recall our discussion of classes and instances, I hinted then that a class can contain methods and variables that are shared among all instances of the class. These shared members are called *static variables* and *static methods*. The most common use of static variables in a class is to hold predefined constants or unchanging objects all of the instances can use.

There are two advantages to this approach. The more obvious advantage is that static members take up space only in the class; the members are not replicated in each instance. The second advantage is that static members can be accessed even if no instances of the class exist. A hypothetical Component class might have a static variable called maximumWidth. Some other class that has to deal with this component, such as a layout manager, might want to know the maximum width of such a component, even if there aren't any around at the moment. Since maximumWidth is a static variable, the layout manager can get this information.

An instance of the `Color` class represents a color. For convenience, the `Color` class contains some static, predefined color objects with friendly names like `green`, `red`, and (my favorite) `magenta`. `Color.green` is thus a predefined `Color` object that is set to a green color. In this case, these static members of `Color` are not changeable, so they are effectively constants and can be optimized as such by the compiler. Constant static members make up for the lack of a `#define` construct in Java. However, static variables don't, in general, have to be constant. I'll say more about static class members in Chapter 5, *Objects in Java*. The alternative to using these predefined colors is to create a color manually by specifying its red, green, blue (RGB) components using a `Color` class constructor.

Arrays

Next, we turn our attention to the array. We have declared a variable called `someColors`, which is an array of `Color` objects. Arrays are syntactically supported by the Java language; however, they are true, first-class objects. This means that an array is, itself, a type of object that knows how to hold an indexed list of some other type of object. An array is indexed by integers; when you index an array, the resulting value is the object in the corresponding slot in the array. Our code uses the `colorIndex` variable to index `someColors`. It's also possible to have an array of simple primitive types, rather than objects.

When we declare an array, we can initialize it by using the familiar C-like curly brace construct. Specifying a comma-separated list of elements inside of curly braces is a convenience that instructs the compiler to create an instance of the array with those elements and assign it to our variable. Alternatively, we could have just declared our `someColors` variable and, later, allocated an array object for it and assigned individual elements to that array's slots. See Chapter 4, *The Java Language* for a complete discussion of arrays.

Our Color Methods

So, we now have an array of `Color` objects and a variable with which to index them. What do we do with them? Well, we have declared two private methods that do the actual work for us. The `private` modifier on these methods specifies that they can be called only by other methods in the same instance of the class. They are not visible outside of the object. We declare members to be `private` to hide the detailed inner workings of a class from the outside world. This is called *encapsulation* and is another tenet of object-oriented design, as well as good programming practice. Private methods are also often created as helper functions for use solely within the class implementation.

The first method, `currentColor()`, is simply a convenience routine that returns the `Color` object representing the current text color. It returns the `Color` object in the `someColors` array at the index specified by our `colorIndex` variable:

```
synchronized private Color currentColor() {
    return someColors[ colorIndex ];
}
```

We could just as readily have used the expression `someColors[colorIndex]` everywhere we use currentColor(); however, creating methods to wrap common tasks is another way of shielding ourselves from the details of our class. In an alternative implementation, we might have shuffled off details of all color-related code into a separate class. We could have created a class that takes an array of colors in its constructor and then provided two methods: one to ask for the current color and one to cycle to the next color (just some food for thought).

The second method, changeColor(), is responsible for incrementing the colorIndex variable to point to the next Color in the array. changeColor() is called from our action() method whenever the button is pressed.

```
synchronized private void changeColor() {
    if ( ++colorIndex == someColors.length )
        colorIndex = 0;
    setForeground( currentColor() );
    repaint();
}
```

We increment colorIndex and compare it to the length of the someColors array. All array objects have a variable called length that specifies the number of elements in the array. If we have reached the end of the array, we reset our index to zero and start over. After changing the currently selected color, we do two things. First, we call the applet's setForeground() method, which changes the color used to draw text in the applet and the color of the button's label. Then we call repaint() to cause the applet to be redrawn with the new color for the draggable message.

So, what is the synchronized keyword that appears in front of our currentColor() and changeColor() methods? Synchronization has to do with threads, which we'll examine in the next section. For now, all you need know is that the synchronized keyword indicates these two methods can never be running at the same time. They must always run one after the other.

The reason is that in changeColor() we increment colorIndex before testing its value. That means that for some brief period of time while Java is running through our code, colorIndex can have a value that is past the end of our array. If our currentColor() method happened to run at that same moment, we would see a run-time "array out of bounds" error. There are, of course, ways in which we could fudge around the problem in this case, but this simple example is representative of more general synchronization issues we need to address. In the next section, you'll see that Java makes dealing with these problems easy through language-level synchronization support.

2.4 Hello Web! IV: Netscape's Revenge

We have explored quite a few features of Java with the first three versions of the HelloWeb applet. But until now, our applet has been rather passive; it has waited patiently for events to come its way and responded to the whims of the user. Now our applet is going to take some initiative--HelloWeb4 will blink! The code for our latest version is shown below.

```
import java.applet.Applet;
import java.awt.*;
import java.awt.event.*;
public class HelloWeb4 extends Applet
    implements MouseMotionListener, ActionListener, Runnable {
    int messageX = 125, messageY = 95;
    String theMessage;
    Button theButton;
    int colorIndex = 0;
    static Color[] someColors = {
        Color.black, Color.red, Color.green, Color.blue, Color.magenta };
    Thread blinkThread;
    boolean blinkState;
    public void init() {
        theMessage = getParameter("message");
        theButton = new Button("Change Color");
        add(theButton);
        addMouseMotionListener(this);
        theButton.addActionListener(this);
    }

    public void paint( Graphics graphics ) {
        graphics.setColor( blinkState ? Color.white : currentColor() );
        graphics.drawString( theMessage, messageX, messageY );
    }
    public void mouseDragged( MouseEvent e ) {
        messageX = e.getX();
        messageY = e.getY();
        repaint();
    }
    public void mouseMoved( MouseEvent e ) { }
    public void actionPerformed( ActionEvent e ) {
        if ( e.getSource() == theButton ) {
            changeColor();
        }
    }
    synchronized private void changeColor() {
        if ( ++colorIndex == someColors.length )
            colorIndex = 0;
        theButton.setForeground( currentColor() );
        repaint();
    }
    synchronized private Color currentColor() {
        return someColors[ colorIndex ];
    }
    public void run() {
        while ( true ) {
            blinkState = !blinkState;
            repaint();
            try {
                Thread.sleep(500);
            } catch (Exception e ) {
                // Handle error condition here...
            }
        }
    }
    public void start() {
        if ( blinkThread == null ) {
            blinkThread = new Thread(this);
            blinkThread.start();
        }
    }
    public void stop() {
        if ( blinkThread != null ) {
            blinkThread.stop();
            blinkThread = null;
        }
    }
}
```

If you create `HelloWeb4` as you have the other applets and then run it in a Java-enabled Web browser, you'll see that the text does in fact blink. My apologies if you don't like blinking text--I'm not overly fond of it either--but it does make for a simple, instructive example.

Threads

All the changes we've made in `HelloWeb4` have to do with setting up a separate thread of execution to make the text of our applet blink. Java is a *multithreaded* language, which means there can be many threads running at the same time. A *thread* is a separate flow of control within a program. Conceptually, threads are similar to processes, except that unlike processes, multiple threads share the same address space, which means that they can share variables and methods (but they have their own local variables). Threads are also quite lightweight in comparison to processes, so it's conceivable for a single application to be running hundreds of threads concurrently.

Multithreading provides a way for an application to handle many different tasks at the same time. It's easy to imagine multiple things going on at the same time in an application like a Web browser. The user could be listening to an audio clip while scrolling an image, and in the background the browser is downloading an image. Multithreading is especially useful in GUI-based applications, as it can improve the interactive performance of these applications.

Unfortunately for us, programming with multiple threads can be quite a headache. The difficulty lies in making sure routines are implemented so they can be run by multiple concurrent threads. If a routine changes the value of a state variable, for example, then only one thread can be executing the routine at a time. Later in this section, we'll examine briefly the issue of coordinating multiple thread's access to shared data. In other languages, synchronization of threads can be an extremely complex and error-prone endeavor. You'll see that Java gives you a few simple tools that help you deal with many of these problems. Java threads can be started, stopped, suspended, and prioritized. Threads are preemptive, so a higher priority thread can interrupt a lower priority thread when vying for processor time. See Chapter 6, *Threads* for a complete discussion of threads.

The Java run-time system creates and manages a number of threads. I've already mentioned the AWT thread, which manages `repaint()` requests and event processing for GUI components that belong to the `java.awt` package. A Java-enabled Web browser typically has at least one separate thread of execution it uses to manage the applets it displays. Until now, our example has done most of its work from methods of the `Applet` class, which means that is has been borrowing time from these threads. Methods like `mouseDragged()` and `actionPerformed()` are invoked by the AWT thread and run on its time. Similarly, our `init()` method is called by a thread in the Web browser. This means we are somewhat limited in the amount of processing we do within these methods. If we were, for instance, to go into an endless loop in our `init()` method, our applet would never appear, as it would never finish initializing. If we want an applet to perform any extensive processing, such as animation, a lengthy calculation, or communication, we should create separate threads for these tasks.

The Thread Class

As you might have guessed, threads are created and controlled as `Thread` objects. We have added a new instance variable, blinkThread, to our example to hold the Thread that handles our blinking activity:

```
Thread blinkThread;
```

An instance of the Thread class corresponds to a single thread. It contains methods to start, control, and stop the thread's execution. Our basic plan is to create a Thread object to handle our blinking code. We call the Thread's start() method to begin execution. Once the thread starts, it continues to run until we call the Thread's stop() method to terminate it.

But Java doesn't allow pointers to methods, so how do we tell the thread which method to run? Well, the Thread object is rather picky; it always expects to execute a method called run() to perform the action of the thread. The run() method can, however, with a little persuasion, be located in any class we desire.

We specify the location of the run() method in one of two ways. First, the Thread class itself has a method called run(). One way to execute some Java code in a separate thread is to subclass Thread and override its run() method to do our bidding. In this case, we simply create an instance of this subclass and call its start() method.

But it's not always desirable or possible to create a subclass of Thread to contain our run() method. In this case, we need to tell the Thread which object contains the run() method it should execute. The Thread class has a constructor that takes an object reference as its argument. If we create a Thread object using this constructor and call its start() method, the Thread executes the run() method of the target object, rather than its own. In order to accomplish this, Java needs to have a guarantee that the object we are passing it does indeed contain a compatible run() method. We already know how to make such a guarantee: we use an interface. Java provides an interface named Runnable that must be implemented by any class that wants to become a Thread.

The Runnable Interface

The second technique I described for creating a Thread object involved passing an object that implements the Runnable interface to the Thread constructor. The Runnable interface specifies that the object contains a run() method that takes no arguments and returns no value. This method is called automatically when the system needs to start the thread.

Sticking with our technique for implementing our applet in a single class, we have opted to add the run() method for blinkThread to our HelloWeb4 class. This means that HelloWeb4 needs to implement the Runnable interface. We indicate that the class implements the interface in our class declaration:

```
public class HelloWeb4 extends Applet
    implements MouseMotionListener, ActionListener, Runnable {...}
```

At compile time, the Java compiler checks to make sure we abide by this statement. We have carried through by adding an appropriate run() method to our applet. Our run() method has the task of changing the color of our text a couple of times a second. It's a very short routine, but I'm going to delay looking at it until we tie up some loose ends in dealing with the Thread itself.

start( ) and stop( )

Now that we know how to create a Thread to execute our applet's run( ) method, we need to figure out where to actually do it. The start( ) and stop( ) methods of the Applet class are similar to init( ). The start( ) method is called when an applet is first displayed. If the user then leaves the Web document or scrolls the applet off the screen, the stop( ) method is invoked. If the user subsequently returns, the start( ) method is called again, and so on. Unlike init( ), start( ) and stop( ) can be called repeatedly during the lifetime of an applet.

The start( ) and stop( ) methods of the Applet class have absolutely nothing to do with the Thread object, except that they are a good place for an applet to start and stop a thread. An applet is responsible for managing the threads that it creates. It would be considered rude for an applet to continue such tasks as animation, making noise, or performing extensive calculations long after it's no longer visible on the screen. It's common practice, therefore, to start a thread when an applet becomes visible and stop it when the applet is no longer visible.

Here's the start( ) method from HelloWeb4:

```
public void start() {
    if ( blinkThread == null ) {
        blinkThread = new Thread(this);
        blinkThread.start();
    }
}
```

The method first checks to see if there is an object assigned to blinkThread; recall that an uninitialized instance variable has a default value of null. If not, the method creates a new instance of Thread, passing the target object that contains the run( ) method to the constructor. Since HelloWeb4 contains our run( ) method, we pass the special variable this to the constructor to let the thread know where to find the run( ) method it should run. this always refers to our object. Finally, after creating the new Thread, we call its start( ) method to begin execution.

Our stop( ) method takes the complimentary position:

```
public void stop() {
    if ( blinkThread != null ) {
        blinkThread.stop();
        blinkThread = null;
    }
}
```

This method checks to see if `blinkThread` is empty. If not, it calls the thread's `stop()` method to terminate its execution. By setting the value of `blinkThread` back to `null`, we have eliminated all references to the thread object we created in the `start()` method, so the garbage collector can dispose of the object.

run( )

Our `run()` method does its job by setting the value of the variable `blinkState`. We have added `blinkState`, a `boolean` value, to represent whether we are currently blinking on or off:

```
boolean blinkState;
```

The `setColor()` line of our `paint()` method has been modified slightly to handle blinking. The call to `setColor()` now draws the text in white when `blinkState` is `true`:

```
gc.setColor( blinkState ? Color.white : currentColor() );
```

Here we are being somewhat terse and using the C-like ternary operator to return one of two alternate color values based on the value of `blinkState`.

Finally, we come to the `run()` method itself:

```
public void run() {
    while ( true ) {
        blinkState = !blinkState;
        repaint();
        try {
            Thread.sleep(500);
        }
        catch (InterruptedException e ) {
        }
    }
}
```

At its outermost level, `run()` uses an infinite `while` loop. This means the method will run continuously until the thread is terminated by a call to the controlling `Thread` object's `stop()` method.

The body of the loop does three things on each pass:

- Flips the value of `blinkState` to its opposite value using the `not` operator, `!`.
- Calls `repaint()` so that our `paint()` method can have an opportunity to redraw the text in

accordance with blinkState.

- Uses a try/catch statement to trap for an error in our call to the sleep() method of the Thread class. sleep() is a static method of the Thread class. The method can be invoked from anywhere and has the effect of putting the current thread to sleep for the specified number of milliseconds. The effect here is to give us approximately two blinks per second.

Exceptions

The try/catch statement in Java is used to handle special conditions called *exceptions*. An exception is a message that is sent, normally in response to an error, during the execution of a statement or a method. When an exceptional condition arises, an object is created that contains information about the particular problem or condition. Exceptions act somewhat like events. Java stops execution at the place where the exception occurred, and the exception object is said to be *thrown* by that section of code. Like events, an exception must be delivered somewhere and handled. The section of code that receives the exception object is said to *catch* the exception. An exception causes the execution of the instigating section of code to abruptly stop and transfers control to the code that receives the exception object.

The try/catch construct allows you to catch exceptions for a section of code. If an exception is caused by a statement inside of a try clause, Java attempts to deliver the exception to the appropriate catch clause. A catch clause looks like a method declaration with one argument and no return type. If Java finds a catch clause with an argument type that matches the type of the exception, that catch clause is invoked. A try clause can have multiple catch clauses with different argument types; Java chooses the appropriate one in a way that is analogous to the selection of overloaded methods.

If there is no try/catch clause surrounding the code, or a matching catch clause is not found, the exception is thrown up the call stack to the calling method. If the exception is not caught there, it's thrown up another level, and so on until the exception is handled. This provides a very flexible error-handling mechanism, so that exceptions in deeply nested calls can bubble up to the surface of the call stack for handling. As a programmer, you need to know what exceptions a particular statement can generate, so methods in Java are required to declare the exceptions they can throw. If a method doesn't handle an exception itself, it must specify that it can throw that exception, so that the calling method knows that it may have to handle it. See Chapter 4, *The Java Language* for a complete discussion of exceptions and the try/catch clause.

So, why do we need a try/catch clause around our sleep() call? What kind of exception can Thread's sleep() method throw and why do we care about it, when we don't seem to check for exceptions anywhere else? Under some circumstances, Thread's sleep() method can throw an InterruptedException, indicating that it was interrupted by another thread. Since the run() method specified in the Runnable interface doesn't declare it can throw an InterruptedException, we must catch it ourselves, or the compiler will complain. The try/catch statement in our example has an empty catch clause, which means that it handles the exception by ignoring it. In this case, our thread's functionality is so simple it doesn't matter if it's interrupted. All of the other methods we have used either handle their own exceptions or throw only general-purpose exceptions that are assumed to be possible everywhere and don't need to be explicitly declared.

A Word About Synchronization

At any given time, there can be a number of threads running in the Java interpreter. Unless we explicitly coordinate them, these threads will be executing methods without any regard for what the other threads are doing. Problems can arise when these methods share the same data. If one method is changing the value of some variables at the same time that another method is reading these variables, it's possible that the reading thread might catch things in the middle and get some variables with old values and some with new. Depending on the application, this situation could cause a critical error.

In our `HelloWeb` examples, both our `paint()` and `mouseDrag()` methods access the `messageX` and `messageY` variables. Without knowing the implementation of our particular Java environment, we have to assume that these methods could conceivably be called by different threads and run concurrently. `paint()` could be called while `mouseDrag()` is in the midst of updating `messageX` and `messageY`. At that point, the data is in an inconsistent state and if `paint()` gets lucky, it could get the new x value with the old y value. Fortunately, in this case, we probably would not even notice if this were to happen in our application. We did, however, see another case, in our `changeColor()` and `currentColor()` methods, where there is the potential for a more serious "out of bounds" error to occur.

The `synchronized` modifier tells Java to acquire a *lock* for the class that contains the method before executing that method. Only one method can have the lock on a class at any given time, which means that only one synchronized method in that class can be running at a time. This allows a method to alter data and leave it in a consistent state before a concurrently running method is allowed to access it. When the method is done, it releases the lock on the class.

Unlike synchronization in other languages, the `synchronized` keyword in Java provides locking at the language level. This means there is no way that you can forget to unlock a class. Even if the method throws an exception or the thread is terminated, Java will release the lock. This feature makes programming with threads in Java much easier than in other languages. See Chapter 6, *Threads* for more details on coordinating threads and shared data.

Whew! Now it's time to say goodbye to `HelloWeb`. I hope that you have developed a feel for the major features of the Java language, and that this will help you as you go on to explore the details of programming with Java.

3.2 The Class Path

The concept of a path should be familiar to anyone who has worked on a DOS or UNIX platform. It's a piece of environment information that provides an application with a list of places to look for some resource. The most common example is a path for executable programs. In a UNIX shell, the `PATH` environment variable is a colon-separated list of directories that are searched, in order, when the user types the name of a command. The Java `CLASSPATH` environment variable, similarly, is a list of locations that can be searched for packages containing Java class files. Both the Java interpreter and the Java compiler use `CLASSPATH` when searching for files on the local host platform.

Classes loaded from the local host via the class path have special features. For example, the Java interpreter loads classes in the class path just once; after a core class has been loaded, it can't be modified or replaced. The interpreter can also be told to trust classes in the class path and to load them without passing them through the byte-code verification process. This is important because certain kinds of optimizations on Java virtual machine instructions produce valid byte-code that, nonetheless, can't pass the verification process. Byte-code that is precompiled on the native host is an extreme example.

The class path is a list of locations where Java class packages are found. A location can be a path such as a directory name or the name of a class archive file. Java supports archives of class files in the uncompressed ZIP format.[1] It automatically looks inside ZIP archives and retrieves classes, which then allows large groups of classes to be distributed in a single archive file. The precise means and format for setting the class path varies from system to system. On a UNIX system, you set the `CLASSPATH` environment variable with a colon-separated list of directories and class archive files:

> [1] The ZIP format is an open standard for file archiving and compression. There are ZIP utilities available for most platforms; you'll need to get one if you want to store Java classes in ZIP archives. Use ftp://ftp.uu.net/pub/archiving/zip/ to access an archive of freely available ZIP utilities.

```
CLASSPATH=/usr/lib/java/classes.zip:/home/vicky/Java/classes:\
    /home/vicky/.netscape/moz2_0.zip:.
```

On a Windows system, the `CLASSPATH` environment variable is set with a semicolon-separated list of directories and class archive files:

```
CLASSPATH=C:\tools\java\classes.zip;D:\users\vicky\Java\classes;.
```

The class path can also be set with the `-classpath` option to the Java interpreter *java* and the Java compiler *javac*.

The above UNIX example specifies a class path with four locations: a ZIP archive in */usr/lib/java*, a directory in the user's home, another ZIP file in the user's Netscape collection, and the current directory, which is always specified with a dot (`.`). The last component of the class path, the current directory, is useful when tinkering with classes, but as a general rule, it's bad practice to put the current directory in any kind of path.

The Java interpreter searches each of these four locations in order to find classes. *java* expects to find class files in a directory hierarchy or in a directory within a ZIP archive that maps to the fully qualified name of the class. The components of a class-package name become the components of a pathname. Given the above class path, the first time we reference a class with the fully qualified name of `animals.birds.BigBird`, for example, *java* begins the search with the *classes.zip* archive in */usr/lib/java*. It looks for a class archived under the path *animals/birds/BigBird*. If *java* does not find the class there, it looks for the class in */home/vicky/Java/classes/animals/birds/BigBird*. If it's not found there, *java* moves on to the archive file specified next in the class path, and so on.

If you don't specify the `CLASSPATH` environment variable or the `-classpath` option, *java* uses the following default class path:

```
.:$JAVA/classes:$JAVA/lib/classes.zip     UNIX systems
.;$JAVA\classes;$JAVA\lib\classes.zip     Windows systems
```

In this path, `$JAVA` is the main Java directory on your system. Notice that the current directory (`.`) is the first location in the default class path; this means the files in your current directory are always available. If you change the class path and don't include the current directory, these files will no longer be accessible.

3.3 The Java Compiler

In this section, I'm going to say a few words about *javac*, the Java compiler that is supplied as part of Sun's JDK. (If you are happily working in another development environment, you may want to skip ahead to the next section.) The *javac* compiler is written entirely in Java, so it's available for any platform that supports the Java run-time system. The ability to support its own development environments is an important stage in a language's development. Java makes this bootstrapping automatic by supplying a ready-to-run compiler at the same cost as porting the interpreter.

javac turns Java source code into a compiled class that contains Java virtual machine byte-code. By convention, source files are named with a *.java* extension; the resulting class files have a *.class* extension. *javac* considers a file to be a single compilation unit. As you'll see in Chapter 5, *Objects in Java*, classes in a given compilation unit share certain features like `package` and `import` statements.

javac allows you one `public` class per file and insists the file have the same name as the class. If the filename and class name don't match, *javac* issues a compilation error. A single file can contain multiple classes, as long as only one of the classes is `public`. You should avoid packing lots of classes into a single file. The compiler lets you include extra non-`public` classes in a *.java* file, so that you can implement a class that is tightly coupled to another class without a lot of hassle. But you should have more than one class in a file if the `public` class in the file is the only one that ever uses additional classes.

Now for an example. The source code for the following class should be placed in a file called *BigBird.java*:

```
package animals.birds

public class BigBird extends Bird {
    ...
}
```

We can then compile it with:

```
% javac BigBird.java
```

Unlike the Java interpreter, which takes a class name as its argument, *javac* requires an actual filename to process. The above command produces the class file *BigBird.class* and stores it in the same directory as the source file. While it's useful to have the class file in the same directory as the source when you are working on a simple example, for most real applications you'll need to store the class file in an appropriate place in the class path.

You can use the `-d` option to *javac* to specify an alternate directory for storing the class files it generates. The specified directory is used as the root of the class hierarchy, so *.class* files are placed in this directory or in a subdirectory below it, depending on the package name of the class. For example, we can use the following command to put our *BigBird.class* file in an appropriate location:

```
% javac -d /home/vicky/Java/classes BigBird.java
```

When you use the `-d` option, *javac* automatically creates any directories needed to store the class file in the appropriate place. In the above command, the *BigBird.class* file is stored in */home/vicky/Java/classes/animals/birds*.

You can specify multiple *.java* files in a single *javac* command; the compiler simply creates a class file for each source file. But you don't need to list source files for other classes your class references, as long as the other classes have already been compiled. During compilation, Java resolves other class references using the class path. If our class references other classes in `animals.birds` or other packages, the appropriate paths should be listed in the class path at compile time, so that *javac* can find the appropriate class files. You either make sure that the `CLASSPATH` environment variable is set or use the `-classpath` option to *javac*.

The Java compiler is more intelligent than your average compiler and replaces some of the functionality of a *make* utility. For example, *javac* compares the modification times of the source and class files for all referenced classes and recompiles them as necessary. A compiled Java class remembers the source file from which it was compiled, so as long as the source file is in the same directory as the class file, *javac* can recompile the source if necessary. If, in the above example, class `BigBird` references another class, `animals.furry.Grover`, *javac* looks for the source *Grover.java* in an `animals.furry` package and recompiles it if necessary to bring the *Grover.class* class file up to date.

It's important to note that *javac* can do its job even if only the compiled versions of referenced classes are available. Java class files contain all the data type and method signature information source files do, so compiling against binary class files is as type safe (and exception safe) as compiling with Java source code.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

3.5 The Applet Tag

```
Add stuff about 'archive' tag.
```

Applets are embedded in HTML documents with the `<applet>` tag. The `<applet>` tag resembles the HTML `<img>` image tag.[2] It contains attributes that identify the applet to be displayed and, optionally, give the Web browser hints about how it should be displayed. The standard image tag sizing and alignment attributes, such as `height` and `width`, can be used inside the applet tag. Unlike images, however, applets have both an opening `<applet>` and a closing `</applet>` tag. Sandwiched between these can be any number of `<param>` tags that contain application-specific parameters to be passed to the applet itself:

> [2] If you are not familiar with HTML or other markup languages, you may want to refer to *HTML: The Definitive Guide*, from O'Reilly & Associates, for a complete reference on HTML and structured Web documents.

```
<applet attribute [ attribute ] ...  >
[<param parameter >]
[<param parameter >]
...
<\applet>
```

Attributes

Attributes are name/value pairs that are interpreted by a Web browser or applet viewer. (Many HTML tags besides `<applet>` have attributes.) Attributes of the `<applet>` tag specify general features that apply to all applets, such as size and alignment. The definition of the `<applet>` tag lists a fixed set of recognized attributes; specifying an incorrect or nonexistent attribute should be considered an HTML error.

Three attributes, `code`, `width`, and `height`, are always required in the `<applet>` tag. `code` specifies the name of the applet to be loaded; `width` and `height` determine its initial size. Other attributes are optional.

The following is an HTML fragment for a hypothetical, simple clock applet that takes no parameters and requires no special HTML layout:

```
<applet code=AnalogClock width=100 height=100></applet>
```

The HTML file that contains this `<applet>` tag needs to be stored in the same directory as the `AnalogClock.class` class file. The applet tag is not sensitive to spacing, so the above is therefore equivalent to:

```
<applet
    code=AnalogClock
    width=100
    height=100>
<\applet>
```

You can use whatever form seems appropriate.

Parameters

Parameters are analogous to command-line arguments; they provide a way to pass information to an applet. Each `<param>` tag contains a name and a value that are passed as strings to the applet:

```
<param name = parameter_name value = parameter_value>
```

Parameters provide a means of embedding application-specific data and configuration information within an HTML document.[3] Our `AnalogClock` applet, for example, might accept a parameter that selects between local and universal time:

> [3] If you are wondering why the applet's parameters are specified in yet another type of tag, here's the reason. In the original alpha release of Java, applet parameters were included inside of a single `<app>` tag along with formatting attributes. However, this format was not SGML-compliant, so the `<param>` tag was added.

```
<applet code=AnalogClock width=100 height=100>
    <param name=zone value=GMT>
<\applet>
```

Presumably, this `AnalogClock` applet is designed to look for a parameter named `zone` with a possible value of `GMT`.

Parameter names and values can be quoted to contain spaces and other special characters. We could therefore be more verbose and use a parameter value like the following:

```
<param name=zone value="Greenwich Mean Time">
```

The parameters a given applet expects are determined by the developer of that applet. There is no fixed set of parameter names or values; it's up to the applet to interpret the parameter name/value pairs that are passed to it. Any number of parameters can be specified, and the applet may choose to use or ignore them as it sees fit. The applet might also consider parameters to be either optional or required and act accordingly.

Hablo Applet?

Web browsers ignore tags they don't understand; if the Web browser doesn't interpret the `<applet>` or `<param>` tags, they should disappear and any HTML between the `<applet>`and `</applet>` tags should appear normally.

By convention, Java-enabled Web browsers do the opposite and ignore any extra HTML between the `<applet>` and `</applet>` tags. This means we can place some alternate HTML inside the `<applet>` tag, which is then displayed only by Web browsers that can't run the applet.

For our `AnalogClock` example, we could display a small text explanation and an image of the clock applet as a teaser:

```
<applet code=AnalogClock width=100 height=100>
    <param name=zone value=GMT>
    <strong>If you see this you don't have a Java-enabled Web
    browser. Here's a picture of what you are missing.</strong>
    <img src="clockface.gif">
<\applet>
```

The Complete Applet Tag

We can now spell out the full-blown `<applet>` tag:[4]

[4] The HTML working group of the IETF is investigating standardization of embedded objects in HTML. A draft document can be found at ftp://ds.internic.net/internet-drafts/draft-ietf-html-cda-00.txt. They would prefer a slightly less application-centric name such as `<embed>`. However, their discussion, for the most part, parallels the `<applet>` tag.

```
<applet
    code = class name
    width = pixels wide
    height = pixels high
    [ codebase = location URL ]
    [ name = instance name ]
    [ alt = alternate text ]
    [ align = alignment style ]
    [ vspace = vertical pad pixels ]
    [ hspace = horizontal pad pixels ]
>
[ <param name = parameter name value = parameter value> ]
[ <param name = parameter name value = parameter value> ]
...
[ HTML for non Java aware browsers ]
<\applet>
```

The `width`, `height`, `align`, `vspace`, and `hspace` attributes have the same meanings as those of the `<img>` tag and determine the preferred size, alignment, and padding respectively.

The `alt` attribute specifies alternate text that is displayed by browsers that understand the `<applet>` tag and its attributes, but can't actually run applets. This attribute can also describe the applet, since in this case any alternate HTML between `<applet>` and `<\applet>` is ignored.

The `name` attribute specifies an instance name for the executing applet. This is a name specified as a unique label for each copy of an applet on a particular HTML page. For example, if we include our clock twice on the same page (using two applet tags), we could give each instance a unique name to differentiate them:

```
<applet code=AnalogClock name="bigClock" width=300 height=300><\applet>
<applet code=AnalogClock name="smallClock" width=50 height=50><\applet>
```

Applets use instance names to recognize and communicate with other applets on the same page. We could, for instance, create a "clock setter" applet that knows how to set the time on a `AnalogClock` applet and pass it the instance name of a particular target clock on this page as a parameter. This might look something like:

```
<applet code=ClockSetter>
    <param name=clockToSet value="bigClock">
<\applet>
```

Loading Class Files

The `code` attribute of the `<applet>` tag should specify the name of an applet. This is either a simple class name, or a package path and class name. For now, let's look at simple class names; I'll discuss packages in a moment. By default, the Java run-time system looks for the class file in the same location as the HTML document that contains it. This location is known as the base URL for the document.

Consider an HTML document, *clock.html*, that contains our clock applet example:

```
<applet code=AnalogClock width=100 height=100><\applet>
```

Let's say we retrieve the document at the following URL:

```
http://www.time.ch/documents/clock.html
```

Java tries to retrieve the applet class file from the same base location:

```
http://www.time.ch/documents/AnalogClock.class
```

The `codebase` attribute of the `<applet>` tag can be used to specify an alternative base URL for the class file search. Let's say our HTML document now specifies `codebase`, as in the following example:

```
<applet
    codebase=http://www.joes.ch/stuff/
    code=AnalogClock
    width=100
    height=100>
<\applet>
```

Java now looks for the applet class file at:

```
http://www.joes.ch/stuff/AnalogClock.class
```

Packages

Packages are groups of Java classes; see Chapter 5, *Objects in Java* for more information. A package name is a little like an Internet hostname, in that they both use a hierarchical, dot-separated naming convention. A Java class file can be identified by its full name by prefixing the class name with the package name. We might therefore have a package called `time` for time-related Java classes, and perhaps a subordinate package called `time.clock` to hold classes related to one or more clock applications.

In addition to providing a naming scheme, packages can be used to locate classes stored at a particular location. Before a class file is retrieved from a server, its package-name component is translated by the client into a relative path name under the base URL of the document. The components of a class package name are simply turned into the components of a path name, just like with classes on your local system.

Let's suppose that our `AnalogClock` has been placed into the `time.clock` package and now has the fully qualified name of `time.clock.AnalogClock`. Our simple `<applet>` tag would now look like:

```
<applet code=time.clock.AnalogClock width=100 height=100><\applet>
```

Let's say the *clock.html* document is once again retrieved from:

```
http://www.time.ch/documents/clock.html
```

Java now looks for the class file in the following location:

```
http://www.time.ch/documents/time/clock/AnalogClock.class
```

The same is true when specifying an alternative `codebase`:

```
<applet
    codebase=http://www.joes.ch/stuff/
    code=time.clock.AnalogClock
    width=100
    height=100>
<\applet>
```

Java now tries to find the class in the corresponding path under the new base URL:

```
http://www.joes.ch/stuff/time/clock/AnalogClock.class
```

One possible package-naming convention proposes that Internet host and domain names be incorporated as part of package names to form a unique identifier for classes produced by a given organization. If a company with the domain name `foobar.com` produced our `AnalogClock` class, they might distribute it in a package called `com.foobar.time.clock`. The fully qualified name of the `AnalogClock` class would then be `com.foo.time.clock.AnalogClock`. This would presumably be a unique name stored on an arbitrary server. A future version of the Java class loader might use this to automatically search for classes on remote hosts.

Perhaps soon we'll run Sun's latest and greatest Web browser directly from its source with:

```
% java com.sun.java.hotjava.HotJava
```

Viewing Applets

Sun's JDK comes with an applet-viewer program aptly called *appletviewer*. To use *appletviewer*, specify the URL of the document on the command line. For example, to view our `AnalogClock` at the URL shown above, use the following command:

```
% appletviewer http://www.time.ch/documents/clock.html
```

The *appletviewer* retrieves all applets in the specified document and displays each one in a separate window. *appletviewer* is not a Web browser; it doesn't attempt to display HTML. It's primarily a convenience for testing and debugging applets. If the document doesn't contain `<applet>` tags, *appletviewer* does nothing.

4.2 Comments

Java supports both C-style block comments delimited by `/*` and `*/` and C++-style line comments indicated by `//`:

```
/*  This is a
        multiline
            comment.    */

// This is a single line comment
// and so // is this
```

As in C, block comments can't be nested. Single-line comments are delimited by the end of a line; extra `//` indicators inside a single line have no effect. Line comments are useful for short comments within methods because you can still wrap block comments around large chunks of code during development.

By convention, a block comment beginning with `/**` indicates a special "doc comment." A doc comment is commentary that is extracted by automated documentation generators, such as Sun's *javadoc* program that comes with the Java Development Kit. A doc comment is terminated by the next `*/`, just as with a regular block comment. Leading spacing up to a `*` on each line is ignored; lines beginning with `@` are interpreted as special tags for the documentation generator:

```
/**
 * I think this class is possibly the most amazing thing you will
 * ever see. Let me tell you about my own personal vision and
 * motivation in creating it.
 * <p>
 * It all began when I was a small child, growing up on the
 * streets of Idaho. Potatoes were the rage, and life was good...
 *
 * @see PotatoPeeler
 * @see PotatoMasher
 * @author John 'Spuds' Smith
 * @version 1.00, 19 Dec 1996
 */
```

javadoc creates HTML class documentation by reading the source code and the embedded comments. The author and version information is presented in the output and the `@see` tags make hypertext links to the appropriate class documentation. The compiler also looks at the doc comments; in particular, it is interested in the `@deprecated` tag, which means that the method has been declared obsolete and should be avoided in new programs. The compiler generates a warning message whenever it sees you use a deprecated feature in your code.

Doc comments can appear above class, method, and variable definitions, but some tags may not be applicable to all. For example, a variable declaration can contain only a `@see` tag. Table 4.1 summarizes the tags used in doc comments.

Table 4.1: Doc Comment Tags

Tag	**Description**	**Applies to**
`@see`	Associated class name	Class, method, or variable
`@author`	Author name	Class
`@version`	Version string	Class
`@param`	Parameter name and description	Method
`@return`	Description of return value	Method
`@exception`	Exception name and description	Method
`@deprecated`	Declares an item obsolete	Class, method, or variable

4.3 Types

The type system of a programming language describes how its data elements (variables and constants) are associated with actual storage. In a statically typed language, such as C or C++, the type of a data element is a simple, unchanging attribute that often corresponds directly to some underlying hardware phenomenon, like a register value or a pointer indirection. In a more dynamic language like Smalltalk or Lisp, variables can be assigned arbitrary elements and can effectively change their type throughout their lifetime. A considerable amount of overhead goes into validating what happens in these languages at run-time. Scripting languages like Tcl and awk achieve ease of use by providing drastically simplified type systems in which only certain data elements can be stored in variables, and values are unified into a common representation such as strings.

As I described in Chapter 1, *Yet Another Language?*, Java combines the best features of both statically and dynamically typed languages. As in a statically typed language, every variable and programming element in Java has a type that is known at compile-time, so the interpreter doesn't normally have to check the type validity of assignments while the code is executing. Unlike C or C++ though, Java also maintains run-time information about objects and uses this to allow safe run-time polymorphism.

Java data types fall into two categories. *Primitive types* represent simple values that have built-in functionality in the language; they are fixed elements like literal constants and numeric expressions. *Reference types* (or class types) include objects and arrays; they are called reference types because they are passed "by reference" as I'll explain shortly.

Primitive Types

Numbers, characters, and boolean values are fundamental elements in Java. Unlike some other (perhaps more pure) object-oriented languages, they are not objects. For those situations where it's desirable to treat a primitive value as an object, Java provides "wrapper" classes (see Chapter 7, *Basic Utility Classes*). One major advantage of treating primitive values as such is that the Java compiler can more readily optimize their usage.

Another advantage of working with the Java virtual-machine architecture is that primitive types are precisely defined. For example, you never have to worry about the size of an `int` on a particular platform; it's always a 32-bit, signed, two's complement number. Table 4.2 summarizes Java's primitive types.

Table 4.2: Java Primitive Data Types

Type	**Definition**
`boolean`	`true` or `false`
`char`	16-bit Unicode character
`byte`	8-bit signed two's complement integer
`short`	16-bit signed two's complement integer
`int`	32-bit signed two's complement integer
`long`	64-bit signed two's complement integer
`float`	32-bit IEEE 754 floating-point value
`double`	64-bit IEEE 754 floating-point value

If you think the primitive types look like an idealization of C scalar types on a byte-oriented 32-bit machine, you're absolutely right. That's how they're supposed to look. The 16-bit characters were forced by Unicode, and generic pointers were deleted for other reasons we'll touch on later, but in general the syntax and semantics of Java primitive types are meant to fit a C programmer's mental habits. If you're like most of this book's readers, you'll probably find this saves you a lot of mental effort in learning the language.

Declaration and initialization

Variables are declared inside of methods or classes in C style. For example:

```
int foo;
double d1, d2;
boolean isFun;
```

Variables can optionally be initialized with an appropriate expression when they are declared:

```
int foo = 42;
double d1 = 3.14, d2 = 2 * 3.14;
boolean isFun = true;
```

Variables that are declared as instance variables in a class are set to default values if they are not initialized. In this case, they act much like static variables in C or C++. Numeric types default to the appropriate flavor of zero, characters are set to the null character "\0," and boolean variables have the value false. Local variables declared in methods, on the other hand, must be explicitly initialized before they can be used.

Integer literals

Integer literals can be specified in octal (base 8), decimal (base 10), or hexadecimal (base 16). A decimal integer is specified by a sequence of digits beginning with one of the characters 1-9:

```
int i = 1230;
```

Octal numbers are distinguished from decimal by a leading zero:

```
int i = 01230;                // i = 664 decimal
```

(An interesting, but meaningless, observation is that this would make the number 0 an octal value in the eyes of the compiler.)

As in C, a hexadecimal number is denoted by the leading characters 0x or 0X (zero "x"), followed by digits and the characters a-f or A-F, which represent the decimal values 10-15 respectively:

```
int i = 0xFFFF;               // i = 65535 decimal
```

Integer literals are of type int unless they are suffixed with an L, denoting that they are to be produced as a long value:

```
long l = 13L;
long l = 13;                  // equivalent--13 is converted from type int
```

(The lowercase character l ("el") is also acceptable, but should be avoided because it often looks like the numeral 1).

When a numeric type is used in an assignment or an expression involving a type with a larger range, it can be promoted to the larger type. For example, in the second line of the above example, the number 13 has the default type of int, but it's promoted to type long for assignment to the long variable. Certain other numeric and comparison operations also cause this kind of arithmetic promotion. A numeric value can never be assigned to a type with a smaller range without an explicit (C-style) cast, however:

```
int i = 13;
byte b = i;                   // Compile time error--explicit cast needed
byte b = (byte) i;            // Okay
```

Conversions from floating point to integer types always require an explicit cast because of the potential loss of precision.

Floating-point literals

Floating-point values can be specified in decimal or scientific notation. Floating-point literals are of type `double` unless they are suffixed with an `f` denoting that they are to be produced as a `float` value:

```
double d = 8.31;
double e = 3.00e+8;
float f = 8.31F;
float g = 3.00e+8F;
```

Character literals

A literal character value can be specified either as a single-quoted character or as an escaped ASCII or Unicode sequence:

```
char a = 'a';
char newline = '\n';
char octalff = \u00ff;
```

Reference Types

In C, you can make a new, complex data type by creating a `structure`. In Java (and other object-oriented languages), you instead create a `class` that defines a new type in the language. For instance, if we create a new class called `Foo` in Java, we are also implicitly creating a new type called `Foo`. The type of an item governs how it's used and where it's assigned. An item of type `Foo` can, in general, be assigned to a variable of type `Foo` or passed as an argument to a method that accepts a `Foo` value.

In an object-oriented language like Java, a type is not necessarily just a simple attribute. Reference types are related in the same way as the classes they represent. Classes exist in a hierarchy, where a subclass is a specialized kind of its parent class. The corresponding types have a similar relationship, where the type of the child class is considered a subtype of the parent class. Because child classes always extend their parents and have, at a minimum, the same functionality, an object of the child's type can be used in place of an object of the parent's type. For example, if I create a new class, `Bar`, that extends `Foo`, there is a new type `Bar` that is considered a subtype of `Foo`. Objects of type `Bar` can then be used anywhere an object of type `Foo` could be used; An object of type `Bar` is said to be assignable to a variable of type `Foo`. This is called *subtype polymorphism* and is one of the primary features of an object-oriented language. We'll look more closely at classes and objects in Chapter 5, *Objects in Java*.

Primitive types in Java are used and passed "by value." In other words, when a primitive value is assigned or passed as an argument to a method, it's simply copied. Reference types, on the other hand, are always accessed "by reference." A *reference* is simply a handle or a name for an object. What a variable of a reference type holds is a reference to an object of its type (or of a subtype). A reference is like a pointer in C or C++, except that its type is strictly enforced and the reference value itself is a primitive entity that can't be examined directly. A reference value can't be created or changed other than through assignment to an appropriate object. When references are assigned or passed to methods, they are copied by value. You can think of a reference as a pointer type that is automatically dereferenced whenever it's mentioned.

Let's run through an example. We specify a variable of type `Foo`, called `myFoo`, and assign it an appropriate object:

```
Foo myFoo = new Foo();
Foo anotherFoo = myFoo;
```

`myFoo` is a reference type variable that holds a reference to the newly constructed `Foo` object. For now, don't worry about the details of creating an object; we'll cover that in Chapter 5, *Objects in Java*. We designate a second `Foo` type variable, `anotherFoo`, and assign it to the same object. There are now two identical references: `myFoo` and `anotherFoo`. If we change things in the state of the `Foo` object itself, we will see the same effect by looking at it with either reference. The comparable code in C++ would be:

```
// C++
Foo& myFoo = *(new Foo());
Foo& anotherFoo = myFoo;
```

We can pass one of the variables to a method, as in:

```
myMethod( myFoo );
```

An important, but sometimes confusing distinction to make at this point is that the reference itself is passed by value. That is, the argument passed to the method (a local variable from the method's point of view) is actually a third copy of the reference. The method can alter the state of the `Foo` object itself through that reference, but it can't change the caller's reference to `myFoo`. That is, the method can't change the caller's `myFoo` to point to a different Foo object. For the times we want a method to change a reference for us, we have to pass a reference to the object that contains it, as shown in Chapter 5, *Objects in Java*.

Reference types always point to objects, and objects are always defined by classes. However, there are two special kinds of reference types that specify the type of object they point to in a slightly different way. Arrays in Java have a special place in the type system. They are a special kind of object automatically created to hold a number of some other type of object, known as the base type. Declaring an array-type reference implicitly creates the new class type, as you'll see in the next section.

Interfaces are a bit sneakier. An interface defines a set of methods and a corresponding type. Any object that implements all methods of the interface can be treated as an object of that type. Variables and method arguments can be declared to be of interface types, just like class types, and any object that implements the interface can be assigned to them. This allows Java to cross the lines of the class hierarchy in a type safe way, as you'll see in Chapter 5, *Objects in Java*.

A Word About Strings

Strings in Java are objects; they are therefore a reference type. `String` objects do, however, have some special help from the Java compiler that makes them look more primitive. Literal string values in Java source code are turned into `String` objects by the compiler. They can be used directly, passed as arguments to methods, or assigned to `String` type variables:

```
System.out.println( "Hello World..." );
String s = "I am the walrus...";
String t = "John said: \"I am the walrus...\"";
```

The `+` symbol in Java is overloaded to provide string concatenation; this is the only overloaded operator in Java:

```
String quote = "Four score and " + "seven years ago,";
String more = quote + " our" + " fathers" +  " brought...";
```

Java builds a single `String` object from the concatenated strings and provides it as the result of the expression. We will discuss the `String` class in Chapter 7, *Basic Utility Classes*.

4.4 Statements and Expressions

Although the method declaration syntax of Java is quite different from that of C++, Java statement and expression syntax is very much like that of C. Again, the design intention was to make the low-level details of Java easily accessible to C programmers, so that they can concentrate on learning the parts of the language that are really different. Java *statements* appear inside of methods and class and variable initializers; they describe all activities of a Java program. Variable declarations and initializations like those in the previous section are statements, as are the basic language structures like conditionals and loops. *Expressions* are statements that produce a result that can be used as part of another statement. Method calls, object allocations, and, of course, mathematical expressions are examples of expressions.

One of the tenets of Java is to keep things simple and consistent. To that end, when there are no other constraints, evaluations and initializations in Java always occur in the order in which they appear in the code--from left to right. We'll see this rule used in the evaluation of assignment expressions, method calls, and array indexes, to name a few cases. In some other languages, the order of evaluation is more complicated or even implementation dependent. Java removes this element of danger by precisely and simply defining how the code is evaluated. This doesn't, however, mean you should start writing obscure and convoluted statements. Relying on the order of evaluation of expressions is a bad programming habit, even when it works. It produces code that is hard to read and harder to modify. Real programmers, however, are not made of stone, and you may catch me doing this once or twice when I can't resist the urge to write terse code.

Statements

As in C or C++, statements and expressions in Java appear within a *code block*. A code block is syntactically just a number of statements surrounded by an open curly brace (`{`) and a close curly brace (`}`). The statements in a code block can contain variable declarations:

```
{
    int size = 5;
    setName("Max");
    ...
}
```

Methods, which look like C functions, are in a sense code blocks that take parameters and can be called by name.

```
setupDog( String name ) {
    int size = 5;
    setName( name );
    ...
}
```

Variable declarations are limited in scope to their enclosing code block. That is, they can't be seen outside of the nearest set of braces:

```
{
    int i = 5;
}

i = 6;           // compile time error, no such variable i
```

In this way, code blocks can be used to arbitrarily group other statements and variables. The most common use of code blocks, however, is to define a group of statements for use in a conditional or iterative statement.

Since a code block is itself collectively treated as a statement, we define a conditional like an `if/else` clause as follows:

```
if ( condition )
    statement;
[ else
    statement; ]
```

Thus, `if/else` in Java has the familiar functionality of taking either of the forms:

```
if ( condition )
    statement;
```

or:

```
if ( condition )  {
    [ statement; ]
    [ statement; ]
    [ ... ]
}
```

Here the *condition* is a boolean expression. In the second form, the statement is a code block, and all of its enclosed statements are executed if the conditional succeeds. Any variables declared within that block are visible only to the statements within the successful branch of the condition. Like the if/else conditional, most of the remaining Java statements are concerned with controlling the flow of execution. They act for the most part like their namesakes in C or C++.

The do and while iterative statements have the familiar functionality, except that their conditional test is also a boolean expression. You can't use an integer expression or a reference type; in other words you must explicitly test your value. In other words, while i==0 is legitimate, i is not, unless i is boolean. Here are the forms of these two statements:

```
while ( conditional )
    statement;

do
    statement;
while ( conditional );
```

The for statement also looks like it does in C:

```
for ( initialization; conditional; incrementor )
    statement;
```

The variable initialization expression can declare a new variable; this variable is limited to the scope of the for statement:

```
for (int i = 0; i < 100; i++ ) {
    System.out.println( i )
    int j = i;
    ...
}
```

Java doesn't support the C comma operator, which groups multiple expressions into a single expression. However, you can use multiple, comma-separated expressions in the initialization and increment sections of the for loop. For example:

```
for (int i = 0, j = 10; i < j; i++, j-- ) {
   ... }
```

The Java `switch` statement takes an integer type (or an argument that can be promoted to an integer type) and selects among a number of alternative `case` branches[2] :

> [2] An object-based `switch` statement is desirable and could find its way into the language someday.

```
switch ( int expression ) {
    case int expression :
        statement;
    [ case int expression
        statement;
    ...
    default :
        statement;  ]
}
```

No two of the `case` expressions can evaluate to the same value. As in C, an optional `default` case can be specified to catch unmatched conditions. Normally, the special statement `break` is used to terminate a branch of the `switch`:

```
switch ( retVal ) {
    case myClass.GOOD :
        // something good
        break;
    case myClass.BAD :
        // something bad
        break;
    default :
        // neither one
        break;
}
```

The Java `break` statement and its friend `continue` perform unconditional jumps out of a loop or conditional statement. They differ from the corresponding statements in C by taking an optional label as an argument. Enclosing statements, like code blocks and iterators, can be labeled with identifier statements:

```
one:
    while ( condition ) {
        ...
        two:
            while ( condition ) {
                ...
                // break or continue point
            }
        // after two
    }
// after one
```

In the above example, a `break` or `continue` without argument at the indicated position would have the normal, C-style effect. A `break` would cause processing to resume at the point labeled "after two"; a `continue` would immediately cause the `two` loop to return to its condition test.

The statement `break two` at the indicated point would have the same effect as an ordinary `break`, but `break one` would break two levels and resume at the point labeled "after one." Similarly, `continue two` would serve as a normal `continue`, but `continue one` would return to the test of the `one` loop. Multilevel `break` and `continue` statements remove much of the need for the evil `goto` statement in C and C++.

There are a few Java statements we aren't going to discuss right now. The `try`, `catch`, and `finally` statements are used in exception handling, as we'll discuss later in this chapter. The `synchronized` statement in Java is used to coordinate access to statements among multiple threads of execution; see Chapter 6, *Threads* for a discussion of thread synchronization.

On a final note, I should mention that the Java compiler flags "unreachable" statements as compile-time errors. Of course, when I say unreachable, I mean those statements the compiler determines won't be called by a static look at compile-time.

Expressions

As I said earlier, expressions are statements that produce a result when they are evaluated. The value of an expression can be a numeric type, as in an arithmetic expression; a reference type, as in an object allocation; or the special type `void`, which results from a call to a method that doesn't return a value. In the last case, the expression is evaluated only for its side effects (i.e., the work it does aside from producing a value). The type of an expression is known at compile-time. The value produced at run-time is either of this type or, in the case of a reference type, a compatible (assignable) type.

Operators

Java supports almost all standard C operators. These operators also have the same precedence in Java as they do in C, as you can see in Table 4.3.

Table 4.3: Java Operators

Precedence	Operator	Operand Type	Description
1	++, --	Arithmetic	Increment and decrement
1	+, -	Arithmetic	Unary plus and minus
1	~	Integral	Bitwise complement
1	!	Boolean	Logical complement
1	(*type*)	Any	Cast
2	*, /, %	Arithmetic	Multiplication, division, remainder
3	+, -	Arithmetic	Addition and subtraction
3	+	String	String concatenation
4	<<	Integral	Left shift
4	>>	Integral	Right shift with sign extension
4	>>>	Integral	Right shift with no extension
5	<, <=, >, >=	Arithmetic	Numeric comparison
5	instanceof	Object	Type comparison
6	==, !=	Primitive	Equality and inequality of value
6	==, !=	Object	Equality and inequality of reference
7	&	Integral	Bitwise AND
7	&	Boolean	Boolean AND
8	^	Integral	Bitwise XOR
8	^	Boolean	Boolean XOR
9	|	Integral	Bitwise OR
9	|	Boolean	Boolean OR
10	&&	Boolean	Conditional AND
11	||	Boolean	Conditional OR
12	?:	NA	Conditional ternary operator
13	=	Any	Assignment
13	*=, /=, %=, +=, -=, <<=, >>=, >>>=, &=, ^=, |=	Any	Assignment with operation

There are a few operators missing from the standard C collection. For example, Java doesn't support the comma operator for combining expressions, although the `for` statement allows you to use it in the initialization and increment sections. Java doesn't allow direct pointer manipulation, so it does not support the reference (`*`), dereference (`&`), and `sizeof` operators.

Java also adds some new operators. As we've seen, the + operator can be used with String values to perform string concatenation. Because all integral types in Java are signed values, the >> operator performs a right-shift operation with sign extension. The >>> operator treats the operand as an unsigned number and performs a right shift with no extension. The new operator is used to create objects; we will discuss it in detail shortly.

Assignment

While variable initialization (i.e., declaration and assignment together) is considered a statement, variable assignment alone is an expression:

```
int i, j;
i = 5;                           // expression
```

Normally, we rely on assignment for its side effects alone, but, as in C, an assignment can be used as a value in another part of an expression:

```
j = ( i = 5 );
```

Again, relying on order of evaluation extensively (in this case, using compound assignments in complex expressions) can make code very obscure and hard to read. Do so at your own peril.

null

The expression null can be assigned to any reference type. It has the meaning of "no reference." A null reference can't be used to select a method or variable and attempting to do so generates a NullPointerException at run-time.

Variable access

Using the dot (.) to access a variable in an object is a type of expression that results in the value of the variable accessed. This can be either a numeric type or a reference type:

```
int i;
String s;
i = myObject.length;
s = myObject.name;
```

A reference type expression can be used in further evaluations, by selecting variables or calling methods within it:

```
int len = myObject.name.length();
int initialLen = myObject.name.substring(5, 10).length();
```

Here we have found the length of our `name` variable by invoking the `length()` method of the `String` object. In the second case, we took an intermediate step and asked for a substring of the `name` string. The `substring` method of the `String` class also returns a `String` reference, for which we ask the length. (Chapter 7, *Basic Utility Classes* describes all of these `String` methods in detail.)

Method invocation

A method invocation is basically a function call, or in other words, an expression that results in a value, the type of which is the return type of the method. Thus far, we have seen methods invoked via their name in simple cases:

```
System.out.println( "Hello World..." );
int myLength = myString.length();
```

When we talk about Java's object-oriented features in Chapter 5, *Objects in Java*, we'll look at some rules that govern the selection of methods.

Like the result of any expression, the result of a method invocation can be used in further evaluations, as we saw above. Whether to allocate intermediate variables and make it absolutely clear what your code is doing or to opt for brevity where it's appropriate is a matter of coding style.

Object creation

Objects in Java are allocated with the `new` operator:

```
Object o = new Object();
```

The argument to `new` is a *constructor* that specifies the type of object and any required parameters to create it. The return type of the expression is a reference type for the created object.

We'll look at object creation in detail in Chapter 5, *Objects in Java*. For now, I just want to point out that object creation is a type of expression, and that the resulting object reference can be used in general expressions. In fact, because the binding of `new` is "tighter" than that of the dot-field selector, you can easily allocate a new object and invoke a method in it for the resulting expression:

```
int hours = new Date().getHours();
```

The `Date` class is a utility class that represents the current time. Here we create a new instance of `Date` with the `new` operator and call its `getHours()` method to retrieve the current hour as an integer value. The `Date` object reference lives long enough to service the method call and is then cut loose and garbage collected at some point in the future.

Calling methods in object references in this way is, again, a matter of style. It would certainly be clearer to allocate an intermediate variable of type `Date` to hold the new object and then call its `getHours()` method. However, some of us still find the need to be terse in our code.

instanceof

The `instanceof` operator can be used to determine the type of an object at run-time. `instanceof` returns a `boolean` value that indicates whether an object is an instance of a particular class or a subclass of that class:

```
Boolean b;
String str = "foo";
b = ( str instanceof String );     // true
b = ( str instanceof Object );     // also true
b = ( str instanceof Date );       // false--not a Date or subclass
```

`instanceof` also correctly reports if an object is of the type of an arry or a specified interface.

```
        if ( foo instanceof byte[] )
            ...
```

(See Chapter 5, *Objects in Java* for a full discussion of interfaces.)

It is also important to note that the value *null* is not considered an instance of any object. So the following test will return false, no matter what the declared type of the variable:

```
String s = null;
if ( s istanceof String )
    // won't happen
```

4.5 Exceptions

> Do, or do not... There is no try.
>
> --Yoda (*The Empire Strikes Back*)

Java's roots are in embedded systems--software that runs inside specialized devices like hand-held computers, cellular phones, and fancy toasters. In those kinds of applications, it's especially important that software errors be handled properly. Most users would agree that it's unacceptable for their phone to simply crash or for their toast (and perhaps their house) to burn because their software failed. Given that we can't eliminate the possibility of software errors, a step in the right direction is to at least try to recognize and deal with the application-level errors that we can anticipate in a methodical and systematic way.

Dealing with errors in a language like C is the responsibility of the programmer. There is no help from the language itself in identifying error types, and there are no tools for dealing with them easily. In C and C++, a routine generally indicates a failure by returning an "unreasonable" value (e.g., the idiomatic `-1` or `null`). As the programmer, you must know what constitutes a bad result, and what it means. It's often awkward to work around the limitations of passing error values in the normal path of data flow.[3] An even worse problem is that certain types of errors can legitimately occur almost anywhere, and it's prohibitive and unreasonable to explicitly test for them at every point in the software.

> [3] The somewhat obscure `setjmp()` and `longjmp()` statements in C can save a point in the execution of code and later return to it unconditionally from a deeply buried location. In a limited sense, this is the functionality of exceptions in Java.

Java offers an elegant solution to these problems with exception handling. (Java exception handling is similar to, but not quite the same as, exception handling in C++.) An *exception* indicates an unusual condition or an error condition. Program control becomes unconditionally transferred or thrown to a specially designated section of code where it's caught and handled. In this way, error handling is somewhat orthogonal to the normal flow of the program. We don't have to have special return values for all our methods; errors are handled by a separate mechanism. Control can be passed long distance from a deeply nested routine and handled in a single location when that is desirable, or an error can be handled immediately at its source. There are still a few methods that return `-1` as a special value, but these are limited to situations in which there isn't really an error.[4]

> [4] For example, the `getHeight()` method of the `Image` class returns `-1` if the height isn't known yet. No error has occurred; the height will be available in the future. In this situation, throwing an exception would be inappropriate.

A Java method is required to specify the exceptions it can throw (i.e., the ones that it doesn't catch itself); this means that the compiler can make sure we handle them. In this way, the information about what errors a method can produce is promoted to the same level of importance as its argument and return types. You may still decide to punt and ignore obvious errors, but in Java you must do so explicitly.

Exceptions and Error Classes

Exceptions are represented by instances of the class `java.lang.Exception` and its subclasses. Subclasses of `Exception` can hold specialized information (and possibly behavior) for different kinds of exceptional conditions. However, more often they are simply "logical" subclasses that exist only to serve as a new exception type (more on that later). Figure 4.1 shows the subclasses of `Exception`; these classes are defined in various packages in the Java API, as indicated in the diagram.

Figure 4.1: Java exception classes

[Graphic: Figure 4-1]

An `Exception` object is created by the code at the point where the error condition arises. It can hold whatever information is necessary to describe the exceptional condition, including a full stack trace for debugging. The exception object is passed, along with the flow of control, to the handling block of code. This is where the terms "throw" and "catch" come from: the `Exception` object is thrown from one point in the code and caught by the other, where execution resumes.

The Java API also defines the `java.lang.Error` class for eggregious or unrecoverable errors. The subclasses of `Error` are shown in Figure 4.2. You needn't worry about these errors (i.e., you do not have to catch them); they normally indicate linkage problems or virtual machine errors. An error of this kind usually causes the Java interpreter to display a message and exit.

Figure 4.2: Java error classes

[Graphic: Figure 4-2]

Exception Handling

The `try/catch` guarding statements wrap a block of code and catch designated types of exceptions that occur within it:

```
try {
    readFromFile("foo");
    ...
}
```

```
catch ( Exception e ) {
    // Handle error
    System.out.println( "Exception while reading file: " + e );
    ...
}
```

In the above example, exceptions that occur within the body of the `try` statement are directed to the `catch` clause for possible handling. The `catch` clause acts like a method; it specifies an argument of the type of exception it wants to handle, and, if it's invoked, the `Exception` object is passed into its body as an argument. Here we receive the object in the variable `e` and print it along with a message.

A `try` statement can have multiple `catch` clauses that specify different specific types (subclasses) of `Exception`:

```
try {
    readFromFile("foo");
    ...
}
catch ( FileNotFoundException e ) {
    // Handle file not found
    ...
}
catch ( IOException e ) {
    // Handle read error
    ...
}
catch ( Exception e ) {
    // Handle all other errors
    ...
}
```

The `catch` clauses are evaluated in order, and the first possible (assignable) match is taken. At most one `catch` clause is executed, which means that the exceptions should be listed from most specific to least. In the above example, we'll assume that the hypothetical `readFromFile()` can throw two different kinds of exceptions: one that indicates the file is not found; the other indicates a more general read error. Any subclass of `Exception` is assignable to the parent type `Exception`, so the third `catch` clause acts like the `default` clause in a `switch` statement and handles any remaining possibilities.

It should be obvious, but one beauty of the `try/catch` statement is that any statement in the `try` block can assume that all previous statements in the block succeeded. A problem won't arise suddenly because a programmer forgot to check the return value from some method. If an earlier statement fails, execution jumps immediately to the `catch` clause; later statements are never executed.

Bubbling Up

What if we hadn't caught the exception? Where would it have gone? Well, if there is no enclosing `try/catch` statement, the exception pops to the top of the method in which it appeared and is, in turn, thrown from that method. In this way, the exception bubbles up until it's caught, or until it pops out of the top of the program, terminating it with a run-time error message. There's a bit more to it than that because, in this case, the compiler would have reminded us to deal with it, but we'll get back to that in a moment.

Let's look at another example. In Figure 4.3, the method `getContent()` invokes the method `openConnection()` from within a `try/catch` statement. `openConnection()`, in turn, invokes the method `sendRequest()`, which calls the method `write()` to send some data.

Figure 4.3: Exception propagation

[Graphic: Figure 4-3]

In this figure, the second call to `write()` throws an `IOException`. Since `sendRequest()` doesn't contain a `try/catch` statement to handle the exception, it's thrown again, from the point that it was called in the method `openConnection()`. Since `openConnection()` doesn't catch the exception either, it's thrown once more. Finally it's caught by the `try` statement in `getContent()` and handled by its `catch` clause.

Since an exception can bubble up quite a distance before it is caught and handled, we may need a way to determine exactly where it was thrown. All exceptions can dump a *stack trace* that lists their method of origin and all of the nested method calls that it took to arrive there, using the printStackTrace() method.

```
try {
    // complex task
} catch ( Exception e ) {
    // dump information about exactly where the exception ocurred
    e.printStackTrack( System.err );
    ...
}
```

The *throws* Clause and *checked* Exceptions

I mentioned earlier that Java makes us be explicit about our error handling. But Java is programmer-friendly, and it's not possible to require that every conceivable type of error be handled in every situation. So, Java exceptions are divided into two categories: *checked exceptions* and *unchecked exceptions*. Most application level exceptions are checked, which means that any method that throws one, either by generating it itself (as we'll discuss below) or by passively ignoring one that occurs within it, must declare that it can throw that type of exception in a special `throws` clause in its method declaration. We haven't yet talked in detail about declaring methods; we'll cover that in Chapter 5, *Objects in Java*. For now all you need know is that methods have to declare the checked exceptions they can throw or allow to be thrown.

Again in Figure 4.3, notice that the methods `openConnection()` and `sendRequest()` both specify that they can throw an `IOException`. If we had to throw multiple types of exceptions we could declare them separated with commas:

```
void readFile( String s ) throws IOException, InterruptedException {
    ...
}
```

The throws clause tells the compiler that a method is a possible source of that type of checked exception and that anyone calling that method must be prepared to deal with it. The caller may use a *try/catch* block to catch it, or it may, itself, declare that it can throw the exception.

Exceptions that are subclasses of the `java.lang.RuntimeException` class are unchecked. See Figure 4.1 for the subclasses of `RuntimeException`. It's not a compile-time error to ignore the possibility of these exceptions being thrown; additionally, methods don't have to declare they can throw them. In all other respects, run-time exceptions behave the same as other exceptions. We are perfectly free to catch them if we wish; we simply aren't required to.

Checked exceptions

> Exceptions a reasonable application should try to handle gracefully.

Unchecked exception (Runtime exceptions)

> Exceptions from which we would not normally expect our software to try to recover.

The category of checked exceptions includes application-level problems like missing files and unavailable hosts. As good programmers (and upstanding citizens), we should design software to recover gracefully from these kinds of conditions. The category of unchecked exceptions includes problems such as "out of memory" and "array index out of bounds." While these may indicate application-level programming errors, they can occur almost anywhere and aren't generally easy to recover from. Fortunately, because there are unchecked exceptions, you don't have to wrap every one of your array-index operations in a `try/catch` statement.

Throwing Exceptions

We can throw our own exceptions: either instances of `Exception` or one of its predefined subclasses, or our own specialized subclasses. All we have to do is create an instance of the `Exception` and throw it with the `throw` statement:

```
throw new Exception();
```

Execution stops and is transferred to the nearest enclosing `try/catch` statement. (Note that there is little point in keeping a reference to the `Exception` object we've created here.) An alternative constructor of the `Exception` class lets us specify a string with an error message:

```
throw new Exception("Something really bad happened");
```

By convention, all types of Exception have a String constructor like this. Note that the String message above is somewhat facetious and vague. Normally you won't be throwing a plain old Exception, but a more specific subclass. For example:

```
public void checkRead( String s ) {
    if ( new File(s).isAbsolute() || (s.indexOf("..") != -1) )
        throw new SecurityException(
           x"Access to file : "+ s +" denied.");
}
```

In the above, we partially implement a method to check for an illegal path. If we find one, we throw a SecurityException, with some information about the transgression.

Of course, we could include whatever other information is useful in our own specialized subclasses of `Exception` (or SecurityException). Often though, just having a new type of exception is good enough, because it's sufficient to help direct the flow of control. For example, if we are building a parser, we might want to make our own kind of exception to indicate a particular kind of failure.

```
class ParseException extends Exception {
    ParseException() {
        super(); }
    ParseException( String desc ) {
        super( desc ) };
}
```

See Chapter 5, *Objects in Java* for a full description of classes and class constructors. The body of our exception class here simply allows a ParseException to be created in the conventional ways that we have created exceptions above. Now that we have our new exception type, we we might guard for it in the following kind of situation:

```
// Somewhere in our code
...
try {
    parseStream( input );
} catch ( ParseException pe ) {
    // Bad input...
} catch ( IOException ioe ) {
    // Low level communications problem
}
```

As you can see, although our new exception doesn't currently hold any specialized information about the problem (it certainly could), it does let us distinguish a parse error from an arbitrary communications error in the same chunk of code. You might call this kind of specialization of an exception to be making a "logical" exception.

Re-throwing exceptions

Sometimes you'll want to take some action based on an exception and then turn around and throw a new exception in its place. For example, suppose that we want to handle an IOException by freeing up some resources before allowing the failure to pass on to the rest of the application. You can do this in the obvious way, by simply catching the exception and then throwing it again or throwing a new one.

```
  *** I was going to say something about fillInStackTrack() here ***
```

Try Creep

The `try` statement imposes a condition on the statements they guard. It says that if an exception occurs within it, the remaining statements will be abandoned. This has consequences for local variable initialization. If the compiler can't determine whether a local variable assignment we placed inside a `try/catch` block will happen, it won't let us use the variable:

```
void myMethod() {
    int foo;

    try {
        foo = getResults();
    }
    catch ( Exception e ) {
        ...
    }

    int bar = foo;  // Compile time error--foo may not
                    // have been initialized
```

In the above example, we can't use `foo` in the indicated place because there's a chance it was never assigned a value. One obvious option is to move the assignment inside the `try` statement:

```
try {
    foo = getResults();
    int bar = foo;  // Okay because we only get here
                    // if previous assignment succeeds
}
catch ( Exception e ) {
    ...
}
```

Sometimes this works just fine. However, now we have the same problem if we want to use `bar` later in `myMethod()`. If we're not careful, we might end up pulling everything into the `try` statement. The situation changes if we transfer control out of the method in the `catch` clause:

```
try {
    foo = getResults();
}
catch ( Exception e ) {
    ...
    return;
}

int bar = foo;  // Okay because we only get here
                // if previous assignment succeeds
```

Your code will dictate its own needs; you should just be aware of the options.

The finally Clause

What if we have some clean up to do before we exit our method from one of the `catch` clauses? To avoid duplicating the code in each `catch` branch and to make the cleanup more explicit, Java supplies the `finally` clause. A `finally` clause can be added after a `try` and any associated `catch` clauses. Any statements in the body of the `finally` clause are guaranteed to be executed, no matter why control leaves the `try` body:

```
try {
    // Do something here
}
catch ( FileNotFoundException e ) {
    ...
}
catch ( IOException e ) {
    ...
}
catch ( Exception e ) {
    ...
}
finally {
    // Cleanup here
}
```

In the above example the statements at the cleanup point will be executed eventually, no matter how control leaves the `try`. If control transfers to one of the `catch` clauses, the statements in `finally` are executed after the `catch` completes. If none of the `catch` clauses handles the exception, the `finally` statements are executed before the exception propagates to the next level.

If the statements in the `try` execute cleanly, or even if we perform a `return`, `break`, or `continue`, the statements in the `finally` clause are executed. To perform cleanup operations, we can even use `try` and `finally` without any `catch` clauses:

```
try {
    // Do something here
    return;
}
finally {
    System.out.println("Whoo-hoo!");
}
```

Exceptions that occur in a `catch` or `finally` clause are handled normally; the search for an enclosing `try/catch` begins outside the offending `try` statement.

Arrays

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

4.6 Arrays

An array is a special type of object that can hold an ordered collection of elements. The type of the elements of the array is called the *base type* of the array; the number of elements it holds is a fixed attribute called its *length*. (For a collection with a variable length, see the discussion of `Vector` objects in Chapter 7, *Basic Utility Classes*.) Java supports arrays of all numeric and reference types.

The basic syntax of arrays looks much like that of C or C++. We create an array of a specified length and access the elements with the special index operator, `[]`. Unlike other languages, however, arrays in Java are true, first-class objects, which means they are real objects within the Java language. An array is an instance of a special Java array class and has a corresponding type in the type system. This means that to use an array, as with any other object, we first declare a variable of the appropriate type and then use the `new` operator to create an instance of it.

Array objects differ from other objects in Java in three respects:

- Java implicitly creates a special array class for us whenever we declare an array type variable. It's not strictly necessary to know about this process in order to use arrays, but it helps in understanding their structure and their relationship to other objects in Java.

- Java lets us use the special `[]` operator to access array elements, so that arrays look as we expect. We could implement our own classes that act like arrays, but because Java doesn't have user-defined operator overloading, we would have to settle for having methods like `get()` and `put()` instead of using the special `[]` notation.

- Java provides a corresponding special form of the `new` operator that lets us construct an instance of an array and specify its length with the `[]` notation.

Array Types

An array type variable is denoted by a base type followed by empty brackets `[]`. Alternatively, Java accepts a C-style declaration, with the brackets placed after the array name. The following are equivalent:

```
int [] arrayOfInts;
int arrayOfInts [];
```

In each case, `arrayOfInts` is declared as an array of integers. The size of the array is not yet an issue, because we are declaring only the array type variable. We have not yet created an actual instance of the array class, with its associated storage. It's not even possible to specify the length of an array as part of its type.

An array of objects can be created in the same way:

```
String [] someStrings;
Button someButtons [];
```

Array Creation and Initialization

Having declared an array type variable, we can now use the `new` operator to create an instance of the array. After the `new` operator, we specify the base type of the array and its length, with a bracketed integer expression:

```
arrayOfInts = new int [42];
someStrings = new String [ number + 2 ];
```

We can, of course, combine the steps of declaring and allocating the array:

```
double [] someNumbers = new double [20];
Component widgets [] = new Component [12];
```

As in C, array indices start with zero. Thus, the first element of `someNumbers []` is `0` and the last element is `19`. After creation, the array elements are initialized to the default values for their type. For numeric types, this means the elements are initially zero:

```
int [] grades = new int [30];
grades[0] = 99;
grades[1] = 72;
// grades[2] == 0
```

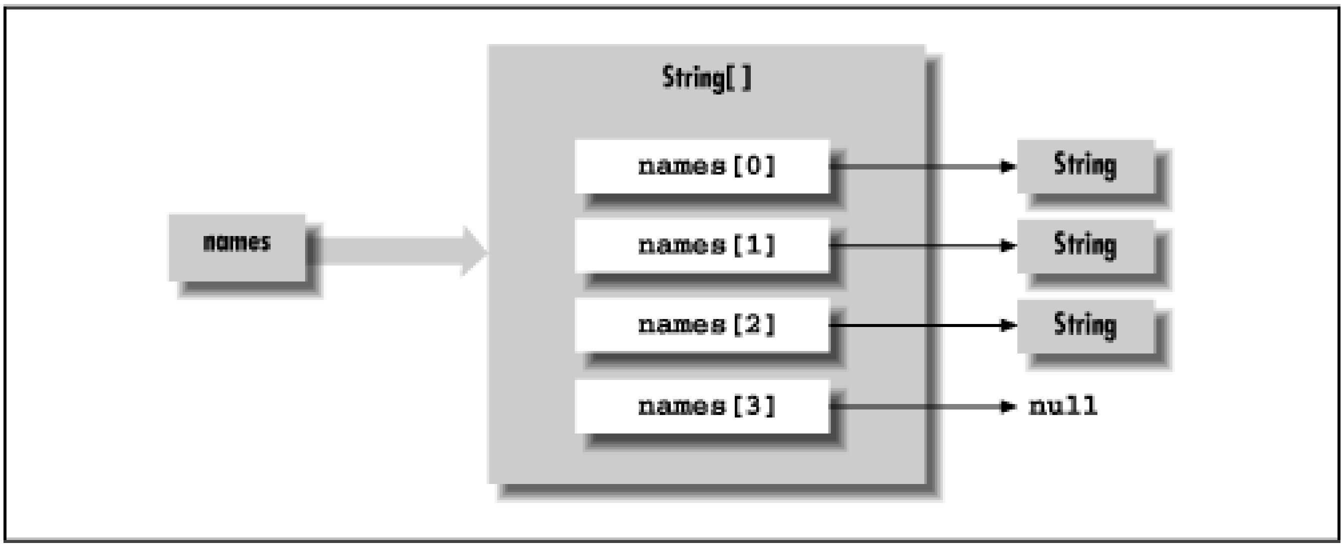
The elements of an array of objects are references to the objects, not actual instances of the objects. The default value of each element is therefore `null`, until we assign instances of appropriate objects:

```
String names [] = new String [4];
names [0] = new String();
names [1] = "Boofa";
names [2] = someObject.toString();
// names[3] == null
```

This is an important distinction that can cause confusion. In many other languages, the act of creating an array is the same as allocating storage for its elements. In Java, an array of objects actually contains only reference variables and those variables, have the value `null` until they are assigned to real objects.[5] Figure 4.4 illustrates the `names` array of the previous example:

> [5] The analog in C or C++ would be an array of pointers to objects. However, pointers in C or C++ are themselves two- or four-byte values. Allocating an array of pointers is, in actuality, allocating the storage for some number of those pointer objects. An array of references is conceptually similar, although references are not themselves objects. We can't manipulate references or parts of references other than by assignment, and their storage requirements (or lack thereof) are not part of the high-level language specification.

Figure 4.4: The names array



`names` is a variable of type `String[]` (i.e., a string array). The `String[]` object can be thought of as containing four `String` type variables. We have assigned `String` objects to the first three array elements. The fourth has the default value `null`.

Java supports the C-style curly braces `{}` construct for creating an array and initializing its elements when it is declared:

```
int [] primes = { 1, 2, 3, 5, 7, 7+4 };    // primes[2] == 3
```

An array object of the proper type and length is implicitly created and the values of the comma-separated list of expressions are assigned to its elements.

We can use the {} syntax with an array of objects. In this case, each of the expressions must evaluate to an object that can be assigned to a variable of the base type of the array, or the value null. Here are some examples:

```
String [] verbs = { "run", "jump", someWord.toString() };
Button [] controls = { stopButton, new Button("Forwards"),
    new Button("Backwards") };
// all types are subtypes of Object
Object [] objects = { stopButton, "A word", null };
```

You should create and initialize arrays in whatever manner is appropriate for your application. The following are equivalent:

```
Button [] threeButtons = new Button [3];
Button [] threeButtons = { null, null, null };
```

Using Arrays

The size of an array object is available in the public variable length:

```
char [] alphabet = new char [26];
int alphaLen = alphabet.length;             // alphaLen == 26

String [] musketeers = { "one", "two", "three" };
int num = musketeers.length;                // num == 3
```

length is the only accessible field of an array; it is a variable, not a method.

Array access in Java is just like array access in C; you access an element by putting an integer-valued expression between brackets after the name of the array. The following example creates an array of Button objects called keyPad and then fills the array with Button objects:

```
Button [] keyPad = new Button [ 10 ];
for ( int i=0; i < keyPad.length; i++ )      keyPad[ i ] = new Button(
Integer.toString( i ) );
```

Attempting to access an element that is outside the range of the array generates an ArrayIndexOutOfBoundsException. This is a type of RuntimeException, so you can either catch it and handle it yourself, or ignore it, as we already discussed:

```
String [] states = new String [50];

try {
    states[0] = "California";
    states[1] = "Oregon";
    ...
    states[50] = "McDonald's Land";  // Error--array out of bounds
}
catch ( ArrayIndexOutOfBoundsException err ) {
    System.out.println( "Handled error: " + err.getMessage() );
}
```

It's a common task to copy a range of elements from one array into another. Java supplies the `arraycopy()` method for this purpose; it's a utility method of the `System` class:

```
System.arraycopy( source, sourceStart, destination,
                  destStart, length );
```

The following example doubles the size of the `names` array from an earlier example:

```
String [] tmpVar = new String [ 2 * names.length ];
System.arraycopy( names, 0, tmpVar, 0, names.length );
names = tmpVar;
```

A new array, twice the size of `names`, is allocated and assigned to a temporary variable `tmpVar`. `arraycopy()` is used to copy the elements of `names` to the new array. Finally, the new array is assigned to `names`. If there are no remaining references to the old array object after `names` has been copied, it will be garbage collected on the next pass.

Anonymous Arrays

You often want to create "throw-away" arrays: arrays that are only used in one place, and never referenced anywhere else. Such arrays don't need to have a name, because you never need to refer to them again in that context. For example, you may want to create a collection of objects to pass as an argument to some method. It's easy enough to create a normal, named array--but if you don't actually work with the array (if you use the array only as a holder for some collection), you shouldn't have to. Java makes it easy to create "anonymous" (i.e., unnamed) arrays.

Let's say you need to call a method named `setPets()`, which takes an array of `Animal` objects as arguments. `Cat` and `Dog` are subclasses of `Animal`. Here's how to call `setPets()` using an anonymous array:

```
Dog pokey = new Dog ("gray");
Cat squiggles = new Cat ("black");
Cat jasmine = new Cat ("orange");
setPets ( new Animal [] { pokey, squiggles, jasmine });
```

The syntax looks just like the initialization of an array in a variable declaration. We implicitly define the size of the array and fill in its elements using the curly brace notation. However, since this is not a variable declaration we have to explicitly use the new operator to create the array object.

You can use anonymous arrays to simulate variable length argument lists (often called VARARGS), a feature of many programming languages that Java doesn't provide. The advantage of anonymous arrays over variable length argument lists is that it allows stricter type checking; the compiler always knows exactly what arguments are expected, and therefore can verify that method calls are correct.

Multidimensional Arrays

Java supports multidimensional arrays in the form of arrays of array type objects. You create a multidimensional array with C-like syntax, using multiple bracket pairs, one for each dimension. You also use this syntax to access elements at various positions within the array. Here's an example of a multidimensional array that represents a chess board:

```
ChessPiece [][] chessBoard;
chessBoard = new ChessPiece [8][8];
chessBoard[0][0] = new ChessPiece( "Rook" );
chessBoard[1][0] = new ChessPiece( "Pawn" );
...
```

Here `chessBoard` is declared as a variable of type `ChessPiece[][]` (i.e., an array of `ChessPiece` arrays). This declaration implicitly creates the type `ChessPiece[]` as well. The example illustrates the special form of the `new` operator used to create a multidimensional array. It creates an array of `ChessPiece[]` objects and then, in turn, creates each array of `ChessPiece` objects. We then index `chessBoard` to specify values for particular `ChessPiece` elements. (We'll neglect the color of the pieces here.)

Of course, you can create arrays of with more than two dimensions. Here's a slightly impractical example:

```
Color [][][] rgbCube = new Color [256][256][256];
rgbCube[0][0][0] = Color.black;
rgbCube[255][255][0] = Color.yellow;
```

```
...
```

As in C, we can specify the initial index of a multidimensional array to get an array type object with fewer dimensions. In our example, the variable `chessBoard` is of type `ChessPiece[][]`. The expression `chessBoard[0]` is valid and refers to the first element of `chessBoard`, which is of type `ChessPiece[]`. For example, we can create a row for our chess board:

```
ChessPiece [] startRow =  {
    new ChessPiece("Rook"), new ChessPiece("Knight"),
    new ChessPiece("Bishop"), new ChessPiece("King"),
    new ChessPiece("Queen"), new ChessPiece("Bishop"),
    new ChessPiece("Knight"), new ChessPiece("Rook")
};

chessBoard[0] = startRow;
```

We don't necessarily have to specify the dimension sizes of a multidimensional array with a single `new` operation. The syntax of the `new` operator lets us leave the sizes of some dimensions unspecified. The size of at least the first dimension (the most significant dimension of the array) has to be specified, but the sizes of any number of the less significant array dimensions may be left undefined. We can assign appropriate array type values later.

We can create a checkerboard of `boolean` values (which is not quite sufficient for a real game of checkers) using this technique:

```
boolean [][] checkerBoard;
checkerBoard = new boolean [8][];
```

Here, `checkerBoard` is declared and created, but its elements, the eight `boolean[]` objects of the next level, are left empty. Thus, for example, `checkerBoard[0]` is `null` until we explicitly create an array and assign it, as follows:

```
checkerBoard[0] = new boolean [8];
checkerBoard[1] = new boolean [8];
...
checkerBoard[7] = new boolean [8];
```

The code of the previous two examples is equivalent to:

```
boolean [][] checkerBoard = new boolean [8][8];
```

One reason we might want to leave dimensions of an array unspecified is so that we can store arrays given to us by another method.

Note that since the length of the array is not part of its type, the arrays in the checkerboard do not necessarily have to be of the same length. Here's a defective (but perfectly legal) checkerboard:

```
checkerBoard[2] = new boolean [3];
checkerBoard[3] = new boolean [10];
```

Since Java implements multidimensional arrays as arrays of arrays, multidimensional arrays do not have to be rectangular. For example, here's how you could create and initialize a triangular array:

```
int [][][] triangle = new int [5][];
for (int i = 0; i < triangle.length; i++) {
    triangle[i] = new int [i + 1];
    for (int j = 0; j < i + 1; j++)
        triangle[i][j] = i + j;    }
```

Inside Arrays

I said earlier that arrays are instances of special array classes in the Java language. If arrays have classes, where do they fit into the class hierarchy and how are they related? These are good questions; however, we need to talk more about the object-oriented aspects of Java before I can answer them. For now, take it on faith that arrays fit into the class hierarchy; details are in Chapter 5, *Objects in Java*.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.2 Methods

Methods appear inside class bodies. They contain local variable declarations and other Java statements that are executed by a calling thread when the method is invoked. Method declarations in Java look like ANSI C-style function declarations with two restrictions:

- A method in Java always specifies a return type (there's no default). The returned value can be a primitive numeric type, a reference type, or the type `void`, which indicates no returned value.
- A method always has a fixed number of arguments. The combination of method overloading and true arrays removes most of the need for a variable number of arguments. These techniques are type-safe and easier to use than C's variable argument list mechanism.

Here's a simple example:

```
class Bird {
    int xPos, yPos;

    double fly ( int x, int y ) {
        double distance = Math.sqrt( x*x + y*y );
        flap( distance );
        xPos = x;
        yPos = y;
        return distance;
    }
    ...
}
```

In this example, the class `Bird` defines a method, `fly()`, that takes as arguments two integers: `x` and `y`. It returns a `double` type value as a result.

Local Variables

The `fly()` method declares a local variable called `distance` that it uses to compute the distance flown. A local variable is temporary; it exists only within the scope of its method. Local variables are allocated and initialized when a method is invoked; they are normally destroyed when the method returns. They can't be referenced from outside the method itself. If the method is executing concurrently in different threads, each thread has its own copies of the method's local variables. A method's arguments also serve as local variables within the scope of the method.

An object created within a method and assigned to a local variable may or may not persist after the method has returned. As with all objects in Java, it depends on whether any references to the object remain. If an object is created, assigned to a local variable, and never used anywhere else, that object will no longer be referenced when the local variable is destroyed, so garbage collection will remove the object. If, however, we assign the object to an instance variable, pass it as an argument to another method, or pass it back as a return value, it may be saved by another variable holding its reference. We'll discuss object creation and garbage collection in more detail shortly.

Shadowing

If a local variable and an instance variable have the same name, the local variable *shadows* or hides the name of the instance variable within the scope of the method. In the following example, the local variables `xPos` and `yPos` hide the instance variables of the same name:

```
class Bird {
    int xPos, yPos;
    int xNest, yNest;
    ...
    double flyToNest() {
        int xPos = xNest;
        int yPos = yNest:
        return ( fly( xPos, yPos ) );
    }
    ...
}
```

When we set the values of the local variables in `flyToNest()`, it has no effect on the values of the instance variables.

this

The special reference `this` refers to the current object. You can use it any time you need to refer explicitly to the current object instance. Often, you don't need to use `this` because the reference to the current object is implicit; this is the case with using instance variables and methods inside of a class. But we can use `this` to refer explicitly to instance variables in the object, even if they are shadowed.

The subsequent example shows how we can use `this` to allow us argument names that shadow instance variable names. This is a fairly common technique, as it saves your having to deliberately make up alternate names (as we'll try to emphasize in this book, names are important). Here's how we could implement our `fly()` method with shadowed variables:

```
class Bird {
    int xPos, yPos;

    double fly ( int xPos, int yPos ) {
        double distance = Math.sqrt( xPos*xPos + yPos*yPos );
        flap( distance );
        this.xPos = xPos;
        this.yPos = yPos;
        return distance;
    }
    ...
}
```

In this example, the expression `this.xPos` refers to the instance variable `xPos` and assigns it the value of the local variable `xPos`, which would otherwise hide its name. The only reason we need to use `this` in the above example is because we've used argument names that hide our instance variables, and we want to refer to the instance variables.

Static Methods

Static methods (class methods), like static variables, belong to the class and not to an individual instance of the class. What does this mean? Well, foremost, a static method lives outside of any particular class instance. It can be invoked by name, through the class name, without any objects around. Because it is not bound to a particular object instance, a static method can only directly access other static members of classes. It can't directly see any instance variables or call any instance methods, because to do so we'd have to ask: "on which instance?" Static methods can be called from instances, just like instance methods, but the important thing is that they can also be used independently.

Our `fly()` method uses a static method: `Math.sqrt()`. This method is defined by the `java.lang.Math` class; we'll explore this class in detail in Chapter 7, *Basic Utility Classes*. For now, the important thing to note is that `Math` is the name of a class and not an instance of a `Math` object (you can't even make an instance of `Math`). Because `static` methods can be invoked wherever the class name is available, class methods are closer to normal C-style functions. Static methods are particularly useful for utility methods that perform work that might be useful either independently of instances of the class or in creating instances of the class.

For example, in our `Bird` class we can enumerate all types of birds that can be created:

```
class Bird {
    ...
    static String [] getBirdTypes( ) {
    String [] types;
    // Create list...
        return types;
    }
    ...
}
```

Here we've defined a `static` method `getBirdTypes()` that returns an array of strings containing bird names. We can use `getBirdTypes()` from within an instance of `Bird`, just like an instance method. However, we can also call it from other classes, using the `Bird` class name as a reference:

```
String [] names = Bird.getBirdTypes();
```

Perhaps a special version of the `Bird` class constructor accepts the name of a bird type. We could use this list to decide what kind of bird to create.

Local Variable Initialization

In the `flyToNest()` example, we made a point of initializing the local variables `xPos` and `yPos`. Unlike instance variables, local variables must be initialized before they can be used. It's a compile-time error to try to access a local variable without first assigning it a value:

```
void myMethod() {
    int foo = 42;
    int bar;

    // bar += 1;       // Compile time error, bar uninitialized

    bar = 99;
    bar += 1;       // ok here
}
```

Notice that this doesn't imply local variables have to be initialized when declared, just that the first time they are referenced must be in an assignment. More subtle possibilities arise when making assignments inside of conditionals:

```
void myMethod {
    int foo;

    if ( someCondition ) {
        foo = 42;
        ...
    }

    foo += 1;                  // Compile time error
                               // foo may not have been initialized
```

In the above example, `foo` is initialized only if `someCondition` is `true`. The compiler doesn't let you make this wager, so it flags the use of `foo` as an error. We could correct this situation in several ways. We could initialize the variable to a default value in advance or move the usage inside of the conditional. We could also make sure the path of execution doesn't reach the uninitialized variable through some other means, depending on what makes sense for our particular application. For example, we could return from the method abruptly:

```
int foo;
...
if ( someCondition ) {
    foo = 42;
    ...
} else
    return;

foo += 1;
```

In this case, there's no chance of reaching `foo` in an unused state and the compiler allows the use of `foo` after the conditional.

Why is Java so picky about local variables? One of the most common (and insidious) sources of error in C or C++ is forgetting to initialize local variables, so Java tries to help us out. If it didn't, Java would suffer the same potential irregularities as C or C++.[2]

[2] As with `malloc`'ed storage in C or C++, Java objects and their instance variables are allocated on a heap, which allows them default values once, when they are created. Local variables, however, are allocated on the Java virtual machine stack. As with the stack in C and C++, failing to initialize these could mean successive method calls could receive garbage values, and program execution might be inconsistent or implementation dependent.

Argument Passing and References

Let's consider what happens when you pass arguments to a method. All primitive data types (e.g., `int`, `char`, `float`) are passed by value. Now you're probably used to the idea that reference types (i.e., any kind of object, including arrays and strings) are used through references. An important distinction (that we discussed briefly in Chapter 4) is that the references themselves (the pointers to these objects) are actually primitive types, and are passed by value too.

Consider the following piece of code:

```
// somewhere
    int i = 0;
    SomeKindOfObject obj = new SomeKindOfObject();
    myMethod( i, obj );
    ...
void myMethod(int j, SomeKindOfObject o) {
    ...
}
```

The first chunk of code calls `myMethod()`, passing it two arguments. The first argument, `i`, is passed by value; when the method is called, the value of `i` is copied into the method's parameter `j`. If `myMethod()` changes the value of `i`, it's changing only its copy of the local variable.

In the same way, a copy of the reference to `obj` is placed into the reference variable `o` of `myMethod()`. Both references refer to the same object, of course, and any changes made through either reference affect the actual (single) object instance, but there are two copies of the pointer. If we change the value of, say, `o.size`, the change is visible through either reference. However, if `myMethod()` changes the reference `o` itself--to point to another object--it's affecting only its copy. In this sense, passing the reference is like passing a pointer in C and *unlike* passing by reference in C++.

What if `myMethod()` needs to modify the calling method's notion of the `obj` reference as well (i.e., make `obj` point to a different object)? The easy way to do that is to wrap `obj` inside some kind of object. A good candidate would be to wrap the object up as the lone element in an array:

```
SomeKindOfObject [] wrapper = { obj };
```

All parties could then refer to the object as wrapper[0] and would have the ability to change the reference. This is not very asthetically pleasing, but it does illustrate that what is needed is the level of indirection. Another possibility is to use `this` to pass a reference to the calling object.

Let's look at another piece of code that could be from an implementation of a linked list:

```
class Element {
    public Element nextElement;

    void addToList( List list ) {
        list.addToList( this );
    }
}

class List {
    void addToList( Element element ) {
        ...
        element.nextElement = getNextElement();
    }
}
```

Every element in a linked list contains a pointer to the next element in the list. In this code, the `Element` class represents one element; it includes a method for adding itself to the list. The `List` class itself contains a method for adding an arbitrary `Element` to the list. The method `addToList()` calls `addToList()` with the argument `this` (which is, of course, an `Element`). `addToList()` can use the `this` reference to modify the `Element`'s `nextElement` instance variable. The same technique can be used in conjunction with interfaces to implement callbacks for arbitrary method invocations.

Method Overloading

Method overloading is the ability to define multiple methods with the same name in a class; when the method is invoked, the compiler picks the correct one based on the arguments passed to the method. This implies, of course, that overloaded methods must have different numbers or types of arguments. In a later section we'll look at method overriding, which occurs when we declare methods with identical signatures in different classes.

Method overloading is a powerful and useful feature. It's another form of polymorphism (ad-hoc polymorphism). The idea is to create methods that act in the same way on different types of arguments and have what appears to be a single method that operates on any of the types. The Java `PrintStream`'s `print()` method is a good example of method overloading in action. As you've probably deduced by now, you can print a string representation of just about anything using the expression:

```
System.out.print( argument )
```

The variable `out` is a reference to an object (a `PrintStream`) that defines nine different versions of the `print()` method. They take, respectively, arguments of the following types: `Object`, `String`, char[], char, int, long, float, double, and boolean.

```
class PrintStream {
    void print( Object arg ) { ... }
    void print( String arg ) { ... }
    void print( char [] arg ) { ... }
    ...
}
```

You can invoke the print() method with any of these types as an argument, and it's printed in an appropriate way. In a language without method overloading, this would require something more cumbersome, such as a separate method for printing each type of object. Then it would be your responsibility to remember what method to use for each data type.

In the above example, print() has been overloaded to support two reference types: Object and String. What if we try to call print() with some other reference type? Say, perhaps, a Date object? The answer is that since Date is a subclass of Object, the Object method is selected. When there's not an exact type match, the compiler searches for an acceptable, assignable match. Since Date, like all classes, is a subclass of Object, a Date object can be assigned to a variable of type Object. It's therefore an acceptable match, and the Object method is selected.

But what if there's more than one possible match? Say, for example, we tried to print a subclass of String called MyString. (Of course, the String class is final, so it can't be subclassed, but allow me this brief transgression for purposes of explanation.) MyString is assignable to either String or to Object. Here the compiler makes a determination as to which match is "better" and selects that method. In this case it's the String method.

The intuitive explanation is that the String class is closer to MyString in the inheritance hierarchy. It is a *more specific* match. A more rigorous way of specifying it would be to say that a given method is more specific than another method with respect to some arguments it wants to accept if the argument types of the first method are all assignable to the argument types of the second method. In this case, the String method is more specific to a subclass of String than the Object method because type String is assignable to type Object. The reverse is obviously not true.

If you're paying close attention, you may have noticed I said that the compiler resolves overloaded methods. Method overloading is not something that happens at run-time; this is an important distinction. It means that the selected method is chosen once, when the code is compiled. Once the overloaded method is selected, the choice is fixed until the code is recompiled, even if the class containing the called method is later revised and an even more specific overloaded method is added. This is in contrast to overridden (virtual) methods, which are located at run-time and can be found even if they didn't exist when the calling class was compiled. We'll talk about method overriding later in the chapter.

One last note about overloading. In earlier chapters, we've pointed out that Java doesn't support programmer-defined overloaded operators, and that + is the only system-defined overloaded operator. If you've been wondering what an overloaded operator is, I can finally clear up that mystery. In a language like C++, you can customize operators such as + and * to work with objects that you create. For example, you could create a class `Complex` that implements complex numbers, and then overload methods corresponding to + and * to add and multiply `Complex` objects. Some people argue that operator overloading makes for elegant and readable programs, while others say it's just "syntactic sugar" that makes for obfuscated code. The Java designers clearly espoused the later opinion when they chose not to support programmer-defined overloaded operators.

5.3 Object Creation

Objects in Java are allocated from a system heap space, much like `malloc`'ed storage in C or C++. Unlike C or C++, however, we needn't manage that memory ourselves. Java takes care of memory allocation and deallocation for you. Java explicitly allocates storage for an object when you create it with the `new` keyword. More importantly, objects are removed by garbage collection when they're no longer referenced.

Constructors

You allocate an object by specifying the `new` operator with an object *constructor*. A constructor is a special method with the same name as its class and no return type. It's called when a new class instance is created, which gives the class an opportunity to set up the object for use. Constructors, like other methods, can accept arguments and can be overloaded (they are not, however, inherited like other methods; we'll discuss inheritance later).

```
class Date {
    long time;

    Date() {
        time = currentTime();
    }

    Date( String date ) {
        time = parseDate( date );
    }
    ...
}
```

In the above example, the class `Date` has two constructors. The first takes no arguments; it's known as the default constructor. Default constructors play a special role in that, if we don't define any constructors for a class, an empty default constructor is supplied for us. The default constructor is what gets called whenever you create an object by calling its constructor with no arguments. Here we have implemented the default constructor so that it sets the instance variable `time` by calling a hypothetical method: `currentTime()`, which resembles the functionality of the real `java.util.Date` class.

The second constructor takes a `String` argument. Presumably, this `String` contains a string representation of the time that can be parsed to set the `time` variable.

Given the constructors above, we create a `Date` object in the following ways:

```
Date now = new Date();
Date christmas = new Date("Dec 25, 1997");
```

In each case, Java chooses the appropriate constructor at compile-time based on the rules for overloaded method selection.

If we later remove all references to an allocated object, it'll be garbage collected, as we'll discuss shortly:

```
christmas = null;          // fair game for the garbage collector
```

Setting the above reference to `null` means it's no longer pointing to the "Dec 25, 1997" object. Unless that object is referenced by another variable, it's now inaccessible and can be garbage collected. Actually, setting `christmas` to any other value would have the same results, but using the value `null` is a clear way to indicate that `christmas` no longer has a useful value.

A few more notes about constructors. Constructors can't be `abstract`, `synchronized`, or `final`. Constructors can, however, be declared with the visibility modifiers public, private, or protected, to control their accessibility. We'll talk in detail about visibility modifiers later in the chapter.

Working with Overloaded Constructors

A constructor can refer to another constructor in the same class or the immediate superclass using special forms of the `this` and `super` references. We'll discuss the first case here, and return to that of the superclass constructor again after we have talked more about subclassing and inheritance.

A constructor can invoke another, overloaded constructor in its class using the reference `this()` with appropriate arguments to select the desired constructor. If a constructor calls another constructor, it must do so as its first statement (we'll explain why in a bit):

```
class Car {
    String model;
    int doors;
    Car( String m, int d ) {
        model = m;
        doors = d;
        // other, complicated setup
        ...
    }

    Car( String m ) {
        this( m, 4 );
    }
    ...
}
```

In the example above, the class `Car` has two overloaded constructors. The first, more explicit one, accepts arguments specifying the car's model and its number of doors and uses them to set up the object. We have also provided a simpler constructor that takes just the model as an argument and, in turn, calls the first constructor with a default value of four doors. The advantage of this approach is that you can have a single constructor do all the complicated setup work; other auxiliary constructors simply feed the appropriate arguments to that constructor.

The important point is the call to `this()`, which must appear as the first statement our second constructor. The syntax is restricted in this way because there's a need to identify a clear chain of command in the calling of constructors. At one end of the chain, Java invokes the constructor of the superclass (if we don't do it explicitly) to ensure that inherited members are initialized properly before we proceed. There's also a point in the chain, just after the constructor of the superclass is invoked, where the initializers of the current class's instance variables are evaluated. Before that point, we can't even reference the instance variables of our class. We'll explain this situation again in complete detail after we have talked about inheritance.

For now, all you need to know is that you can invoke a second constructor only as the first statement of another constructor. In addition, you can't do anything at that point other than pass along arguments of the current constructor. For example, the following is illegal and causes a compile-time error:

```
Car( String m ) {
    int doors = determineDoors();
    this( m, doors );   // Error
}                       // Constructor call must be first statement
```

The simple model name constructor can't do any additional setup before calling the more explicit constructor. It can't even refer to an instance member for a constant value:

```
class Car {
    ...
    final int default_doors = 4;
    ...

    Car( String m ) {
        this( m, default_doors ); // Error
                                  // Referencing uninitialized variable
    }
    ...
}
```

The instance variable `defaultDoors` above is not initialized until a later point in the chain of constructor calls, so the compiler doesn't let us access it yet. Fortunately, we can solve this particular problem by making the identifier `static` as well:

```
class Car {
    ...
    static final int DEFAULT_DOORS = 4;
    ...

    Car( String m ) {
        this( m, DEFAULT_DOORS );  // Okay now
    }
    ...
}
```

The `static` members of our class have been initialized for some time (since the class was first loaded), so it's safe to access them.

Static and Nonstatic Code Blocks

It's possible to declare a code block (some statements within curly braces) directly within the scope of a class. This code block doesn't belong to any method; instead, it's executed just once, at the time the object is constructed, or, in the case of a code block marked static, at the time the class is loaded.

Nonstatic code blocks can be thought of as just an extension of instance variable initialization. They are called at the time the instance variable's initializers are evaluated (after superclass construction), in the textual order in which they appear in the class source.

```
class MyClass {
    Properties myProps = new Properties();
    // set up myProps
    {
        myProps.put("foo", "bar");
        myProps.put("boo", "gee);
    }
    int a = 5;
    ...
```

You can use static code blocks to initialize `static` class members in this way. So the static members of a class can have complex initialization just like objects:

```
class ColorWheel {
    static Hashtable colors = new Hashtable();

    // set up colors
    static {
        colors.put("Red", Color.red );
        colors.put("Green", Color.green );
        colors.put("Blue", Color.blue );
        ...
    }
    ...
}
```

In the above example, the class `ColorWheel` provides a variable `colors` that maps the names of colors to `Color` objects in a `Hashtable`. The first time the class `ColorWheel` is referenced and loaded, the `static` components of `ColorWheel` are evaluated, in the order they appear in the source. In this case, the `static` code block simply adds elements to the `colors` `Hashtable`.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.5 Subclassing and Inheritance

Classes in Java exist in a class hierarchy. A class in Java can be declared as a *subclass* of another class using the `extends` keyword. A subclass *inherits* variables and methods from its *superclass* and uses them as if they're declared within the subclass itself:

```
class Animal {
    float weight;
    ...
    void eat() {
        ...
    }
    ...
}

class Mammal extends Animal {
    int heartRate;
    // inherits weight
    ...
    void breathe() {
        ...
    }
    // inherits eat()
}
```

In the above example, an object of type `Mammal` has both the instance variable `weight` and the method `eat()`. They are inherited from `Animal`.

A class can extend only one other class. To use the proper terminology, Java allows *single inheritance* of class implementation. Later we'll talk about interfaces, which take the place of *multiple inheritance* as it's primarily used in C++.

A subclass can, of course, be further subclassed. Normally, subclassing specializes or refines a class by adding variables and methods:

```
class Cat extends Mammal {
    boolean longHair;
    // inherits weight and heartRate
    ...
    void purr() {
        ...
    }
    // inherits eat() and breathe()
}
```

The `Cat` class is a type of `Mammal` that is ultimately a type of `Animal`. `Cat` objects inherit all the characteristics of `Mammal` objects and, in turn, `Animal` objects. `Cat` also provides additional behavior in the form of the `purr()` method and the `longHair` variable. We can denote the class relationship in a diagram, as shown in Figure 5.3.

Figure 5.3: A class hierarchy

[Graphic: Figure 5-3]

A subclass inherits all members of its superclass not designated as `private`. As we'll discuss shortly, other levels of visibility affect what inherited members of the class can be seen from outside of the class and its subclasses, but at a minimum, a subclass always has the same set of visible members as its parent. For this reason, the type of a subclass can be considered a subtype of its parent, and instances of the subtype can be used anywhere instances of the supertype are allowed. For example:

```
Cat simon = new Cat();
Animal creature = simon;
```

The `Cat` `simon` in the above example can be assigned to the `Animal` type variable `creature` because `Cat` is a subtype of `Animal`.

Shadowed Variables

In the previous section on methods, we saw that a local variable of the same name as an instance variable hides the instance variable. Similarly, an instance variable in a subclass can shadow an instance variable of the same name in its parent class, as shown in Figure 5.4.

Figure 5.4: The scope of shadowed variables

[Graphic: Figure 5-4]

In Figure 5.4, the variable `weight` is declared in three places: as a local variable in the method `foodConsumption()` of the class `Mammal`, as an instance variable of the class `Mammal`, and as an instance variable of the class `Animal`. The actual variable selected depends on the scope in which we are working.

In the above example, all variables were of the same type. About the only reason for declaring a variable with the same type in a subclass is to provide an alternate initializer. A more important use of shadowed variables involves changing their types. We could, for example, shadow an `int` variable with a `double` variable in a subclass that needs decimal values instead of integer values. We do this without changing the existing code because, as its name suggests, when we shadow variables, we don't replace them but instead mask them. Both variables still exist; methods of the superclass see the original variable, and methods of the subclass see the new version. The determination of what variables the various methods see is static and happens at compile-time.

Here's a simple example:

```
class IntegerCalculator {
    int sum;
    ...
}

class DecimalCalculator extends IntegerCalculator {
    double sum;
    ...
}
```

In this example, we override the instance variable sum to change its type from int to double.[3] Methods defined in the class IntegerCalculator see the integer variable sum, while methods defined in DecimalCalculator see the decimal variable sum. However, both variables actually exist for a given instance of DecimalCalculator, and they can have independent values. In fact, any methods that DecimalCalculator inherits from IntegerCalculator actually see the integer variable sum.

[3] Note that a better way to design our calculators would be to have an abstract Calculator class with two subclasses: IntegerCalculator and DecimalCalculator.

Since both variables exist in DecimalCalculator, we need to reference the variable inherited from IntegerCalculator. We do that using the super reference:

```
int s = super.sum
```

Inside of DecimalCalculator, the super keyword used in this manner refers to the sum variable defined in the superclass. I'll explain the use of super more fully in a bit.

Another important point about shadowed variables has to do with how they work when we refer to an object by way of a less derived type. For example, we can refer to a DecimalCalculator object as an IntegerCalculator. If we do so and then access the variable sum, we get the integer variable, not the decimal one:

```
DecimalCalculator dc = new DecimalCalculator();
IntegerCalculator ic = dc;

int s = ic.sum;                  // Accesses IntegerCalculator sum
```

After this detailed explanation, you may still be wondering what shadowed variables are good for. Well, to be honest, the usefulness of shadowed variables is limited, but it's important to understand the concepts before we talk about doing the same thing with methods. We'll see a different and more dynamic type of behavior with method shadowing, or more correctly, *method overriding*.

Overriding Methods

In a previous section, we saw we could declare overloaded methods (i.e., methods with the same name but a different number or type of arguments) within a class. Overloaded method selection works the way I described on all methods available to a class, including inherited ones. This means that a subclass can define some overloaded methods that augment the overloaded methods provided by a superclass.

But a subclass does more than that; it can define a method that has exactly the *same* method signature (arguments and return type) as a method in its superclass. In that case, the method in the subclass *overrides* the method in the superclass and effectively replaces its implementation, as shown in Figure 5.5. Overriding methods to change the behavior of objects is another form of polymorphism (sub-type polymorphism): the one most people think of when they talk about the power of object-oriented languages.

Figure 5.5: Method overriding

[Graphic: Figure 5-5]

In Figure 5.5, `Mammal` overrides the `reproduce()` method of `Animal`, perhaps to specialize the method for the peculiar behavior of `Mammals` giving live birth.[4] The `Cat` object's sleeping behavior is overridden to be different from that of a general `Animal`, perhaps to accommodate cat naps. The `Cat` class also adds the more unique behaviors of purring and hunting mice.

[4] We'll ignore the platypus, which is an obscure nonovoviviparous mammal.

From what you've seen so far, overridden methods probably look like they shadow methods in superclasses, just as variables do. But overridden methods are actually more powerful than that. An overridden method in Java acts like a `virtual` method in C++. When there are multiple implementations of a method in the inheritance hierarchy of an object, the one in the most derived class always overrides the others, even if we refer to the object by way of a less derived type. In other words, if we have a `Cat` instance assigned to a variable of the more general type `Animal` and we call its `sleep()` method, we get the `sleep()` method implemented in the `Cat` class, not the one in `Animal`:

```
Cat simon = new Cat();
Animal creature = simon;

creature.sleep();          // Accesses Cat sleep();
```

In other respects, the variable `creature` looks like an `Animal`. For example, access to a shadowed variable would find the implementation in the `Animal` class, not the `Cat` class. However, because methods are virtual, the appropriate method in the `Cat` class can be located, even though we are dealing with an `Animal` object. This means we can deal with specialized objects as if they were more general types of objects and still take advantage of their specialized implementations of behavior.

Much of what you'll be doing when you're writing a Java applet or application is overriding methods defined by various classes in the Java API. For example, think back to the applets we developed in the tutorial in Chapter 2, *A First Applet*. Almost all of the methods we implemented for those applets were overridden methods. Recall that we created a subclass of `Applet` for each of the examples. Then we overrode various methods: `init()` set up our applet, `mouseDrag()` to handle mouse movement, and `paint()` to draw our applet.

A common programming error in Java (at least for me) is to miss and accidentally overload a method when trying to override it. Any difference in the number or type of arguments or the return type of a method produces two overloaded methods instead of a single, overridden method. Make it a habit to look twice when overriding methods.

Overridden methods and dynamic binding

In a previous section, I mentioned that overloaded methods are selected by the compiler at compile-time. Overridden methods, on the other hand, are selected dynamically at run-time. Even if we create an instance of a subclass our code has never seen before (perhaps a new object type loaded from the network), any overridden methods that it contains will be located and invoked at run-time to replace those that existed when we last compiled our code.

In contrast, if we load a new class that implements an additional, more specific overloaded method, our code will continue to use the implementation it discovered at compile-time. Another effect of this is that casting (i.e., explicitly telling the compiler to treat an object as one of its assignable types) affects the selection of overloaded methods, but not overridden methods.

Static method binding

Static methods do not belong to any object instance, they are accessed directly through a class name, so they are not dynamically selected at run-time like instance methods. That is why static methods are called "static"--they are always bound at compile time.

A `static` method in a superclass can be shadowed by another `static` method in a subclass, as long as the original method was not declared `final`. However, you can't override a `static` method with a non`static` method. In other words, you can't change a `static` method into an instance method in a subclass.

Dynamic method selection and peformance

When Java has to dynamically search for overridden methods in subclasses, there's a small performance penalty. In languages like C++, the default is for methods to act like shadowed variables, so you have to explicitly declare the methods you want to be virtual. Java is more dynamic, and the default is for all instance methods to be virtual. In Java you can, however, go the other direction and explicitly declare that an instance method can't be overridden, so that it will not be subject to dynamic binding and will not suffer in terms of performance. This is done with the `final` modifier. We have seen `final` used with variables to effectively make them constants. When `final` is applied to a method, it means that that method can't be overridden (in some sense, its implementation is constant). `final` can also be applied to an entire class, which means the class can't be subclassed.

Compiler optimiziations

When *javac*, the Java compiler, is run with the `-O` switch, it performs certain optimizations. It can inline `final` methods to improve performance (while slightly increasing the size of the resulting class file). `private` methods, which are effectively `final`, can also be inlined, and `final` classes may also benefit from more powerful optimizations.

Another kind of optimization allows you to include debugging code in your Java source without penalty. Java doesn't have a pre-processor, to explicitly control what source is included, but you can get some of the same effects by making a block of code conditional on a constant (i.e., `static` and `final`) variable. The Java compiler is smart enough to remove this code when it determines that it won't be called. For example:

```
static final boolean DEBUG = false;
...
static void debug (String message) {
    if (DEBUG) {
        System.err.println(message);
        // do other stuff
        ...
    }
}
```

If we compile the above code using the -O switch, the compiler will recognize that the condition on the DEBUG variable is always false, and the body of the debug() method will be optimized away. But that's not all--since debug() itself is also final it can be inlined, and an empty inlined method generates no code at all. So, when we compile with DEBUG set to false, calls to the debug() method will generate no residual code at all.

Method selection revisited

By now you should have a good, intuitive idea as to how methods are selected from the pool of potentially overloaded and overridden method names of a class. If, however, you are dying for a dry definition, I'll provide one now. If you are satisfied with your understanding, you may wish to skip this little exercise in logic.

In a previous section, I offered an inductive rule for overloaded method resolution. It said that a method is considered more specific than another if its arguments are polymorphically assignable to the arguments of the second method. We can now expand this rule to include the resolution of overridden methods by adding the following condition: to be more specific than another method, the type of the class containing the method must also be assignable to the type of the class holding the second method.

What does that mean? Well, the only classes whose types are assignable are classes in the same inheritance hierarchy. So, what we're talking about now is the set of all methods of the same name in a class or any of its parent or child classes. Since subclass types are assignable to superclass types, but not vice versa, the resolution is pushed, in the way that we expect, down the chain, towards the subclasses. This effectively adds a second dimension to the search, in which resolution is pushed down the inheritance tree towards more refined classes and, simultaneously, towards the most specific overloaded method within a given class.

Exceptions and overridden methods

When we talked about exception handling in Chapter 4, *The Java Language*, there's one thing I didn't mention because it wouldn't have made sense then. An important restriction on overridden methods is that they must adhere to the `throws` clause of the parent method's signature. If an overridden method throws an exception, the exception must be of the type specified by the parent or a subtype of that exception. Because the exception can be a subtype of the one specified by the parent, the overridden method can refine the type of exception thrown to go along with its new behavior. For example:

```
// A more refined exception
class MeatInedibleException extends InedibleException { ...
}
```

```
class Animal {
    void eat( Food f ) throws InedibleException { ...
}
class Herbivore extends Animal {
    void eat( Food f ) throws InedibleException {
        if ( f instanceof Meat )
            throw new MeatInedibleException();
        ....
    }
}
```

In the example above, Animal specifies that it can throw an InedibleException from its eat() method. Herbivore is a subclass Animal, so it must be able to do this too. However, Herbivore's eat() method actually throws a more specific exception: MeatInedibleException. It can do this because MeatInedibleException is a subtype of InedibleException (remember that Exceptions are classes too). Our calling code's *catch* clause can therefore be more specific:

```
Animal creature = ...
try {
    creature.eat( food );
} catch ( MeatInedibleException ) {
    // creature can't eat this food because it's meat
} catch ( InedibleException ) {
    // creature can't eat this food
}
```

this and *super*

The special references `this` and `super` allow you to refer to the members of the current object instance or those of the superclass, respectively. We have seen `this` used elsewhere to pass a reference to the current object and to refer to shadowed instance variables. The reference `super` does the same for the parents of a class. You can use it to refer to members of a superclass that have been shadowed or overridden. A common arrangement is for an overridden method in a subclass to do some preliminary work and then defer to the method of the superclass to finish the job.

```
class Animal {
    void eat( Food f ) throws InedibleException {
        // consume food
    }
}
```

```
class Herbivore extends Animal {
    void eat( Food f ) throws InedibleException {
        // check if edible
        ...
        super.eat( f );
    }
}
```

In the above example, our Herbivore class overrides the Animal eat() method to first do some checking on the food object. After doing its job it simply calls the (otherwise overridden) implementation of eat() in its superclass, using super.

super prompts a search for the method or variable to begin in the scope of the immediate superclass rather than the current class. The inherited method or variable found may reside in the immediate superclass, or in a more distant one. The usage of the super reference when applied to overridden methods of a superclass is special; it tells the method resolution system to stop the dynamic method search at the superclass, instead of in the most derived class (as it otherwise does). Without super, there would be no way to access overridden methods.

Casting

As in C++, a *cast* explicitly tells the compiler to change the apparent type of an object reference. Unlike in C++, casts in Java are checked both at compile- and at run-time to make sure they are legal. Attempting to cast an object to an incompatible type at run-time results in a ClassCastException. Only casts between objects in the same inheritance hierarchy (and as we'll see later, to appropriate interfaces) are legal in Java and pass the scrutiny of the compiler and the run-time system.

Casts in Java affect only the treatment of references; they never change the form of the actual object. This is an important rule to keep in mind. You never change the object pointed to by a reference by casting it; you change only the compiler's (or run-time system's) notion of it.

A cast can be used to *narrow* the type of a reference--to make it more specific. Often, we'll do this when we have to retrieve an object from a more general type of collection or when it has been previously used as a less derived type. (The prototypical example is using an object in a Vector or Hashtable, as you'll see in Chapter 7, *Basic Utility Classes*.) Continuing with our Cat example:

```
Animal creature = ...
Cat simon = ...

creature = simon;         // Okay
// simon = creature;      // Compile time error, incompatible type
simon = (Cat)creature;    // Okay
```

We can't reassign the reference in `creature` to the variable `simon` even though we know it holds an instance of a `Cat` (Simon). We have to perform the indicated cast. This is also called *downcasting* the reference.

Note that an implicit cast was performed when we went the other way to *widen* the reference `simon` to type `Animal` during the first assignment. In this case, an explicit cast would have been legal, but superfluous.

If casting seems complicated, here's a simple way to think about it. Basically, you can't lie about what an object is. If you have a `Cat` object, you can cast it to a less derived type (i.e., a type above it in the class hierarchy) such as `Animal` or even `Object`, since all Java classes are a subclass of `Object`. If you have an `Object` you know is a `Cat`, you can downcast the `Object` to be an `Animal` or a `Cat`. However, if you aren't sure if the `Object` is a `Cat` or a `Dog` at run-time, you should check it with `instanceof` before you perform the cast. If you get the cast wrong, Java throws a `ClassCastException`.

As I mentioned earlier, casting can affect the selection of compile-time items like variables and overloaded methods, but not the selection of overridden methods. Figure 5.6 shows the difference. As shown in the top half of the diagram, casting the reference `simon` to type `Animal` (widening it) affects the selection of the shadowed variable `weight` within it. However, as the lower half of the diagram indicates, the cast doesn't affect the selection of the overridden method `sleep()`.

Figure 5.6: Casting and its effect on method and variable selection

[Graphic: Figure 5-6]

Using superclass constructors

When we talked earlier about constructors, we discussed how the special statement `this()` invokes an overloaded constructor upon entry to another constructor. Similarly, the statement `super()` explicitly invokes the constructor of a superclass. Of course, we also talked about how Java makes a chain of constructor calls that includes the superclass's constructor, so why use `super()` explicitly? When Java makes an implicit call to the superclass constructor, it calls the default constructor. So, if we want to invoke a superclass constructor that takes arguments, we have to do so explicitly using `super()`.

If we are going to call a superclass constructor with `super()`, it must be the first statement of our constructor, just as `this()` must be the first call we make in an overloaded constructor. Here's a simple example:

```
class Person {
    Person ( String name ) {
        //  setup based on name
        ...
    }
    ...
}

class Doctor extends Person {
    Doctor ( String name, String specialty ) {
        super( name );
        // setup based on specialty
        ...
    }
    ...
}
```

In this example, we use `super()` to take advantage of the implementation of the superclass constructor and avoid duplicating the code to set up the object based on its name. In fact, because the class `Person` doesn't define a default (no arguments) constructor, we have no choice but to call `super()` explicitly. Otherwise, the compiler would complain that it couldn't find an appropriate default constructor to call. Said another way, if you subclass a class that has only constructors that take arguments, you have to invoke one of the superclass's constructors explicitly from your subclass constructor.

Instance variables of the class are initialized upon return from the superclass constructor, whether that's due to an explicit call via `super()` or an implicit call to the default superclass constructor.

We can now give the full story of how constructors are chained together and when instance variable initialization occurs. The rule has three parts and is applied repeatedly for each successive constructor invoked.

- If the first statement of a constructor is an ordinary statement--i.e., not a call to `this()` or `super()`--Java inserts an implicit call to `super()` to invoke the default constructor of the superclass. Upon returning from that call, Java initializes the instance variables of the current class and proceeds to execute the statements of the current constructor.

- If the first statement of a constructor is a call to a superclass constructor via `super()`, Java invokes the selected superclass constructor. Upon its return, Java initializes the current class's instance variables and proceeds with the statements of the current constructor.

- If the first statement of a constructor is a call to an overloaded constructor via `this()`, Java invokes the selected constructor and upon its return simply proceeds with the statements of the current constructor. The call to the superclass's constructor has happened within the overloaded constructor, either explicitly or implicitly, so the initialization of instance variables has already occurred.

Abstract Methods and Classes

As in C++, a method can be declared with the `abstract` modifier to indicate that it's just a prototype. An abstract method has no body; it's simply a signature definition followed by a semicolon. You can't directly use a class that contains an abstract method; you must instead create a subclass that implements the abstract method's body.

```
abstract vaporMethod( String name );
```

In Java, a class that contains one or more abstract methods must be explicitly declared as an abstract class, also using the `abstract` modifier :

```
abstract class vaporClass {
    ...
    abstract vaporMethod( String name );
    ...
}
```

An abstract class can contain other, nonabstract methods and ordinary variable declarations; however, it can't be instantiated. To be used, it must be subclassed and its abstract methods must be overridden with methods that implement a body. Not all abstract methods have to be implemented in a single subclass, but a subclass that doesn't override all its superclass's abstract methods with actual, concrete implementations must also be declared `abstract`.

Abstract classes provide a framework for classes that are to be "filled in" by the implementor. The `java.io.InputStream` class, for example, has a single abstract method called `read()`. Various subclasses of `InputStream` implement `read()` in their own ways to read from their own sources. The rest of the `InputStream` class, however, provides extended functionality built on the simple `read()` method. A subclass of `InputStream` inherits these nonabstract methods that provide functionality based on the simple `read()` method that the subclass implements.

It's often desirable to specify only the prototypes for a whole set of methods and provide no implementation. In C++, this would be a purely abstract class. In Java, you should instead use an *interface*. An interface is like a purely abstract class; it defines a set of methods a class must implement (i.e., the behavior of a class). However, unlike in C++, a class in Java can simply say that it `implements` an interface and go about implementing those methods. As we'll discuss later, a class that implements an interface doesn't have to inherit from any particular part of the inheritance hierarchy or use a particular implementation.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.6 Packages and Compilation Units

A *package* is a name for a group of related classes. In Chapter 3, *Tools of the Trade*, we discussed how Java uses package names to locate classes during compilation and at run-time. In this sense, packages are somewhat like libraries; they organize and manage sets of classes. Packages provide more than just source code-level organization though. They also create an additional level of scope for their classes and the variables and methods within them. We'll talk about the visibility of classes in this section. In the next section, we'll discuss the effect that packages have on access to variables and methods between classes.

Compilation Units

The source code for a Java class is called a *compilation unit*. A compilation unit normally contains a single class definition and is named for that class. The definition of a class named `MyClass`, for instance, should appear in a file named *MyClass.java*. For most of us, a compilation unit is just a file with a *.java* extension, but in an integrated development environment, it could be an arbitrary entity. For brevity here, we'll refer to a compilation unit simply as a file.

The division of classes into their own compilation units is important because, as described in Chapter 3, *Tools of the Trade*, the Java compiler assumes much of the responsibility of a *make* utility. The compiler relies on the names of source files to find and compile dependent classes. It's possible (and common) to put more than one class definition into a single file, but there are some restrictions we'll discuss shortly.

A class is declared to belong to a particular package with the `package` statement. The `package` statement must appear as the first statement in a compilation unit. There can be only one `package` statement, and it applies to the entire file:

```
package mytools.text;

class TextComponent {
     ...
}
```

In the above example, the class `TextComponent` is placed in the package `mytools.text`.

A Word About Package Names

You should recall from Chapter 3, *Tools of the Trade* that package names are constructed in a hierarchical way, using a dot-separated naming convention. Package-name components construct a unique path for the compiler and run-time systems to locate files; however, they don't affect the contents directly in any other way. There is no such thing as a subpackage (the package name space is really flat, not hierarchical) and packages under a particular part of a package hierarchy are related only by association. For example, if we create another package called `mytools.text.poetry` (presumably for text classes specialized in some way to work with poetry), those classes would not be considered part of the `mytools.text` package and would have no special access to its members. In this sense, the package-naming convention can be misleading.

Class Visibility

By default, a class is accessible only to other classes within its package. This means that the class `TextComponent` is available only to other classes in the `mytools.text` package. To be visible elsewhere, a class must be declared as `public`:

```
package mytools.text;

public class TextEditor {
     ...
}
```

The class `TextEditor` can now be referenced anywhere. There can be only a single `public` class defined in a compilation unit; the file must be named for that class.

By hiding unimportant or extraneous classes, a package builds a subsystem that has a well-defined interface to the rest of the world. Public classes provide a facade for the operation of the system and the details of its inner workings can remain hidden, as shown in Figure 5.7. In this sense, packages hide classes in the way classes hide `private` members.

Figure 5.7: Class visibility and packages

[Graphic: Figure 5-7]

Figure 5.7 shows part of the the hypothetical `mytools.text` package. The classes `TextArea` and `TextEditor` are declared `public` and can be used elsewhere in an application. The class `TextComponent` is part of the implementation of `TextArea` and is not accessible from outside of the package.

Importing Classes

Classes within a package can refer to each other by their simple names. However, to locate a class in another package, we have to supply a qualifier. Continuing with the above example, an application refers directly to our editor class by its fully qualified name of `mytools.text.TextEditor`. But we'd quickly grow tired of typing such long class names, so Java gives us the `import` statement. One or more `import` statements can appear at the top of a compilation unit, beneath the `package` statement. The `import` statements list the full names of classes to be used within the file. Like a `package` statement, `import` statements apply to the entire compilation unit. Here's how you might use an `import` statement:

```
package somewhere.else;

import mytools.text.TextEditor;

class MyClass {
    TextEditor editBoy;
    ...
}
```

As shown in the example above, once a class is imported, it can be referenced by its simple name throughout the code. It's also possible to import all of the classes in a package using the `*` notation:

```
import mytools.text.*;
```

Now we can refer to all `public` classes in the `mytools.text` package by their simple names.

Obviously, there can be a problem with importing classes that have conflicting names. If two different packages contain classes that use the same name, you just have to fall back to using fully qualified names to refer to those classes. Other than the potential for naming conflicts, there's no penalty for importing classes. Java doesn't carry extra baggage into the compiled class files. In other words, Java class files don't contain other class definitions, they only reference them.

The Unnamed Package

A class that is defined in a compilation unit that doesn't specify a package falls into the large, amorphous unnamed package. Classes in this nameless package can refer to each other by their simple names. Their path at compile- and run-time is considered to be the current directory, so package-less classes are useful for experimentation, testing, and brevity in providing examples for books about Java.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.8 Interfaces

Interfaces are kind of like Boy Scout (or Girl Scout) merit badges. When a scout has learned to build a bird house, he can walk around wearing a little patch with a picture of one on his sleeve. This says to the world, "I know how to build a bird house." Similarly, an *interface* is a list of methods that define some set of behavior for an object. Any class that implements each of the methods listed in the interface can declare that it implements the interface and wear, as its merit badge, an extra type--the interface's type.

Interface types act like class types. You can declare variables to be of an interface type, you can declare arguments of methods to accept interface types, and you can even specify that the return type of a method is an interface type. In each of these cases, what is meant is that any object that implements the interface (i.e., wears the right merit badge) can fill that spot. In this sense, interfaces are orthogonal to the class hierarchy. They cut across the boundaries of what kind of object an item is and deal with it only in terms of what it can do. A class implements as many interfaces as it desires. In this way, interfaces in Java replace the need for multiple inheritance (and all of its messy side effects).

An interface looks like a purely `abstract` class (i.e., a class with only `abstract` methods). You define an interface with the `interface` keyword and list its methods with no bodies:

```
interface Driveable {
    boolean startEngine();
    void stopEngine();
    float accelerate( float acc );
    boolean turn( Direction dir );
}
```

The example above defines an interface called `Driveable` with four methods. It's acceptable, but not necessary, to declare the methods in an interface with the `abstract` modifier, so we haven't used it here. Interfaces define capabilities, so it's common to name interfaces after their capabilities in a passive sense. "Driveable" is a good example; "runnable" and "updateable" would be two more.

Any class that implements all the methods can then declare it implements the interface by using a special `implements` clause in its class definition:

```
class Automobile implements Driveable {
    ...
    boolean startEngine() {
        if ( notTooCold )
            engineRunning = true;
        ...
    }

    void stopEngine() {
        engineRunning = false;
    }

    float accelerate( float acc ) {
        ...
    }

    boolean turn( Direction dir ) {
        ...
    }
    ...
}
```

The class `Automobile` implements the methods of the `Driveable` interface and declares itself `Driveable` using an `implements` clause.

As shown in Figure 5.9, another class, such as `LawnMower`, can also implement the `Driveable` interface. The figure illustrates the `Driveable` interface being implemented by two different classes. While it's possible that both `Automobile` and `Lawnmower` could derive from some primitive kind of vehicle, they don't have to in this scenario. This is a significant advantage of interfaces over standard multiple inheritance as implemented in C++.

Figure 5.9: Implementing the Driveable interface

[Graphic: Figure 5-9]

After declaring the interface, we have a new type, `Driveable`. We can declare variables of type `Driveable` and assign them any instance of a `Driveable` object:

```
Automobile auto = new Automobile();
Lawnmower mower = new Lawnmower();
Driveable vehicle;

vehicle = auto;
vehicle.startEngine();
vehicle.stopEngine();
...
vehicle = mower;
vehicle.startEngine();
vehicle.stopEngine();
```

Both `Automobile` and `Lawnmower` implement `Driveable` and can be considered of that type.

Interfaces as Callbacks

Interfaces can be used to implement callbacks in Java. A *callback* is a situation where you'd like to pass a reference to some behavior and have another object invoke it later. In C or C++, this is prime territory for function pointers; in Java, we'll use interfaces instead.

Consider two classes: a `TickerTape` class that displays data and a `TextSource` class that provides an information feed. We'd like our `TextSource` to send any new text data. We could have `TextSource` store a reference to a `TickerTape` object, but then we could never use our `TextSource` to send data to any other kind of object. Instead, we'd have to proliferate subclasses of `TextSource` that dealt with different types. A more elegant solution is to have `TextSource` store a reference to an interface type, `TextUpdateable`:

```
interface TextUpdateable {
    receiveText( String text );
}

class TickerTape implements TextUpdateable {
    TextSource source;

    init() {
        source = new TextSource( this );
        ...
    }

    public receiveText( String text ) {
        scrollText( text ):
    }
    ...
}

class TextSource {
    TextUpdateable receiver;

    TextSource( TextUpdateable r ) {
        receiver = r;
    }

    private sendText( String s ) {
        receiver.receiveText( s );
    }
    ...
}
```

The only thing `TextSource` really cares about is finding the right method to invoke to send text. Thus, we can list that method in an interface called `TextUpdateable` and have our `TickerTape` implement the interface. A `TickerTape` object can then be used anywhere we need something of the type `TextUpdateable`. In this case, the `TextSource` constructor takes a `TextUpdateable` object and stores the reference in an instance variable of type `TextUpdateable`. Our `TickerTape` object simply passes a reference to itself as the callback for text updates, and the source can invoke its `receiveText()` method as necessary.

Interface Variables

Although interfaces allow us to specify behavior without implementation, there's one exception. An interface can contain constant variable identifiers; these identifiers appear in any class that implements the interface. This functionality allows for predefined parameters that can be used with the methods:

```
interface Scaleable {
    static final int BIG = 0, MEDIUM = 1, SMALL = 2;

    void setScale( int size );
}
```

The `Scaleable` interface defines three integers: `BIG`, `MEDIUM`, and `SMALL`. All variables defined in interfaces are implicitly `final` and `static`; we don't have to use the modifiers here but, for clarity, we recommend you do so.

A class that implements `Scaleable` sees these variables:

```
class Box implements Scaleable {

    void setScale( int size ) {
        switch( size ) {
            case BIG:
                ...
            case MEDIUM:
                ...
            case SMALL:
                ...
        }
    }
    ...
}
```

Empty Interfaces

Sometimes, interfaces are created just to hold constants; anyone who implements the interfaces can see the constant names, much as if they were included by a C/C++ include file. This is a somewhat degenerate, but acceptable use of interfaces.

Sometimes completely empty interfaces will be used to serve as a marker that a class has some special property. The java.io.Serializeable interface is a good example (See Chapter 8). Classes that implement Serializable don't add any methods or variables. Their additional type simply identifies them to Java as classes that want to be able to be serialized.

Interfaces and Packages

Interfaces behave like classes within packages. An interface can be declared `public` to make it visible outside of its package. Under the default visibility, an interface is visible only inside of its package. There can be only one `public` interface declared in a compilation unit.

Subinterfaces

An interface can extend another interface, just as a class can extend another class. Such an interface is called a *subinterface*:

```
interface DynamicallyScaleable extends Scaleable {
    void changeScale( int size );
}
```

The interface `DynamicallyScaleable` extends our previous `Scaleable` interface and adds an additional method. A class that implements `DynamicallyScaleable` must implement all methods of both interfaces.

Interfaces can't specify that they implement other interfaces, instead they are allowed to extend more than one interface. (This is multiple inheritence for interfaces). More than one superinterface can be specified with the comma operator:

```
    interface DynamicallyScaleable extends Scaleable, SomethingElseable {
        ...
```

Inside Arrays

At the end of Chapter 4, *The Java Language*, I mentioned that arrays have a place in the Java class hierarchy, but I didn't give you any details. Now that we've discussed the object-oriented aspects of Java, I can give you the whole story.

Array classes live in a parallel Java class hierarchy under the `Object` class. If a class is a direct subclass of `Object`, then an array class for that base type also exists as a direct subclass of `Object`. Arrays of more derived classes are subclasses of the corresponding array classes. For example, consider the following class types:

```
class Animal { ... }
class Bird extends Animal { ... }
class Penguin extends Bird { ... }
```

Figure 5.10 illustrates the class hierarchy for arrays of these classes.

Figure 5.10: Arrays in the Java class hierarchy

[Graphic: Figure 5-10]

Arrays of the same dimension are related to one another in the same manner as their base type classes. In our example, Bird is a subclass of Animal, which means that the Bird[] type is a subtype of Animal[]. In the same way a Bird object can be used in place of an Animal object, a Bird[] array can be assigned to an Animal[] array:

```
Animal [][] animals;
Bird [][] birds = new Bird [10][10];
birds[0][0] = new Bird();

// make animals and birds reference the same array object
animals = birds;
System.out.println( animals[0][0] );               // prints Bird
```

Because arrays are part of the class hierarchy, we can use instanceof to check the type of an array:

```
if ( birds instanceof Animal[][] )                 // yes
```

An array is a subtype of Object and can therefore be assigned to Object type variables:

```
Object something;
something = animals;
```

Since Java knows the actual type of all objects, you can also cast back if appropriate:

```
animals = (Animal [][])something;
```

Under unusual circumstances, Java may not be able to check the types of objects you place into arrays at compile-time. In those cases, it's possible to receive an ArrayStoreException if you try to assign the wrong type of object to an array element. Consider the following:

```
class Dog { ... }
class Poodle extends Dog { ... }
class Chihuahua extends Dog { ... }

Dog [] dogs;
Poodle [] poodles = new Poodle [10];

dogs = poodles;

dogs[3] = new Chihuahua();     // Run-time error, ArrayStoreException
```

Both Poodle and Chihuahua are subclasses of Dog, so an array of Poodle objects can therefore be assigned to an array of Dog objects, as I described previously. The problem is that an object assignable to an element of an array of type Dog[] may not be assignable to an element of an array of type Poodle. A Chihuahua object, for instance, can be assigned to a Dog element because it's a subtype of Dog, but not to a Poodle element.[6]

[6] In some sense this could be considered a tiny hole in the Java type system. It doesn't occur elsewhere in Java, only with arrays. This is because array objects exhibit *covariance* in overriding their assignment and extraction methods. Covariance allows array subclasses to override methods with arguments or return values that are subtypes of the overridden methods, where the methods would normally be overloaded or prohibited. This allows array subclasses to operate on their base types with type safety, but also means that subclasses have different capabilities than their parents, leading to the problem shown above.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

5.10 The Object and Class Classes

`java.lang.Object` is the mother of all objects; it's the primordial class from which all other classes are ultimately derived. Methods defined in `Object` are therefore very important because they appear in every instance of any class, throughout all of Java. At last count, there were nine `public` methods in `Object`. Five of these are versions of `wait()` and `notify()` that are used to synchronize threads on object instances, as we'll discuss in Chapter 6, *Threads*. The remaining four methods are used for basic comparison, conversion, and administration.

Every object has a `toString()` method that is called when it's to be represented as a text value. `PrintStream` objects use `toString()` to print data, as discussed in Chapter 8, *Input/Output Facilities*. `toString()` is also used when an object is referenced in a string concatenation. Here are some examples:

```
MyObj myObject = new MyObj();
Answer theAnswer = new Answer();

System.out.println( myObject );
String s = "The answer is: " + theAnswer ;
```

To be friendly, a new kind of object should override `toString()` and implement its own version that provides appropriate printing functionality. Two other methods, `equals()` and `hashCode()`, may also require specialization when you create a new class.

Equality

`equals()` compares whether two objects are equivalent. Precisely what that means for a particular class is something that you'll have to decide for yourself. Two `String` objects, for example, are considered equivalent if they hold precisely the same characters in the same sequence:

```
String userName = "Joe";
```

```
...
if ( userName.equals( suspectName ) )
    arrest( userName );
```

Note that using `equals()` is *not* the same as:

```
// if ( userName == suspectName )      // Wrong!
```

The above code tests to see if the two `String` objects are the same object, which is sufficient but not necessary for them to be equivalent objects.

A class should override the `equals()` method if it needs to implement its own notion of equality. If you have no need to compare objects of a particular class, you don't need to override `equals()`.

Watch out for accidentally overloading `equals()` when you mean to override it. `equals()` takes an `Object` as an argument and returns a `boolean` value. While you'll probably want to check only if an object is equivalent to an object of its own type, in order to properly override `equals()`, the method should accept a generic `Object` as its argument. Here's an example of implementing `equals()`:

```
class Sneakers extends Shoes {
    public boolean equals( Object arg ) {
        if ( (arg != null) && (arg instanceof Sneakers) ) {
            // compare arg with this object to check equivalence
            // If comparison is okay...
            return true;
        }
        return false;
    }
    ...
}
```

A `Sneakers` object can now be properly compared by any current or future Java classes. If we had instead used a `Sneakers` type object as the argument to `equals()`, all would be well for classes that reference our objects as `Sneakers`, but methods that simply use `Shoes` would not see the overloaded method and would compare `Sneakers` against other `Sneakers` improperly.

Hashcodes

The `hashCode()` method returns an integer that is a hashcode for a class instance. A hashcode is like a signature for an object; it's an arbitrary-looking identifying number that is (with important exceptions) generally different for different instances of the class. Hashcodes are used in the process of storing objects in a `Hashtable`, or a similar kind of collection. The hashcode is essentially an index into the collection. See Chapter 7, *Basic Utility Classes* for a complete discussion of `Hashtable` objects and hashcodes.

The default implementation of `hashCode()` in `Object` assigns each object instance a unique number to be used as a hashcode. If you don't override this method when you create a new class, each instance of the class will have a unique hashcode. This is sufficient for most objects. However, if the class has a notion of equivalent objects, then you should probably override `hashCode()` so that equivalent objects are given the same hashcode.

java.lang.Class

The last method of `Object` we need to discuss is `getClass()`. This method returns a reference to the `Class` object that produced the object instance.

A good measure of the complexity of an object-oriented language is the degree of abstraction of its class structures. We know that every object in Java is an instance of a class, but what exactly is a class? In C++, objects are formulated by and instantiated from classes, but classes are really just artifacts of the compiler. Thus, you see only classes mentioned in C++ source code, not at run-time. By comparison, classes in Smalltalk are real, run-time entities in the language that are themselves described by "meta-classes" and "meta-class classes." Java strikes a happy medium between these two languages with what is, effectively, a two-tiered system that uses `Class` objects.

Classes in Java source code are represented at run-time by instances of the `java.lang.Class` class. There's a `Class` object for every class you use; this `Class` object is responsible for producing instances for its class. This may sound overwhelming, but you don't have to worry about any of it unless you are interested in loading new kinds of classes dynamically at run-time.

We can get the `Class` associated with a particular object with the `getClass()` method:

```
String myString = "Foo!"
Class c = myString.getClass();
```

We can also get the Class reference for a particular class statically, using the special `.class` notation:

```
Class c = String.class;
```

The .class reference looks like a static field that exists in every class. However, it is really resolved by the compiler.

One thing we can do with the `Class` object is to ask for the name of the object's class:

```
String s = "Boofa!";
Class strClass = s.getClass();
System.out.println( strClass.getName() ); // prints "java.lang.String"
```

Another thing that we can do with a `Class` is to ask it to produce a new instance of its type of object. Continuing with the above example:

```
try {
    String s2 = (String)strClass.newInstance();
}
catch ( InstantiationException e ) { ... }
catch ( IllegalAccessException e ) { ... }
```

`newInstance()` has a return type of `Object`, so we have to cast it to a reference of the appropriate type. A couple of problems can occur here. An `InstantiationException` indicates we're trying to instantiate an `abstract` class or an interface. `IllegalAccessException` is a more general exception that indicates we can't access a constructor for the object. Note that `newInstance()` can create only an instance of a class that has an accessible default constructor. There's no way for us to pass any arguments to a constructor.

All this becomes more meaningful when we add the capability to look up a `Class` by name. `forName()` is a `static` method of `Class` that returns a `Class` object given its name as a `String`:

```
try {
    Class sneakersClass = Class.forName("Sneakers");
}
catch ( ClassNotFoundException e ) { ... }
```

A `ClassNotFoundException` is thrown if the class can't be located.

Combining the above tools, we have the power to load new kinds of classes dynamically. When combined with the power of interfaces, we can use new data types by name in our applications:

```
interface Typewriter {
    void typeLine( String s );
    ...
}

class Printer implements Typewriter {
    ...
}
```

```
class MyApplication {
    ...
    String outputDeviceName = "Printer";

    try {
        Class newClass = Class.forName( outputDeviceName );
        Typewriter device = (Typewriter)newClass.newInstance();
        ...
        device.typeLine("Hello...");
    }
    catch ( Exception e ) {
}
```

7.2 Math Utilities

Java supports integer and floating-point arithmetic directly. Higher-level math operations are supported through the `java.lang.Math` class. Java provides wrapper classes for all primitive data types, so you can treat them as objects if necessary. Java also provides the `java.util.Random` class for generating random numbers.

Java handles errors in integer arithmetic by throwing an `ArithmeticException`:

```
int zero = 0;

try {
    int i = 72 / zero;
}
catch ( ArithmeticException e ) {       // division by zero
}
```

To generate the error in the above example, we created the intermediate variable `zero`. The compiler is somewhat crafty and would have caught us if we had blatantly tried to perform a division by zero.

Floating-point arithmetic expressions, on the other hand, don't throw exceptions. Instead, they take on the special out-of-range values shown in Table 7.3.

Table 7.3: Special Floating-Point Values

Value	**Mathematical representation**
`POSITIVE_INFINITY`	1.0/0.0
`NEGATIVE_INFINITY`	-1.0/0.0
`NaN`	0.0/0.0

The following example generates an infinite result:

```
double zero = 0.0;
double d = 1.0/zero;

if ( d == Double.POSITIVE_INFINITY )
    System.out.println( "Division by zero" );
```

The special value `NaN` indicates the result is "not a number." The value `NaN` has the special distinction of not being equal to itself (`NaN != NaN`). Use `Float.isNaN()` or `Double.isNaN()` to test for `NaN`.

java.lang.Math

The `java.lang.Math` class serves as Java's math library. All its methods are `static` and used directly ; you can't instantiate a `Math` object. We use this kind of degenerate class when we really want methods to approximate normal functions in C. While this tactic defies the principles of object-oriented design, it makes sense in this case, as it provides a means of grouping some related utility functions in a single class. Table 7.4 summarizes the methods in `java.lang.Math`.

Table 7.4: Methods in java.lang.Math

Method	**Argument type(s)**	**Functionality**
`Math.abs(a)`	`int`, `long`, `float`, `double`	Absolute value
`Math.acos(a)`	`double`	Arc cosine
`Math.asin(a)`	`double`	Arc sine
`Math.atan(a)`	`double`	Arc tangent
`Math.atan2(a,b)`	`double`	Converts rectangular to polar coordinates
`Math.ceil(a)`	`double`	Smallest whole number greater than or equal to `a`
`Math.cos(a)`	`double`	Cosine
`Math.exp(a)`	`double`	Exponential number to the power of `a`
`Math.floor(a)`	`double`	Largest whole number less than or equal to `a`
`Math.log(a)`	`double`	Natural logarithm of `a`
`Math.max(a, b)`	`int`, `long`, `float`, `double`	Maximum
`Math.min(a, b)`	`int`, `long`, `float`, `double`	Minimum
`Math.pow(a, b)`	`double`	`a` to the power of `b`

`Math.random()`	None	Random number generator
`Math.rint(a)`	`double`	Converts double value to integral value in double format
`Math.round(a)`	`float`, `double`	Rounds
`Math.sin(a)`	`double`	Sine
`Math.sqrt(a)`	`double`	Square root
`Math.tan(a)`	`double`	Tangent

`log()`, `pow()`, and `sqrt()` can throw an `ArithmeticException`. `abs()`, `max()`, and `min()` are overloaded for all the scalar values, `int`, `long`, `float`, or `double`, and return the corresponding type. Versions of `Math.round()` accept either `float` or `double` and return `int` or `long` respectively. The rest of the methods operate on and return `double` values:

```
double irrational = Math.sqrt( 2.0 );
int bigger = Math.max( 3, 4 );
long one = Math.round( 1.125798 );
```

For convenience, `Math` also contains the `static final double` values `E` and `PI`:

```
double circumference = diameter * Math.PI;
```

java.math

If a `long` or a `double` just isn't big enough for you, the `java.math` package provides two classes, `BigInteger` and `BigDecimal`, that support arbitrary-precision numbers. These are full-featured classes with a bevy of methods for performing arbitrary-precision math. In the following example, we use `BigInteger` to add two numbers together.

```
try {
    BigDecimal twentyone = new BigDecimal("21");
    BigDecimal seven = new BigDecimal("7");
    BigDecimal sum = twentyone.add(seven);

    int twentyeight = sum.intValue();
}
catch (NumberFormatException nfe) { }
catch (ArithmeticException ae) { }
```

Wrappers for Primitive Types

In languages like Smalltalk, numbers and other simple types are objects, which makes for an elegant language design, but has trade-offs in efficiency and complexity. By contrast, there is a schism in the Java world between class types (i.e., objects) and primitive types (i.e., numbers, characters, and boolean values). Java accepts this trade-off simply for efficiency reasons. When you're crunching numbers you want your computations to be lightweight; having to use objects for primitive types would seriously affect performance. For the times you want to treat values as objects, Java supplies a wrapper class for each of the primitive types, as shown in Table 7.5.

Table 7.5: Primitive Type Wrappers

Primitive	**Wrapper**
`void`	`java.lang.Void`
`boolean`	`java.lang.Boolean`
`char`	`java.lang.Character`
`byte`	`java.lang.Byte`
`short`	`java.lang.Short`
`int`	`java.lang.Integer`
`long`	`java.lang.Long`
`float`	`java.lang.Float`
`double`	`java.lang.Double`

An instance of a wrapper class encapsulates a single value of its corresponding type. It's an immutable object that serves as a container to hold the value and let us retrieve it later. You can construct a wrapper object from a primitive value or from a `String` representation of the value. The following code is equivalent:

```
Float pi = new Float( 3.14 );
Float pi = new Float( "3.14" );
```

Wrapper classes throw a `NumberFormatException` when there is an error in parsing from a string:

```
try {
    Double bogus = new Double( "huh?" );
}
catch ( NumberFormatException e ) {     // bad number
}
```

You should arrange to catch this exception if you want to deal with it. Otherwise, since it's a subclass of `RuntimeException`, it will propagate up the call stack and eventually cause a run-time error if not caught.

Sometimes you'll use the wrapper classes simply to parse the `String` representation of a number:

```
String sheep = getParameter("sheep");
int n = new Integer( sheep ).intValue();
```

Here we are retrieving the value of the `sheep` parameter. This value is returned as a `String`, so we need to convert it to a numeric value before we can use it. Every wrapper class provides methods to get primitive values out of the wrapper; we are using `intValue()` to retrieve an `int` out of `Integer`. Since parsing a `String` representation of a number is such a common thing to do, the `Integer` and `Long` classes also provide the `static` methods `Integer.parseInt()` and `Long.parseLong()` that read a `String` and return the appropriate type. So the second line above is equivalent to:

```
int n = Integer.parseInt( sheep );
```

All wrappers provide access to their values in various forms. You can retrieve scalar values with the methods `doubleValue()`, `floatValue()`, `longValue()`, and `intValue()`:

```
Double size = new Double ( 32.76 );

double d = size.doubleValue();
float f = size.floatValue();
long l = size.longValue();
int i = size.intValue();
```

The code above is equivalent to the primitive `double` value cast to the various types. For convenience, you can cast between the wrapper classes like `Double` class and the primitive data types.

Another common use of wrappers occurs when we have to treat a primitive value as an object in order to place it in a list or other structure that operates on objects. As you'll see shortly, a `Vector` is an extensible array of `Object`s. We can use wrappers to hold numbers in a `Vector`, along with other objects:

```
Vector myNumbers = new Vector();

Integer thirtyThree = new Integer( 33 );
myNumbers.addElement( thirtyThree );
```

Here we have created an `Integer` wrapper so that we can insert the number into the `Vector` using `addElement()`. Later, when we are taking elements back out of the `Vector`, we can get the number back out of the `Integer` as follows:

```
Integer theNumber = (Integer)myNumbers.firstElement();
int n = theNumber.intValue();           // n = 33
```

Random Numbers

You can use the `java.util.Random` class to generate random values. It's a pseudo-random number generator that can be initialized with a 48-bit seed.[1] The default constructor uses the current time as a seed, but if you want a repeatable sequence, specify your own seed with:

> [1] The generator uses a linear congruential formula. See *The Art of Computer Programming*, Volume 2 "Semi-numerical Algorithms," by Donald Knuth (Addison-Wesley).

```
long seed = mySeed;
Random rnums = new Random( seed );
```

This code creates a random-number generator. Once you have a generator, you can ask for random values of various types using the methods listed in Table 7.6.

Table 7.6: Random Number Methods

Method	**Range**
`nextInt()`	-2147483648 to 2147483647
`nextLong()`	-9223372036854775808 to 9223372036854775807
`nextFloat()`	-1.0 to 1.0
`nextDouble()`	-1.0 to 1.0

By default, the values are uniformly distributed. You can use the `nextGaussian()` method to create a Gaussian distribution of `double` values, with a mean of 0.0 and a standard deviation of 1.0.

The `static` method `Math.random()` retrieves a random `double` value. This method initializes a `private` random-number generator in the `Math` class, using the default `Random` constructor. So every call to `Math.random()` corresponds to a call to `nextDouble()` on that random number generator.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.4 Vectors and Hashtables

Vectors and hashtables are *collection classes*. Each stores a group of objects according to a particular retrieval scheme. Aside from that, they are not particularly closely related things. A *hashtable* is a dictionary; it stores and retrieves objects by a key value. A *vector*, on the other hand, holds an ordered collection of elements. It's essentially a dynamic array. Both of these, however, have more subtle characteristics in common. First, they are two of the most useful aspects of the core Java distribution. Second, they both take full advantage of Java's dynamic nature at the expense of some of its more static type safety.

If you work with dictionaries or associative arrays in other languages, you should understand how useful these classes are. If you are someone who has worked in C or another static language, you should find collections to be truly magical. They are part of what makes Java powerful and dynamic. Being able to work with lists of objects and make associations between them is an abstraction from the details of the types. It lets you think about the problems at a higher level and saves you from having to reproduce common structures every time you need them.

java.util.Vector

A `Vector` is a dynamic array; it can grow to accommodate new items. You can also insert and remove elements at arbitrary positions within it. As with other mutable objects in Java, `Vector` is thread-safe. The `Vector` class works directly with the type `Object`, so we can use them with instances of any kind of class.[3] We can even put different kinds of `Object`s in a `Vector` together; the `Vector` doesn't know the difference.

> [3] In C++, where classes don't derive from a single `Object` class that supplies a base type and common methods, the elements of a collection would usually be derived from some common collectable class. This forces the use of multiple inheritance and brings its associated problems.

As you might guess, this is where things get tricky. To do anything useful with an `Object` after we take it back out of a Vector, we have to cast it back (narrow) it to its original type. This can be done with safety in Java because the cast is checked at run-time. Java throws a ClassCastException if we try to cast an object to the wrong type. However, this need for casting means that your code must remember types or methodically test them with instanceof. That is the price we pay for having a completely dynamic collection class that operates on all types.

You might wonder if you can subclass Vector to produce a class that looks like a Vector, but that works on just one type of element in a type-safe way. Unfortunately, the answer is no. We could override Vector's methods to make a Vector that rejects the wrong type of element at run-time, but this does not provide any new compile-time, static type safety. In C++, templates provide a safe mechanism for parameterizing types by restricting the types of objects used at compile-time. The keyword generic is a reserved word in Java. This means that it's possible that future versions might support C++-style templates, using generic to allow statically checked parameterized types.

We can construct a Vector with default characteristics and add elements to it using addElement() and insertElement():

```
Vector things = new Vector();

String one = "one";
String two = "two";
String three = "three";

things.addElement( one );
things.addElement( three );
things.insertElementAt( two, 1 );
```

things now contains three String objects in the order "one," "two," and "three." We can retrieve objects by their position with elementAt(), firstElement(), and lastElement():

```
String s1 = (String)things.firstElement();       // "one"
String s3 = (String)things.lastElement();        // "three"
String s2 = (String)things.elementAt(1);         // "two"
```

We have to cast each Object back to a String in order to assign it a String reference. ClassCastException is a type of RuntimeException, so we can neglect to guard for the exception if we are feeling confident about the type we are retrieving. Often, as in this example, you'll just have one type of object in the Vector. If we were unsure about the types of objects we were retrieving, we would want to be prepared to catch the ClassCastException or test the type explicitly with the instanceof operator.

We can search for an item in a Vector with the indexOf() method:

```
int i = things.indexOf( three );                 // i = 2
```

indexOf() returns a value of -1 if the object is not found. As a convenience, we can also use contains() simply to test for the presence of the object.

Finally, removeElement() removes a specified Object from the Vector:

```
things.removeElement( two );
```

The element formerly at position three now becomes the second element.

The size() method reports the number of objects currently in the Vector. You might think of using this to loop through all elements of a Vector, using elementAt() to get at each element. This works just fine, but there is a more general way to operate on a complete set of elements like those in a Vector.

java.util.Enumeration

The java.util.Enumeration interface can be used by any sort of set to provide serial access to its elements. An object that implements the Enumeration interface presents two methods: nextElement() and hasMoreElements(). nextElement() returns an Object type, so it can be used with any kind of collection. As with taking objects from a Vector, you need to know or determine what the objects are and cast them to the appropriate types before using them.

Enumeration is useful because any type of object can implement the interface and then use it to provide access to its elements. If you have an object that handles a set of values, you should think about implementing the Enumeration interface. Simply provide a hasMoreElements() test and a nextElement() iterator and declare that your class implements java.util.Enumeration. One advantage of an Enumeration is that you don't have to provide all values up front; you can provide each value as it's requested with nextElement(). And since Enumeration is an interface, you can write general routines that operate on all of the elements Enumeration.

An Enumeration does not guarantee the order in which elements are returned, however, so if order is important you don't want to use an Enumeration. You can iterate through the elements in an Enumeration only once; there is no way to reset it to the beginning or move backwards through the elements.

A Vector returns an Enumeration of its contents when we call the elements() method:

```
Enumeration e = things.elements();
```

```
while ( e.hasMoreElements() ) {
    String s = (String)e.nextElement();
    System.out.println( s ):
}
```

The above code loops three times, as call `nextElement()`, to fetch our strings. The actual type of object returned by `elements()` is a `VectorEnumeration`, but we don't have to worry about that. We can always refer to an `Enumeration` simply by its interface.

Note that `Vector` does not implement the `Enumeration` interface. If it did, that would put a serious limitation on `Vector` because we could cycle through the elements in it only once. That's clearly not the purpose of a `Vector`, which is why `Vector` instead provides a method that returns an `Enumeration`.

java.util.Hashtable

As I said earlier, a hashtable is a dictionary, similar to an associative array. A hashtable stores and retrieves elements with key values; they are very useful for things like caches and minimalist databases. When you store a value in a hashtable, you associate a key with that value. When you need to look up the value, the hashtable retrieves it efficiently using the key. The name hashtable itself refers to how the indexing and storage of elements is performed, as we'll discuss shortly. First I want to talk about how to use a hashtable.

The `java.util.Hashtable` class implements a hashtable that, like `Vector`, operates on the type `Object`. A `Hashtable` stores an element of type `Object` and associates it with a key, also of type `Object`. In this way, we can index arbitrary types of elements using arbitrary types as keys. As with `Vector`, casting is generally required to narrow objects back to their original type after pulling them out of a hashtable.

A `Hashtable` is quite easy to use. We can use the `put()` method to store items:

```
Hashtable dates = new Hashtable();

dates.put( "christmas",
    new GregorianCalendar( 1997, Calendar.DECEMBER, 25 ) );
dates.put( "independence",
    new GregorianCalendar( 1997, Calendar.JULY, 4 ) );
dates.put( "groundhog",
    new GregorianCalendar( 1997, Calendar.FEBRUARY, 2 ) );
```

First we create a new `Hashtable`. Then we add three `GregorianCalendar` objects to the hashtable, using `String` objects as keys. The key is the first argument to `put()`; the value is the second. Only one value can be stored per key. If we try to store a second object under a key that already exists in the `Hashtable`, the old element is booted out and replaced by the new one. The return value of the `put()` method is normally `null`, but if the call to `put()` results in replacing an element, the method instead returns the old stored `Object`.

We can now use the `get()` method to retrieve each of the above dates by name, using the `String` key by which it was indexed:

```
GregorianCalendar g = (GregorianCalendar)dates.get( "christmas" );
```

The `get()` method returns a `null` value if no element exists for the given key. The cast is required to narrow the returned object back to type `GregorianCalendar`. I hope you can see the advantage of using a `Hashtable` over a regular array. Each value is indexed by a key instead of a simple number, so unlike a simple array, we don't have to remember where each `GregorianCalendar` is stored.

Once we've put a value in a `Hashtable`, we can take it back out with the `remove()` method, again using the key to access the value:

```
dates.remove("christmas");
```

We can test for the existence of a key with `containsKey()`:

```
if ( dates.containsKey( "groundhog" ) ) {    // yes
```

Just like with a `Vector`, we're dealing with a set of items. Actually, we're dealing with two sets: keys and values. The `Hashtable` class has two methods, `keys()` and `elements()`, for getting at these sets. The `keys()` method returns an `Enumeration` of the keys for all of the elements in the `Hashtable`. We can use this `Enumeration` to loop through all of the keys:

```
for (Enumeration e = dates.keys(); e.hasMoreElements(); ) {
    String key = (String)e.nextElement();
    ...
}
```

Similarly, `elements()` provides an `Enumeration` of the elements themselves.

Hashcodes and key values

If you've used a hashtable before, you've probably guessed that there's more going on behind the scenes than I've let on so far. An element in a hashtable is not associated with its key by identity, but by something called a *hashcode*. Every object in Java has an identifying hashcode value determined by its `hashCode()` method, which is inherited from the `Object` class. When you store an element in a hashtable, the hashcode of the key object registers the element internally. Later, when you retrieve the item, that same hashcode looks it up efficiently.

A hashcode is usually a random-looking integer value based on the contents of an object, so it's different for different instances of a class. Two objects that have different hashcodes serve as unique keys in a hashtable; each object can reference a different stored object. Two objects that have the same hashcode value, on the other hand, appear to a hashtable as the same key. They can't coexist as keys to different objects in the hashtable.

Generally, we want our object instances to have unique hash codes, so we can put arbitrary items in a hashtable and index them with arbitrary keys. The default `hashCode()` method in the `Object` class simply assigns each object instance a unique number to be used as a hashcode. If a class does not override this method, each instance of the class will have a unique hashcode. This is sufficient for most objects.

However, it's also useful to allow equivalent objects to serve as equivalent keys. `String` objects provide a good example of this case. Although Java does its best to consolidate them, a literal string that appears multiple times in Java source code is often represented by different `String` objects at run-time. If each of these `String` objects has a different hash code, even though the literal value is the same, we could not use strings as keys in a hashtable, like we did the in above examples.

The solution is to ensure that equivalent `String` objects return the same hashcode value so that they can act as equivalent keys. The `String` class overrides the default `hashCode()` method so that equivalent `String` objects return the same hash code, while different `String` objects have unique hashcodes. This is possible because `String` objects are immutable; the contents can't change, so neither can the hashcode.

A few other classes in the Java API also override the default `hashCode()` method in order to provide equivalent hashcodes for equivalent objects. For example, each of the primitive wrapper classes provides a `hashCode()` method for this purpose. Other objects likely to be used as hashtable keys, such as `Color`, `Date`, `File`, and `URL`, also implement their own `hashCode()`methods.

So now maybe you're wondering when you need to override the default `hashCode()` method in your objects. If you're creating a class to use for keys in a hashtable, think about whether the class supports the idea of "equivalent objects." If so, you should implement a `hashCode()` method that returns the same hashcode value for equivalent objects.

To accomplish this, you need to define the hashcode of an object to be some suitably complex and arbitrary function of the contents of that object. The only criterion for the function is that it should be almost certain to provide different values for different contents of the object. Because the capacity of an integer is limited, hashcode values are not guaranteed to be unique. This limitation is not normally a problem though, as there are 2^32 possible hashcodes to choose from. The more sensitive the hashcode function is to small differences in the contents the better. A hashtable works most efficiently when the hashcode values are as randomly and evenly distributed as possible. As an example, you could produce a hashcode for a `String` object by adding the character values at each position in the string and multiplying the result by some number, producing a large random-looking integer.

java.util.Dictionary

`java.util.Dictionary` is the `abstract` superclass of `Hashtable`. It lays out the basic `get()`, `put()`, and `remove()` functionality for dictionary-style collections. You could derive other types of dictionaries from this class. For example, you could implement a dictionary with a different storage format, such as a binary tree.

7.5 Properties

The `java.util.Properties` class is a specialized hashtable for strings. Java uses the `Properties` object to replace the environment variables used in other programming environments. You can use a `Properties` table to hold arbitrary configuration information for an application in an easily accessible format. The `Properties` object can also load and store information using streams (see Chapter 8, *Input/Output Facilities* for information on streams).

Any string values can be stored as key/value pairs in a `Properties` table. However, the convention is to use a dot-separated naming hierarchy to group property names into logical structures, as is done with X resources on UNIX systems.[4] The `java.lang.System` class provides system-environment information in this way, through a system `Properties` table I'll describe shortly.

Create an empty `Properties` table and add `String` key/value pairs just as with any `Hashtable`:

```
Properties props = new Properties();
props.put("myApp.xsize", "52");
props.put("myApp.ysize", "79");
```

Thereafter, you can retrieve values with the `getProperty()`method:

```
String xsize = props.getProperty( "myApp.xsize" );
```

If the named property doesn't exist, `getProperty()` returns `null`. You can get an `Enumeration` of the property names with the `propertyNames()` method:

```
for ( Enumeration e = props.propertyNames(); e.hasMoreElements; ) {
    String name = e.nextElement();
```

[4] Unfortunately, this is just a naming convention right now, so you can't access logical groups of properties as you can with X resources.

```
    ...
}
```

Default Values

When you create a `Properties` table, you can specify a second table for default property values:

```
Properties defaults;
...
Properties props = new Properties( defaults );
```

Now when you call `getProperty()`, the method searches the default table if it doesn't find the named property in the current table. An alternative version of `getProperty()` also accepts a default value; this value is returned if the property is not found in the current list or in the default list:

```
String xsize = props.getProperty( "myApp.xsize", "50" );
```

Loading and Storing

You can save a `Properties` table to an `OutputStream` using the `save()` method. The property information is output in flat ASCII format. Continuing with the above example, output the property information to `System.out` as follows:

```
props.save( System.out, "Application Parameters" );
```

As we'll discuss in Chapter 8, *Input/Output Facilities*, `System.out` is a standard output stream similar to C's `stdout`. We could also save the information to a file by using a `FileOutputStream` as the first argument to `save()`. The second argument to `save()` is a `String` that is used as a header for the data. The above code outputs something like the following to `System.out`:

```
#Application Parameters
#Mon Feb 12 09:24:23 CST 1997
myApp.ysize=79
myApp.xsize=52
```

The `load()` method reads the previously saved contents of a `Properties` object from an `InputStream`:

```
FileInputStream fin;
...
Properties props = new Properties()
```

```
props.load( fin );
```

The `list()` method is useful for debugging. It prints the contents to an `OutputStream` in a format that is more human-readable but not retrievable by `load()`.

System Properties

The `java.lang.System` class provides access to basic system environment information through the `static System.getProperty()` method. This method returns a `Properties` table that contains system properties. System properties take the place of environment variables in other programming environments.

Table 7.7 summarizes system properties that are guaranteed to be defined in any Java environment.

Table 7.7: System Properties

System Property	**Meaning**
`java.vendor`	Vendor-specific string
`java.vendor.url`	URL of vendor
`java.version`	Java version
`java.home`	Java installation directory
`java.class.version`	Java class version
`java.class.path`	The class path
`os.name`	Operating-system name
`os.arch`	Operating-system architecture
`os.version`	Operating-system version
`file.separator`	File separator (such as "/" or " \")
`path.separator`	Path separator (such as ":" or ";")
`line.separator`	Line separator (such as "\n" or "\r\n")
`user.name`	User account name
`user.home`	User's home directory
`user.dir`	Current working directory

Applets are, by current Web browser conventions, prevented from reading the following properties: `java.home`, `java.class.path`, `user.name`, `user.home`, and `user.dir`. As you'll see in the next section, these restrictions are implemented by a `SecurityManager` object.

The Security Manager

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

7.6 The Security Manager

As I described in Chapter 1, *Yet Another Language?*, a Java application's access to system resources, such as the display, the filesystem, threads, external processes, and the network, can be controlled at a single point with a *security manager*. The class that implements this functionality in the Java API is the `java.lang.SecurityManager` class.

An instance of the `SecurityManager` class can be installed once, and only once, in the life of the Java run-time environment. Thereafter, every access to a fundamental system resource is filtered through specific methods of the `SecurityManager` object by the core Java packages. By installing a specialized `SecurityManager`, we can implement arbitrarily complex (or simple) security policies for allowing access to individual resources.

When the Java run-time system starts executing, it's in a wide-open state until a `SecurityManager` is installed. The "null" security manager grants all requests, so the Java virtual environment can perform any activity with the same level of access as other programs running under the user's authority. If the application that is running needs to ensure a secure environment, it can install a `SecurityManager` with the `static System.setSecurityManager()` method. For example, a Java-enabled Web browser like Netscape Navigator installs a `SecurityManager` before it runs any Java applets.

`java.lang.SecurityManager` must be subclassed to be used. This class does not actually contain any `abstract` methods; it's `abstract` as an indication that its default implementation is not very useful. By default, each security method in `SecurityManager` is implemented to provide the strictest level of security. In other words, the default `SecurityManager` simply rejects all requests.

The following example, `MyApp`, installs a trivial subclass of `SecurityManager` as one of its first activities:

```
class FascistSecurityManager extends SecurityManager { }

public class MyApp {
    public static void main( Strings [] args ) {
        System.setSecurityManager( new FascistSecurityManager() );
        // No access to files, network, windows, etc.
        ...
    }
}
```

In the above scenario, `MyApp` does little aside from reading from `System.in` and writing to `System.out`. Any attempts to read or write files, access the network, or even open an window, results in a `SecurityException` being thrown.

After this draconian `SecurityManager` is installed, it's impossible to change the `SecurityManager` in any way. The security of this feature is not dependent on the `SecurityManager`; you can't replace or modify the `SecurityManager` under any circumstances. The upshot of this is that you have to install one that handles all your needs up front.

To do something more useful, we can override the methods that are consulted for access to various kinds of resources. Table 7.7 lists some of the more important access methods. You should not normally have to call these methods yourself, although you could. They are called by the core Java classes before granting particular types of access.

Table 7.8: SecurityManager Methods

Method	**Can I...?**
`checkAccess(Thread g)`	Access this thread?
`checkExit(int status)`	Execute a `System.exit()`?
`checkExec(String cmd)`	`exec()` this process?
`checkRead(String file)`	Read a file?
`checkWrite(String file)`	Write a file?
`checkDelete(String file)`	Delete a file?
`checkConnect(String host, int port)`	Connect a socket to a host?
`checkListen(int port)`	Create a server socket?
`checkAccept(String host, int port)`	Accept this connection?
`checkPropertyAccess(String key)`	Access this system property?
`checkTopLevelWindow(Object window)`	Create this new top-level window?

All these methods, with the exception of `checkTopLevelWindow()`, simply return to grant access. If access is not granted, they throw a `SecurityException`. `checkTopLevelWindow()` returns a `boolean` value. A value of `true` indicates the access is granted; a value of `false` indicates the access is granted with the restriction that the new window should provide a warning border that serves to identify it as an untrusted window.

Let's implement a silly `SecurityManager` that allows only files beginning with the name *foo* to be read:

```
class  FooFileSecurityManager extends SecurityManager {

    public void checkRead( String s ) {
        if ( !s.startsWith("foo") )
            throw new SecurityException("Access to non-foo file: " +
                s + " not allowed." );
    }
}
```

Once the `FooFileSecurityManager` is installed, any attempt to read a filename other than *foo** from any class will fail and cause a `SecurityException` to be thrown. All other security methods are inherited from `SecurityManager`, so they are left at their default restrictiveness.

All restrictions placed on applets by an applet-viewer application are enforced through a `SecurityManager`, which allows untrusted code loaded from over the network to be executed safely. The restrictions placed on applets are currently fairly harsh. As time passes and security considerations related to applets are better understood and accepted, the applet API will hopefully become more powerful and allow forms of persistence and access to designated public information.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

8.2 Files

Unless otherwise restricted, a Java application can read and write to the host filesystem with the same level of access as the user who runs the Java interpreter. Java applets and other kinds of networked applications can, of course, be restricted by the `SecurityManager` and cut off from these services. We'll discuss applet access at the end of this section. First, let's take a look at the tools for basic file access.

Working with files in Java is still somewhat problematic. The host filesystem lies outside of Java's virtual environment, in the real world, and can therefore still suffer from architecture and implementation differences. Java tries to mask some of these differences by providing information to help an application tailor itself to the local environment; I'll mention these areas as they occur.

java.io.File

The `java.io.File` class encapsulates access to information about a file or directory entry in the filesystem. It gets attribute information about a file, lists the entries in a directory, and performs basic filesystem operations like removing a file or making a directory. While the `File` object handles these tasks, it doesn't provide direct access for reading and writing file data; there are specialized streams for that purpose.

File constructors

You can create an instance of `File` from a `String` pathname as follows:

```
File fooFile = new File( "/tmp/foo.txt" );
File barDir = new File( "/tmp/bar" );
```

You can also create a file with a relative path like:

```
File f = new File( "foo" );
```

In this case, Java works relative to the current directory of the Java interpreter. You can determine the current directory by checking the `user.dir` property in the `System Properties` list (`System.getProperty('user.dir')`).

An overloaded version of the `File` constructor lets you specify the directory path and filename as separate `String` objects:

```
File fooFile = new File( "/tmp", "foo.txt" );
```

With yet another variation, you can specify the directory with a `File` object and the filename with a `String`:

```
File tmpDir = new File( "/tmp" );
File fooFile = new File ( tmpDir, "foo.txt" );
```

None of the `File` constructors throw any exceptions. This means the object is created whether or not the file or directory actually exists; it isn't an error to create a `File` object for an nonexistent file. You can use the `exists()` method to find out whether the file or directory exists.

Path localization

One of the reasons that working with files in Java is problematic is that pathnames are expected to follow the conventions of the local filesystem. Java's designers intend to provide an abstraction that deals with most system-dependent filename features, such as the file separator, path separator, device specifier, and root directory. Unfortunately, not all of these features are implemented in the current version.

On some systems, Java can compensate for differences such as the direction of the file separator slashes in the above string. For example, in the current implementation on Windows platforms, Java accepts paths with either forward slashes or backslashes. However, under Solaris, Java accepts only paths with forward slashes.

Your best bet is to make sure you follow the filename conventions of the host filesystem. If your application is just opening and saving files at the user's request, you should be able to handle that functionality with the `java.awt.FileDialog` class. This class encapsulates a graphical file-selection dialog box. The methods of the `FileDialog` take care of system-dependent filename features for you.

If your application needs to deal with files on its own behalf, however, things get a little more complicated. The `File` class contains a few `static` variables to make this task easier. `File.separator` defines a `String` that specifies the file separator on the local host (e.g., "/" on UNIX and Macintosh systems and "\" on Windows systems), while `File.separatorChar` provides the same information in character form. `File.pathSeparator` defines a `String` that separates items in a path (e.g., ":" on UNIX systems; ";" on Macintosh and Windows systems); `File.pathSeparatorChar` provides the information in character form.

You can use this system-dependent information in several ways. Probably the simplest way to localize pathnames is to pick a convention you use internally, say "/", and do a `String` replace to substitute for the localized separator character:

```
// We'll use forward slash as our standard
String path = "mail/1995/june/merle";
path = path.replace('/', File.separatorChar);
File mailbox = new File( path );
```

Alternately, you could work with the components of a pathname and built the local pathname when you need it:

```
String [] path = { "mail", "1995", "june", "merle" };
```

```
StringBuffer sb = new StringBuffer(path[0]);
for (int i=1; i< path.length; i++)
    sb.append( File.separator + path[i] );
  File mailbox = new File( sb.toString() );
```

One thing to remember is that Java interprets the backslash character (\) as an escape character when used in a `String`. To get a backslash in a `String`, you have to use " \\".

File methods

Once we have a valid `File` object, we can use it to ask for information about the file itself and to perform standard operations on it. A number of methods lets us ask certain questions about the `File`. For example, `isFile()` returns `true` if the `File` represents a file, while `isDirectory()` returns `true` if it's a directory. `isAbsolute()` indicates whether the `File` has an absolute or relative path specification.

The components of the `File` pathname are available through the following methods: `getName()`, `getPath()`, `getAbsolutePath()`, and `getParent()`. `getName()` returns a `String` for the filename without any directory information; `getPath()` returns the directory information without the filename. If the `File` has an absolute path specification, `getAbsolutePath()` returns that path. Otherwise it returns the relative path appended to the current working directory. `getParent()` returns the parent directory of the `File`.

Interestingly, the string returned by `getPath()` or `getAbsolutePath()` may not be the same, case-wise, as the actual name of the file. You can retrieve the case-correct version of the file's path using `getCanonicalPath()`. In Windows 95, for example, you can create a `File` object whose `getAbsolutePath()` is `C:\Autoexec.bat` but whose `getCanonicalPath()` is `C:\AUTOEXEC.BAT`.

We can get the modification time of a file or directory with `lastModified()`. This time value is not useful as an absolute time; you should use it only to compare two modification times. We can also get the size of the file in bytes with `length()`. Here's a fragment of code that prints some information about a file:

```
File fooFile = new File( "/tmp/boofa" );

String type = fooFile.isFile() ? "File " : "Directory ";
String name = fooFile.getName();
long len = fooFile.length();
System.out.println(type + name + ", " + len + " bytes " );
```

If the `File` object corresponds to a directory, we can list the files in the directory with the `list()` method:

```
String [] files = fooFile.list();
```

`list()` returns an array of `String` objects that contains filenames. (You might expect that `list()` would return an `Enumeration` instead of an array, but it doesn't.)

If the `File` refers to a nonexistent directory, we can create the directory with `mkdir()` or `mkdirs()`. `mkdir()` creates a single directory; `mkdirs()` creates all of the directories in a `File` specification. Use `renameTo()` to rename a file or directory and `delete()` to delete a file or directory. Note that `File` doesn't provide a method to create a file; creation is handled with a `FileOutputStream` as we'll discuss in a moment.

Table 8.1 summarizes the methods provided by the `File` class.

Table 8.1: File Methods

Method	**Return type**	**Description**
`canRead()`	`boolean`	Is the file (or directory) readable?
`canWrite()`	`boolean`	Is the file (or directory) writable?
`delete()`	`boolean`	Deletes the file (or directory)
`exists()`	`boolean`	Does the file (or directory) exist?
`getAbsolutePath()`	`String`	Returns the absolute path of the file (or directory)
`getCanonicalPath()`	`String`	Returns the absolute, case-correct path of the file (or directory)
`getName()`	`String`	Returns the name of the file (or directory)
`getParent()`	`String`	Returns the name of the parent directory of the file (or directory)
`getPath()`	`String`	Returns the path of the file (or directory)
`isAbsolute()`	`boolean`	Is the filename (or directory name) absolute?
`isDirectory()`	`boolean`	Is the item a directory?
`isFile()`	`boolean`	Is the item a file?
`lastModified()`	`long`	Returns the last modification time of the file (or directory)
`length()`	`long`	Returns the length of the file
`list()`	`String []`	Returns a list of files in the directory
`mkdir()`	`boolean`	Creates the directory
`mkdirs()`	`boolean`	Creates all directories in the path
`renameTo(File dest)`	`boolean`	Renames the file (or directory)

File Streams

Java provides two specialized streams for reading and writing files in the filesystem: `FileInputStream` and `FileOutputStream`. These streams provide the basic `InputStream` and `OutputStream` functionality applied to reading and writing the contents of files. They can be combined with the filtered streams described earlier to work with files in the same way we do other stream communications.

Because `FileInputStream` is a subclass of `InputStream`, it inherits all standard `InputStream` functionality for reading the contents of a file. `FileInputStream` provides only a low-level interface to reading data, however, so you'll typically wrap another stream like a `DataInputStream` around the `FileInputStream`.

You can create a `FileInputStream` from a `String` pathname or a `File` object:

```
FileInputStream foois = new FileInputStream( fooFile );
FileInputStream passwdis = new FileInputStream( "/etc/passwd" );
```

When you create a `FileInputStream`, Java attempts to open the specified file. Thus, the `FileInputStream` constructors can throw a `FileNotFoundException` if the specified file doesn't exist, or an `IOException` if some other I/O error occurs. You should be sure to catch and handle these exceptions in your code. When the stream is first created, its `available()` method and the `File` object's `length()` method should return the same value. Be sure to call the `close()` method when you are done with the file.

To read characters from a file, you can wrap an `InputStreamReader` around a `FileInputStream`. If you want to use the default character encoding scheme, you can use the `FileReader` class instead, which is provided as a convenience. `FileReader` works just like `FileInputStream`, except that it reads characters instead of bytes and wraps a `Reader` instead of an `InputStream`.

The following class, `ListIt`, is a small utility that displays the contents of a file or directory to standard output:

```
import java.io.*;

class ListIt {
    public static void main ( String args[] ) throws Exception {
        File file =  new File( args[0] );

        if ( !file.exists() || !file.canRead() ) {
            System.out.println( "Can't read " + file );
            return;
        }

        if ( file.isDirectory() ) {
            String [] files = file.list();
            for (int i=0; i< files.length; i++)
                System.out.println( files[i] );
        }
        else
            try {
                FileReader fr = new FileReader ( file );
                BufferedReader in = new BufferedReader( fr );
                String line;
                while ((line = in.readLine()) != null)
                    System.out.println(line);
            }
            catch ( FileNotFoundException e ) {
                System.out.println( "File Disappeared" );
            }
    } }
```

`ListIt` constructs a `File` object from its first command-line argument and tests the `File` to see if it exists and is readable. If the `File` is a directory, `ListIt` prints the names of the files in the directory. Otherwise, `ListIt` reads and prints the file.

FileOutputStream is a subclass of OutputStream, so it inherits all the standard OutputStream functionality for writing to a file. Just like FileInputStream though, FileOutputStream provides only a low-level interface to writing data. You'll typically wrap another stream like a DataOutputStream or a PrintStream around the FileOutputStream to provide higher-level functionality. You can create a FileOutputStream from a String pathname or a File object. Unlike FileInputStream however, the FileOutputStream constructors don't throw a FileNotFoundException. If the specified file doesn't exist, the FileOutputStream creates the file. The FileOutputStream constructors can throw an IOException if some other I/O error occurs, so you still need to handle this exception.

If the specified file does exist, the FileOutputStream opens it for writing. When you actually call a write() method, the new data overwrites the current contents of the file. If you need to append data to an existing file, you should use a different constructor that accepts an append flag, as shown here:

```
FileInputStream foois = new FileInputStream( fooFile );
FileInputStream passwdis = new FileInputStream( "/etc/passwd" );
```

Antoher alternative for appending files is to use a RandomAccessFile, as I'll discuss shortly.

To write characters (instead of bytes) to a file, you can wrap an OutputStreamWriter around a FileOutputStream. If you want to use the default character encoding scheme, you can use the FileWriter class instead, which is provided as a convenience. FileWriter works just like FileOutputStream, except that it writes characters instead of bytes and wraps a Writer instead of an OutputStream.

The following example reads a line of data from standard input and writes it to the file */tmp/foo.txt*:

```
String s = new BufferedReader( new InputStreamReader( System.in ) ).readLine();

File out = new File( "/tmp/foo.txt" );
FileWriter fw = new FileWriter ( out );
PrintWriter pw = new PrintWriter( fw, true )
pw.println( s );
```

Notice how we have wrapped a PrintWriter around the FileWriter to facilitate writing the data. To be a good filesystem citizen, you need to call the close() method when you are done with the FileWriter.

java.io.RandomAccessFile

The java.io.RandomAccessFile class provides the ability to read and write data from or to any specified location in a file. RandomAccessFile implements both the DataInput and DataOutput interfaces, so you can use it to read and write strings and Java primitive types. In other words, RandomAccessFile defines the same methods for reading and writing data as DataInputStream and DataOutputStream. However, because the class provides random, rather than sequential, access to file data, it's not a subclass of either InputStream or OutputStream.

You can create a RandomAccessFile from a String pathname or a File object. The constructor also takes a second String argument that specifies the mode of the file. Use "r" for a read-only file or "rw" for a read-write file. Here's how to create a simple database to keep track of user information:

```
try {
    RandomAccessFile users = new RandomAccessFile( "Users", "rw" );
    ...
}
catch (IOException e) {
}
```

When you create a RandomAccessFile in read-only mode, Java tries to open the specified file. If the file doesn't exist, RandomAccessFile throws an IOException. If, however, you are creating a RandomAccessFile in read-write mode, the object creates the file if it doesn't exist. The constructor can still throw an IOException if some other I/O error occurs, so you still need to handle this exception.

After you have created a RandomAccessFile, call any of the normal reading and writing methods, just as you would with a DataInputStream or DataOutputStream. If you try to write to a read-only file, the write method throws an IOException.

What makes a RandomAccessFile special is the seek() method. This method takes a long value and uses it to set the location for reading and writing in the file. You can use the getFilePointer() method to get the current location. If you need to append data on the end of the file, use length() to determine that location. You can write or seek beyond the end of a file, but you can't read beyond the end of a file. The read methods throws a EOFException if you try to do this.

Here's an example of writing some data to our user database:

```
users.seek( userNum * RECORDSIZE );
users.writeUTF( userName );
users.writeInt( userID );
```

One caveat to notice with this example is that we need to be sure that the String length for userName, along with any data that comes after it, fits within the boundaries of the record size.

Applets and Files

For security reasons, applets are not permitted to read and write to arbitrary places in the filesystem. The ability of an applet to read and write files, as with any kind of system resource, is under the control of a SecurityManager object. A SecurityManager is installed by the application that is running the applet, such as an applet viewer or Java-enabled Web browser. All filesystem access must first pass the scrutiny of the SecurityManager. With that in mind, applet-viewer applications are free to implement their own schemes for what, if any, access an applet may have.

For example, Sun's HotJava Web browser allows applets to have access to specific files designated by the user in an access-control list. Netscape Navigator, on the other hand, currently doesn't allow applets any access to the filesystem.

It isn't unusual to want an applet to maintain some kind of state information on the system where it's running. But for a Java applet that is restricted from access to the local filesystem, the only option is to store data over the network on its server. Although, at the moment, the Web is a relatively static, read-only environment, applets have at their disposal powerful, general means for communicating data over networks, as you'll see in Chapter 9, *Network Programming*. The only limitation is that, by convention, an applet's network communication is restricted to the server that launched it. This limits the options for where the data will reside.

The only means of writing data to a server in Java is through a network socket. In Chapter 9, *Network Programming* we'll look at building networked applications with sockets in detail. With the tools of that chapter it's possible to build powerful client/server applications.

9.3 Working with URLs

A URL points to an object on the Internet. It's a collection of information that identifies an item, tells you where to find it, and specifies a method for communicating with it or retrieving it from its source. A URL refers to any kind of information source. It might point to static data, such as a file on a local filesystem, a Web server, or an FTP archive; or it can point to a more dynamic object such as a news article on a news spool or a record in a WAIS database. URLs can even refer to less tangible resources such as Telnet sessions and mailing addresses.

A URL is usually presented as a string of text, like an address.[3] Since there are many different ways to locate an item on the Net, and different mediums and transports require different kinds of information, there are different formats for different kinds of URLs. The most common form specifies three things: a network host or server, the name of the item and its location on that host, and a protocol by which the host should communicate:

> [3] The term URL was coined by the Uniform Resource Identifier (URI) working group of the IETF to distinguish URLs from the more general notion of Uniform Resource Names or URNs. URLs are really just static addresses, whereas URNs would be more persistent and abstract identifiers used to resolve the location of an object anywhere on the Net. URLs are defined in RFC 1738 and RFC 1808.

```
protocol://hostname/location/item
```

`protocol` is an identifier such as "http," "ftp," or "gopher"; *`hostname`* is an Internet hostname; and the *`location`* and *`item`* components form a path that identifies the object on that host. Variants of this form allow extra information to be packed into the URL, specifying things like port numbers for the communications protocol and fragment identifiers that reference parts inside the object.

We sometimes speak of a URL that is relative to a base URL. In that case we are using the base URL as a starting point and supplying additional information. For example, the base URL might point to a directory on a Web server; a relative URL might name a particular file in that directory.

The URL class

A URL is represented by an instance of the `java.net.URL` class. A `URL` object manages all information in a URL string and provides methods for retrieving the object it identifies. We can construct a `URL` object from a

URL specification string or from its component parts:

```
try {
    URL aDoc = new URL( "../../../../foo.bar.com/documents/homepage.html" );
    URL sameDoc =
        new URL("http","foo.bar.com","documents/homepage.html");
}
catch ( MalformedURLException e ) { }
```

The two `URL` objects above point to the same network resource, the *homepage.html* document on the server foo.bar.com. Whether or not the resource actually exists and is available isn't known until we try to access it. At this point, the `URL` object just contains data about the object's location and how to access it. No connection to the server has been made. We can examine the `URL`'s components with the `getProtocol()`, `getHost()`, and `getFile()` methods. We can also compare it to another `URL` with the `sameFile()` method. `sameFile()` determines if two URLs point to the same resource. It can be fooled, but `sameFile` does more than compare the URLs for equality; it takes into account the possibility that one server may have several names, and other factors.

When a `URL` is created, its specification is parsed to identify the protocol component. If the protocol doesn't make sense, or if Java can't find a protocol handler for it, the URL constructor throws a `MalformedURLException`. A protocol handler is a Java class that implements the communications protocol for accessing the URL resource. For example, given an "http" URL, Java prepares to use the HTTP protocol handler to retrieve documents from the specified server.

Stream Data

The most general way to get data back from `URL` is to ask for an `InputStream` from the `URL` by calling `openStream()`. If you're writing an applet that will be running under Netscape, this is about your only choice. In fact, it's a good choice if you want to receive continuous updates from a dynamic information source. The drawback is that you have to parse the contents of an object yourself. Not all types of URLs support the `openStream()` method; you'll get an `UnknownServiceException` if yours doesn't.

The following code reads a single line from an HTML file:

```
try {
    URL url = new URL("../../../../server/index.html");
    DataInputStream dis = new DataInputStream( url.openStream() );
    String line = dis.readLine();
```

We ask for an `InputStream` with `openStream()`, and wrap it in a `DataInputStream` to read a line of text. Here, because we are specifying the "http" protocol in the URL, we still require the services of an HTTP protocol handler. As we'll discuss more in a bit, that brings up some questions about what handlers we have available to us and where. This example partially works around those issues because no content handler is involved; we read the data and interpret it as a content handler would. However, there are even more limitations on what applets can do right now. For the time being, if you construct `URL`s relative to the applet's `codeBase()`, you should be able to use them in applets as in the above example. This should guarantee that the needed protocol is available and accessible to the applet. Again, we'll discuss the more general issues a bit later.

Getting the Content as an Object

`openStream()` operates at a lower level than the more general content-handling mechanism implemented by the `URL` class. We showed it first because, until some things are settled, you'll be limited as to when you can use URLs in their more powerful role. When a proper content handler is available to Java (currently, only if you supply one with your standalone application), you'll be able to retrieve the object the `URL` addresses as a complete object, by calling the `URL`'s `getContent()` method. `getContent()` initiates a connection to the host, fetches the data for you, determines the data's MIME type, and invokes a content handler to turn the data into a Java object.

For example: given the URL http://foo.bar.com/index.html, a call to `getContent()` uses the HTTP protocol handler to receive the data and the HTML content handler to turn the data into some kind of object. A URL that points to a plain-text file would use a text-content handler that might return a `String` object. A GIF file might be turned into an `Image` object for display, using a GIF content handler. If we accessed the GIF file using an "ftp" URL, Java would use the same content handler, but would use the FTP protocol handler to receive the data.

`getContent()` returns the output of the content handler. Now we're faced with a problem: exactly what did we get? Since the content handler can return almost anything, the return type of `getContent()` is `Object`. Before doing anything meaningful with this `Object`, we must cast it into some other data type that we can work with. For example, if we expect a `String`, we'll cast the result of `getContent()` to a `String`:

```
String content;

try
    content = (String)myURL.getContent();
catch ( Exception e ) { }
```

Of course, we are presuming we will in fact get a `String` object back from this `URL`. If we're wrong, we'll get a `ClassCastException`. Since it's common for servers to be confused (or even lie) about the MIME types of the objects they serve, it's wise to catch that exception (it's a subclass of `RuntimeException`, so catching it is optional) or to check the type of the returned object with the `instanceof` operator:

```
if ( content instanceof String ) {
    String s = (String)content;
    ...
```

Various kinds of errors can occur when trying to retrieve the data. For example, `getContent()` can throw an `IOException` if there is a communications error; `IOException` is not a type of `RuntimeException`, so we must catch it explicitly, or declare the method that calls `getContent()` can throw it. Other kinds of errors can happen at the application level: some knowledge of how the handlers deal with errors is necessary.

For example, consider a `URL` that refers to a nonexistent file on an HTTP server. When requested, the server probably returns a valid HTML document that consists of the familiar "404 Not Found" message. An appropriate

HTML content handler is invoked to interpret this and return it as it would any other HTML object. At this point, there are several alternatives, depending entirely on the content handler's implementation. It might return a `String` containing the error message; it could also conceivably return some other kind of object or throw a specialized subclass of `IOException`. To find out that an error occurred, the application may have to look directly at the object returned from `getContent()`. After all, what is an error to the application may not be an error as far as the protocol or content handlers are concerned. "404 Not Found" isn't an error at this level; it's a perfectly valid document.

Another type of error occurs if a content handler that understands the data's MIME type isn't available. In this case, `getContent()` invokes a minimal content handler used for data with an unknown type and returns the data as a raw `InputStream`. A sophisticated application might specialize this behavior to try to decide what to do with the data on its own.

The `openStream()` and `getContent()` methods both implicitly create a connection to the remote `URL` object. For some applications, it may be necessary to use the `openConnection()` method of the `URL` to interact directly with the protocol handler. `openConnection()` returns a `URLConnection` object, which represents a single, active connection to the `URL` resource. We'll examine `URLConnection`s further when we start writing protocol handlers.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9.4 Web Browsers and Handlers

The content- and protocol-handler mechanisms I've introduced can be used by any application that accesses data via URLs. This mechanism is extremely flexible; to handle a URL, you need only the appropriate protocol and content handlers. To extend a Java-built Web browser so that it can handle new and specialized kinds of URLs, you need only supply additional content and protocol handlers. Furthermore, Java's ability to load new classes over the Net means that the handlers don't even need to be a part of the browser. Content and protocol handlers could be downloaded over the Net, from the same site that supplies the data, and used by the browser. If you wanted to supply some completely new data type, using a completely new protocol, you could make your data file plus a content handler and a protocol handler available on your Web server; anyone using a Web browser built in Java would automatically get the appropriate handlers whenever they access your data. In short, Java lets you build automatically extendible Web browsers; instead of being a gigantic do-everything application, the browser becomes a lightweight scaffold that dynamically incorporates extensions as needed. Figure 9.3 shows the conceptual operation of a content handler; Figure 9.4 does the same for a protocol handler.

Figure 9.3: A content handler at work

[Graphic: Figure 9-3]

Figure 9.4: A protocol handler at work

[Graphic: Figure 9-4]

Sun's HotJava was the first browser to demonstrate these features. When HotJava encounters a type of content or a protocol it doesn't understand, it searches the remote server for an appropriate handler class. HotJava also interprets HTML data as a type of content; that is, HTML isn't a privileged data type built into the browser. HTML documents use the same content- and protocol-handler mechanisms as other data types.

Unfortunately, a few nasty flies are stuck in this ointment. Content and protocol handlers are part of the Java API: they're an intrinsic part of the mechanism for working with URLs. However, specific content and protocol handlers aren't part of the API; the `ContentHandler` class and the two classes that make up protocol handlers, `URLStreamHandler` and `URLConnection`, are all abstract classes. They define what an implementation must provide, but they don't actually provide an implementation. This is not as paradoxical as it sounds. After all, the API defines the `Applet` class, but doesn't include any specific applets. Likewise, the standard Java classes don't include content handlers for HTML, GIF, MPEG, or other common data types. Even this isn't a real problem, although a library of standard content handlers would be useful. (JDK provides some content and protocol handlers in the `sun.net.www.content` and `sun.net.www.protocol` packages, but these are undocumented and subject to change.) There are two real issues here:

- There isn't any standard that tells you what kind of object the content handler should return. I danced around the issue just above, but it's a real problem. It's common sense that GIF data should be turned into an `Image` object, but at the moment, that's an application-level decision. If you're writing your own application and your own content handlers, that isn't an issue: you can make any decision you want. But if you're writing content handlers that interface to arbitrary Web browsers, you need a standard that defines what the browser expects. You can use the `sun.net` classes to make a guess, but a real standard hasn't been worked out yet.

- There isn't any standard that tells you where to put content and protocol handlers so that an

> application (like a Web browser) can find them. Again, you can make application-level decisions about where to place your own handlers, but that doesn't solve the real problem: we want our content and protocol handlers to be usable by any browser. It's possible to make an educated guess about what the standard will be, but it's still a guess.

The next release of Sun's HotJava Web browser should certainly take full advantage of handlers,[4] but current versions of Netscape Navigator do not. When the next release of HotJava appears, it may resolve these questions, at least on a de facto basis. (It would certainly be in Sun's interest to publish some kind of standard as soon as possible.) Although we can't tell you what standards will eventually evolve, we can discuss how to write handlers for standalone applications. When the standards issues are resolved, revising these handlers to work with HotJava and other Web browsers should be simple.

> [4] Downloadable handlers will be part of HotJava 1.0, though they are not supported by the "pre-beta 1" release. The current release *does* support local content and protocol handlers. HotJava 1.0 also promises additional classes to support network applications.

The most common Java-capable platform, Netscape Navigator, doesn't use the content- and protocol-handler mechanisms to render Net resources. It's a classic monolithic application: knowledge about certain kinds of objects, like HTML and GIF files, is built-in. It can be extended via a plug-in mechanism, but plug-ins aren't portable (they're written in C) and can't be downloaded dynamically over the Net. Applets running in Netscape can use a limited version of the `URL` mechanism, but the browser imposes many restrictions. As I said earlier, you can construct URLs relative to the applet's code base, and use the `openStream()` method to get a raw input stream from which to read data, but that's it. For the time being, you can't use your own content or protocol handlers to work with applets loaded over the Net. Allowing this would be a simple extension, even without content- and protocol-handler support integrated into Netscape itself. We can only hope they add this support soon.

9.5 Writing a Content Handler

`getContent()` invokes a content handler whenever it's called to retrieve an object at some URL. The content handler must read the flat stream of data produced by the `URL`'s protocol handler (the data read from the remote source), and construct a well-defined Java object from it. By "flat," I mean that the data stream the content handler receives has no artifacts left over from retrieving the data and processing the protocol. It's the protocol handler's job to fetch and decode the data before passing it along. The protocol handler's output is your data, pure and simple.

The roles of content and protocol handlers do not overlap. The content handler doesn't care how the data arrives, or what form it takes. It's concerned only with what kind of object it's supposed to create. For example, if a particular protocol involves sending an object over the network in a compressed format, the protocol handler should do whatever is necessary to unpack it before passing the data on to the content handler. The same content handler can then be used again with a completely different protocol handler to construct the *same* type of object received via a *different* transport mechanism.

Let's look at an example. The following lines construct a `URL` that points to a GIF file on an FTP archive and attempt to retrieve its contents:

```
try {
    URL url = new URL ("ftp://ftp.wustl.edu/graphics/gif/a/apple.gif");
    Image img = (Image)url.getContent();
    ...
```

When we construct the `URL` object, Java looks at the first part of the URL string (i.e., everything prior to the colon) to determine the protocol and locate a protocol handler. In this case, it locates the FTP protocol handler, which is used to open a connection to the host and transfer data for the specified file.

After making the connection, the `URL` object asks the protocol handler to identify the resource's MIME type.[5] It does this through a variety of means, but in this case it probably just looks at the filename extension (*.gif*) and determines that the MIME type of the data is `image/gif`. The protocol handler then looks for the content handler responsible for the `image/gif` type and uses it to construct the right kind of object from the data. The content handler returns an `Image` object, which `getContent()` returns to us as an `Object`; we cast this `Object` back to the `Image` type so we can work with it.

[5] MIME stands for Multipurpose Internet Mail Extensions. It's a standard design to facilitate multimedia email, but it has become more widely used as a way to specify the treatment of data contained in a document.

In an upcoming section, we'll build a simple content handler. To keep things as simple as possible, our example will produce text as output; the `URL`'s `getContent()` method will return this as a `String` object.

Locating Content Handlers

As I said earlier, there's no standard yet for where content handlers should be located. However, we're writing code now and need to know what package to place our class files in. In turn, this determines where to place the class files in the local filesystem. Because we are going to write our own standalone application to use our handler, we'll place our classes in a package in our local class path and tell Java where they reside. However, we will follow the naming scheme that's likely to become the standard. If other applications expect to find handlers in different locations (either locally or on servers), you'll simply have to repackage your class files according to their naming scheme and put them in the correct place.

Package names translate to path names when Java is searching for a class. This holds for locating content-handler classes as well as other kinds of classes. For example, on a UNIX- or DOS-based system, a class in a package named `net.www.content` would live in a directory with *net/www/content/* as part of its pathname. To allow Java to find handler classes for arbitrary new MIME types, content handlers are organized into packages corresponding to the basic MIME type categories. The handler classes themselves are then named after the specific MIME type. This allows Java to map MIME types directly to class names.

According to the scheme we'll follow, a handler for the `image/gif` MIME type is called `gif` and placed in a package called `net.www.content.image`. The fully qualified name of the class would then be `net.www.content.image.gif`, and it would be located in the file *net/www/content/image/gif.class*, somewhere in the local class path or on a server. Likewise, a content handler for the `video/mpeg` MIME type would be called `mpeg`, and there would be an *mpeg.class* file located (again, on a UNIX-/DOS-like filesystem) in a *net/www/content/video/* directory somewhere in a local class path or on a server.

Many MIME type names include a dash (`-`), which is illegal in a class name. You should convert dashes and other illegal characters into underscores when building Java class and package names. Also note that there are no capital letters in the class names. This violates the coding convention used in most Java source files, in which class names start with capital letters. However, capitalization is not significant in MIME type names, so it's simpler to name the handler classes accordingly. Table 9.1 shows how some typical MIME types are converted to package and class names.[6]

[6] The "pre-beta 1" release of HotJava has a temporary solution that is compatible with the convention described here. In the HotJava *properties* file, add the line: `java.content.handler.pkgs=net.www.content`.

Table 9.1: Converting MIME Types to Class and Package Names

MIME type	**Package name**	**Class name**	**Class location**
`image/gif`	`net.www.content.image`	`gif`	*net/www/content/image/*
`image/jpeg`	`net.www.content.image`	`jpeg`	*net/www/content/image/*
`text/html`	`net.www.content.text`	`html`	*net/www/content/text/*

The application/x-tar Handler

In this section, we'll build a simple content handler that reads and interprets *tar* (tape archive) files. *tar* is an archival format widely used in the UNIX-world to hold collections of files, along with their basic type and attribute information.[7] A *tar* file is similar to a ZIP file, except that it's not compressed. Files in the archive are stored sequentially, in flat text or binary with no special encoding. In practice, *tar* files are usually compressed for storage using an application like UNIX *compress* or GNU *gzip* and then named with a filename extension like *.tar.gz* or *.tgz*.

[7] There are several slightly different versions of the *tar* format. This content handler understands the most widely used variant.

Most Web browsers, upon retrieving a *tar* file, prompt the user with a **File Save** dialog. The assumption is that if you are retrieving an archive, you probably want to save it for later unpacking and use. We would like to instead implement a *tar* content handler that allows an application to read the contents of the archive and give us a listing of the files that it contains. In itself, this would not be the most useful thing in the world, because we would be left with the dilemma of how to get at the archive's contents. However, a more complete implementation of our content handler, used in conjunction with an application like a Web browser, could generate output that lets us select and save individual files within the archive.

The code that fetches the *.tar* file and lists its contents looks like this:

```
try {
    URL listing =
        new URL("../../../../somewhere.an.edu/lynx/lynx2html.tar");
    String s = (String)listing.getContents();
    System.out.println( s );
     ...
```

We'll produce a listing similar to the UNIX *tar* application's output:

```
Tape Archive Listing:

0     Tue Sep 28 18:12:47 CDT 1993 lynx2html/
14773 Tue Sep 28 18:01:55 CDT 1993 lynx2html/lynx2html.c
470   Tue Sep 28 18:13:24 CDT 1993 lynx2html/Makefile
172   Thu Apr 01 15:05:43 CST 1993 lynx2html/lynxgate
3656  Wed Mar 03 15:40:20 CST 1993 lynx2html/install.csh
490   Thu Apr 01 14:55:04 CST 1993 lynx2html/new_globals.c
...
```

Our content handler dissects the file to read the contents and generates the listing. The `URL`'s `getContent()` method returns that information to our application as a `String` object.

First we must decide what to call our content handler and where to put it. The MIME-type hierarchy classifies the *tar* format as an "application type extension." Its proper MIME type is then `application/x-tar`. Therefore, our handler belongs to the `net.www.content.application` package, and goes into the class file *net/www/content/application/x_tar.class*. Note that the name of our class is `x_tar`, rather than `x-tar`; you'll remember the dash is illegal in a class name so, by convention, we convert it to an underscore.

Here's the code for the content handler; compile it and place it in the *net/www/content/application/* package, somewhere in your class path:

```
package net.www.content.application;

import java.net.*;
import java.io.*;
import java.util.Date;

public class x_tar extends ContentHandler {
    static int
        RECORDLEN = 512,
        NAMEOFF = 0, NAMELEN = 100,
        SIZEOFF = 124, SIZELEN = 12,
        MTIMEOFF = 136, MTIMELEN = 12;

    public Object getContent(URLConnection uc) throws IOException {
        InputStream is = uc.getInputStream();
        StringBuffer output =
            new StringBuffer( "Tape Archive Listing:\n\n" );
        byte [] header = new byte[RECORDLEN];
        int count = 0;

        while ( (is.read(header) == RECORDLEN) &&
                (header[NAMEOFF] != 0) ) {

            String name =
               new String(header, 0, NAMEOFF, NAMELEN).trim();
            String s = new String(header, 0, SIZEOFF, SIZELEN).trim();
            int size = Integer.parseInt(s, 8);
            s = new String(header, 0, MTIMEOFF, MTIMELEN).trim();
            long l = Integer.parseInt(s, 8);
            Date mtime = new Date( l*1000 );

            output.append( size + " " + mtime + " " + name + "\n" );

            count += is.skip( size ) + RECORDLEN;
            if ( count % RECORDLEN != 0 )
                count += is.skip ( RECORDLEN - count % RECORDLEN);
        }

        if ( count == 0 )
            output.append("Not a valid TAR file\n");

        return( output.toString() );
    }
}
```

The ContentHandler class

Our `x_tar` handler is a subclass of the abstract class `java.net.ContentHandler`. Its job is to implement one method: `getContent()`, which takes as an argument a special "protocol connection" object and returns a constructed Java `Object`. The `getContent()` method of the `URL` class ultimately uses this `getContent()` method when we ask for the contents of the URL.

The code looks formidable, but most of it's involved with processing the details of the *tar* format. If we remove these details, there isn't much left:

```
public class x_tar extends ContentHandler {

    public Object getContent( URLConnection uc ) throws IOException {
        // get input stream
        InputStream is = uc.getInputStream();

        // read stream and construct object
        // ...

        // return the constructed object
        return( output.toString() );
    }
}
```

That's really all there is to a content handler; it's relatively simple.

The URLConnection

The `java.net.URLConnection` object that `getContent()` receives represents the protocol handler's connection to the remote resource. It provides a number of methods for examining information about the `URL` resource, such as header and type fields, and for determining the kinds of operations the protocol supports. However, its most important method is `getInputStream()`, which returns an `InputStream` from the protocol handler. Reading this `InputStream` gives you the raw data for the object the `URL` addresses. In our case, reading the `InputStream` feeds `x_tar` the bytes of the *tar* file it's to process.

Constructing the object

The majority of our `getContent()` method is devoted to interpreting the stream of bytes of the *tar* file and building our output object: the `String` that lists the contents of the *tar* file. Again, this means that this example involves the particulars of reading *tar* files, so you shouldn't fret too much about the details.

After requesting an `InputStream` from the `URLConnection`, `x_tar` loops, gathering information about each file. Each archived item is preceded by a header that contains attribute and length fields. `x_tar` interprets each header and then skips over the remaining portion of the item. It accumulates the results (the file listings) in a `StringBuffer`. (See Chapter 7, *Basic Utility Classes* for a discussion of `StringBuffer`.) For each file, we add a line of text listing the name, modification time, and size. When the listing is complete, `getContent()` returns the `StringBuffer` as a `String` object.

The main `while` loop continues as long as it's able to read another header record, and as long as the record's "name" field isn't full of ASCII null values. (The *tar* file format calls for the end of the archive to be padded with an empty header record, although most *tar* implementations don't seem to do this.) The `while` loop retrieves the name, size, and modification times as character strings from fields in the header. The most common *tar* format stores its numeric values in octal, as fixed-length ASCII strings. We extract the strings and use `Integer.parseInt()` to parse them.

After reading and parsing the header, `x_tar` skips over the data portion of the file and updates the variable `count`, which keeps track of the offset into the archive. The two lines following the initial skip account for *tar*'s "blocking" of the data records. In other words, if the data portion of a file doesn't fit precisely into an integral number of blocks of RECORDLEN bytes, *tar* adds padding to make it fit.

Whew. Well, as I said, the details of parsing *tar* files are not really our main concern here. But x_tar does illustrate a few tricks of data manipulation in Java.

It may surprise you that we didn't have to provide a constructor; our content handler relies on its default constructor. We don't need to provide a constructor because there isn't anything for it to do. Java doesn't pass the class any argument information when it creates an instance of it. You might suspect that the URLConnection object would be a natural thing to provide at that point. However, when you are calling the constructor of a class that is loaded at run-time, you can't pass it any arguments, as we discussed in Chapter 5, *Objects in Java*.

Using our new handler

When I began this discussion of content handlers, I showed a brief example of how our x_tar content handler would work for us. We need to make a few brief additions to that code in order to use our new handler and fetch URLs that point to *.tar* files. Since we're writing a standalone application, we're not only responsible for writing handlers that obey the package/class naming scheme we described earlier; we are also responsible for making our application use the naming scheme.

In a standalone application, the mapping between MIME types and content-handler class names is done by a special java.net.ContentHandlerFactory object we must install. The ContentHandlerFactory accepts a String containing a MIME type and returns the appropriate content handler. It's responsible for implementing the naming convention and creating an instance of our handler. Note that you don't need a content-handler factory if you are writing handlers for use by remote applications; a browser like HotJava, that loads content handlers over the Net, has its own content-handler factory.

To make absolutely clear what's happening, we'll provide a simple factory that knows only about our x_tar handler and install it at the beginning of our application:

```
import java.net.*;
import java.io.*;

class OurContentHandlerFactory implements ContentHandlerFactory {

    public ContentHandler createContentHandler(String mimetype) {
        if ( mimetype.equalsIgnoreCase( "application/x-tar" ) )
            return new net.www.content.application.x_tar();
        else
            return null;
    }
}
```

```
public class TarURLTest {
    public static void main (String [] args) throws Exception {

        URLConnection.setContentHandlerFactory(new
                      OurContentHandlerFactory() );

        URL url = new URL( args[0] );
        String s = (String)url.getContent();
        System.out.println( s );
    }
}
```

The class `OurContentHandlerFactory` implements the `ContentHandlerFactory` interface. It recognizes the MIME-type `application/x-tar` and returns a new instance of our `x_tar` handler. `TarURLTest` uses the static method `URLConnection.setContentHandlerFactory()` to install our new `ContentHandlerFactory`. After it's installed, our factory is called every time we retrieve the contents of a URL object. If it returns a `null` value, Java looks for handlers in a default location.[8]

> [8] If we don't install a `ContentHandlerFactory` (or later, as we'll see a `URLStreamHandlerFactory` for protocol handlers), Java defaults to searching for a vendor-specific package name. If you have Sun's Java Development Kit, it searches for content handlers in the `sun.net.www.content` package hierarchy and protocol handler classes in the `sun.net.www.protocol` package hierarchy.

After installing the factory, `TarURLTest` reads a URL from the command line, opens that URL, and lists its contents. Now you have a portable *tar* command that can read its *tar* files from arbitrary locations on the Net. I'll confess that I was lazy about exception handling in this example. Of course, a real application would need to catch and handle the appropriate exceptions; but we already know how to do that.

A final design note. Our content handler returned the *tar* listing as a `String`. I don't want to harp on the point, but this isn't the only option. If we were writing a content handler to work in the context of a Web browser, we might want it to produce some kind of HTML object that might display the listing as hypertext. Again, knowing the right solution requires that we know what kind of object a browser expects to receive, and currently that's undefined.

In the next section, we'll turn the tables and look at protocol handlers. There we'll be building `URLConnection` objects and someone else will have the pleasure of reconstituting the data.

9.6 Writing a Protocol Handler

A `URL` object uses a protocol handler to establish a connection with a server and perform whatever protocol is necessary to retrieve data. For example, an HTTP protocol handler knows how to talk to an HTTP server and retrieve a document; an FTP protocol handler knows how to talk to an FTP server and retrieve a file. All types of URLs use protocol handlers to access their objects. Even the lowly "file" type URLs use a special "file" protocol handler that retrieves files from the local filesystem. The data a protocol handler retrieves is then fed to an appropriate content handler for interpretation.

While we refer to a protocol handler as a single entity, it really has two parts: a `java.net.URLStreamHandler` and a `java.net.URLConnection`. These are both `abstract` classes we will subclass to create our protocol handler. (Note that these are `abstract` classes, not interfaces. Although they contain abstract methods we are required to implement, they also contain many utility methods we can use or override.) The `URL` looks up an appropriate `URLStreamHandler`, based on the protocol component of the `URL`. The `URLStreamHandler` then finishes parsing the URL and creates a `URLConnection` when it's time to communicate with the server. The `URLConnection` represents a single connection with a server, and implements the communication protocol itself.

Locating Protocol Handlers

Protocol handlers are organized in a package hierarchy similar to content handlers. Unlike content handlers, which are grouped into packages by the MIME types of the objects that they handle, protocol handlers are given individual packages. Both parts of the protocol handler (the `URLStreamHandler` class and the `URLConnection` class) are located in a package named for the protocol they support.

For example, the classes for an FTP protocol handler would be found in the `net.www.protocol.ftp` package. The `URLStreamHandler` is placed in this package and given the name `Handler`; all `URLStreamHandler`s are named `Handler` and distinguished by the package in which they reside. The `URLConnection` portion of the protocol handler is placed in the same package, and can be given any name. There is no need for a naming convention because the corresponding `URLStreamHandler` is responsible for creating the `URLConnection` objects it uses. Table 9.2 gives the obvious examples.[9]

[9] The "pre-beta 1" release of HotJava has a temporary solution that is compatible with the

convention described here. In the HotJava *properties* file, add the line: `java.protocol.handler.pkgs=net.www.protocol`.

Table 9.2: Mapping Protocols into Package and Class Names

Protocol	**Package**	**URLStreamHandler**	**Handler**
	name	**class name**	**class location**
FTP	`net.www.protocol.ftp`	`Handler`	*net/www/protocol/ftp/*
HTTP	`net.www.protocol.http`	`Handler`	*net/www/protocol/http/*

URLs, Stream Handlers, and Connections

The `URL`, `URLStreamHandler`, `URLConnection`, and `ContentHandler` classes work together closely. Before diving into an example, let's take a step back, look at the parts a little more closely, and see how these things communicate. Figure 9.5 shows how these components relate to each other.

Figure 9.5: The protocol handler machinery

[Graphic: Figure 9-5]

We begin with the `URL` object, which points to the resource we'd like to retrieve. The `URLStreamHandler` helps the `URL` class parse the URL specification string for its particular protocol. For example, consider the following call to the `URL` constructor:

```
URL url = new URL("protocol_3A/foo.bar.com/file.ext");
```

The `URL` class parses only the protocol component; later, a call to the `URL` class's `getContent()` or `openStream()` method starts the machinery in motion. The `URL` class locates the appropriate protocol handler by looking in the protocol-package hierarchy. It then creates an instance of the appropriate `URLStreamHandler` class.

The `URLStreamHandler` is responsible for parsing the rest of the URL string, including hostname and filename, and possibly an alternative port designation. This allows different protocols to have their own variations on the format of the URL specification string. Note that this step is skipped when a URL is constructed with the "protocol," "host," and "file" components specified explicitly. If the protocol is straightforward, its `URLStreamHandler` class can let Java do the parsing and accept the default behavior. For this illustration, we'll assume that the `URL` string requires no special parsing. (If we use a nonstandard URL with a strange format, we're responsible for parsing it ourselves, as I'll show shortly.)

The `URL` object next invokes the handler's `openConnection()` method, prompting the handler to create a new `URLConnection` to the resource. The `URLConnection` performs whatever communications are necessary to talk to the resource and begins to fetch data for the object. At that time, it also determines the MIME type of the incoming object data and prepares an `InputStream` to hand to the appropriate content handler. This `InputStream` must send "pure" data with all traces of the protocol removed.

The `URLConnection` also locates an appropriate content handler in the content-handler package hierarchy. The `URLConnection` creates an instance of a content handler; to put the content handler to work, the `URLConnection`'s `getContent()` method calls the content handler's `getContent()` method. If this sounds confusing, it is: we have three `getContent()` methods calling each other in a chain. The newly created `ContentHandler` object then acquires the stream of incoming data for the object by calling the `URLConnection`'s `getInputStream()` method. (Recall that we acquired an `InputStream` in our `x_tar` content handler.) The content handler reads the stream and constructs an object from the data. This object is then returned up the `getContent()` chain: from the content handler, the `URLConnection`, and finally the `URL` itself. Now our application has the desired object in its greedy little hands.

To summarize, we create a protocol handler by implementing a `URLStreamHandler` class that creates specialized `URLConnection` objects to handle our protocol. The `URLConnection` objects implement the `getInputStream()` method, which provides data to a content handler for construction of an object. The base `URLConnection` class implements many of the methods we need; therefore, our `URLConnection` needs only to provide the methods that generate the data stream and return the MIME type of the object data.

Okay. If you're not thoroughly confused by all that terminology (or even if you are), let's move on to the example. It should help to pin down what all these classes are doing.

The crypt Handler

In this section, we'll build a *crypt* protocol handler. It parses URLs of the form:

```
crypt:type//hostname[:port]/location/item
```

`type` is an identifier that specifies what kind of encryption to use. The protocol itself is a simplified version of HTTP; we'll implement the `GET` command and no more. I added the *`type`* identifier to the URL to show how to parse a nonstandard URL specification. Once the handler has figured out the encryption type, it dynamically loads a class that implements the chosen encryption algorithm and uses it to retrieve the data.

Obviously, we don't have room to implement a full-blown public-key encryption algorithm, so we'll use the `rot13InputStream` class from Chapter 8, *Input/Output Facilities*. It should be apparent how the example can be extended by plugging in a more powerful encryption class.

The Encryption class

First, we'll lay out our plug-in encryption class. We'll define an abstract class called `CryptInputStream` that provides some essentials for our plug-in encrypted protocol. From the `CryptInputStream` we'll create a subclass, `rot13CryptInputStream`, that implements our particular kind of encryption:

```
package net.www.protocol.crypt;
import java.io.*;

abstract class CryptInputStream extends InputStream {
    InputStream in;
    OutputStream talkBack;
    abstract public void set( InputStream in, OutputStream talkBack );
}

class rot13CryptInputStream extends CryptInputStream {

    public void set( InputStream in, OutputStream talkBack ) {
        this.in = new example.io.rot13InputStream( in );
    }
    public int read() throws IOException {
        if ( in == null )
            throw new IOException("No Stream");

        return in.read();
    }
}
```

Our `CryptInputStream` class defines a method called `set()` that passes in the `InputStream` it's to translate. Our `URLConnection` calls `set()` after creating an instance of the encryption class. We need a `set()` method because we want to load the encryption class dynamically, and we aren't allowed to pass arguments to the constructor of a class when it's dynamically loaded. We ran into this same restriction in our content handler. In the encryption class, we also provide an `OutputStream`. A more complex kind of encryption might use the `OutputStream` to transfer public-key information. Needless to say, *rot13* doesn't, so we'll ignore the `OutputStream` here.

The implementation of `rot13CryptInputStream` is very simple. `set()` just takes the `InputStream` it receives and wraps it with the `rot13InputStream` filter we developed in Chapter 8, *Input/Output Facilities*. `read()` reads filtered data from the `InputStream`, throwing an exception if `set()` hasn't been called.

The URLStreamHandler

Next we'll build our URLStreamHandler class. The class name is Handler; it extends the abstract URLStreamHandler class. This is the class the Java URL looks up by converting the protocol name (*crypt*) into a package name (net.www.protocol.crypt). The fully qualified name of this class is net.www.protocol.crypt.Handler:

```
package net.www.protocol.crypt;

import java.io.*;
import java.net.*;

public class Handler extends URLStreamHandler {
    String cryptype;

    protected void parseURL(URL u, String spec, int start, int end) {
        int slash = spec.indexOf('/');
        cryptype = spec.substring(start, slash);
        start=slash;
        super.parseURL(u, spec, start, end);
    }

    protected URLConnection openConnection(URL url)
       throws IOException {

        return new CryptURLConnection( url, cryptype );
    }
}
```

Java creates an instance of our URLStreamHandler when we create a URL specifying the *crypt* protocol. Handler has two jobs: to assist in parsing the URL specification strings and to create CryptURLConnection objects when it's time to open a connection to the host.

Our parseURL(default.htm) method overrides the parseURL(default.htm) method in the URLStreamHandler class. It's called whenever the URL constructor sees a URL requesting the *crypt* protocol. For example:

```
URL url = new URL("crypt_3Arot13/foo.bar.com/file.txt");
```

parseURL(default.htm) is passed a reference to the URL object, the URL specification string, and starting and ending indexes that shows what portion of the URL string we're expected to parse. The URL class has already identified the protocol name, otherwise it wouldn't have found our protocol handler. Our version of parseURL(default.htm) retrieves our *type* identifier from the specification, stores it in the variable cryptype, and then passes the rest on to the superclass's parseURL(default.htm) method to complete the job. To find the encryption type, take everything between the starting index we were given and the first slash in the URL string. Before calling super.parseURL(default.htm), we update the start index, so that it points to the character just after the type specifier. This tells the superclass parseURL(default.htm) that we've already parsed everything prior to the first slash, and it's responsible for the rest.

Before going on, I'll note two other possibilities. If we hadn't hacked the URL string for our own purposes by adding a type specifier, we'd be dealing with a standard URL specification. In this case, we wouldn't need to override parseURL(default.htm); the default implementation would have been sufficient. It could have sliced the URL into host, port, and filename components normally. On the other hand, if we had created a completely bizarre URL format, we would need to parse the entire string. There would be no point calling super.parseURL(default.htm); instead, we'd have called the URLStreamHandler's protected method setURL(default.htm) to pass the URL's components back to the URL object.

The other method in our Handler class is openConnection(). After the URL has been completely parsed, the URL object calls openConnection() to set up the data transfer. openConnection() calls the constructor for our URLConnection with appropriate arguments. In this case, our URLConnection object is named CryptURLConnection, and the constructor requires the URL and the encryption type as arguments. parseURL(default.htm) picked the encryption type from the URL string and stored it in the cryptype variable. openConnection() returns a reference to our URLConnection, which the URL object uses to drive the rest of the process.

The URLConnection

Finally, we reach the real guts of our protocol handler, the URLConnection class. This is the class that opens the socket, talks to the server on the remote host, and implements the protocol itself. This class doesn't have to be public, so you can put it in the same file as the Handler class we just defined. We call our class Crypt-URLConnection; it extends the abstract URLConnection class. Unlike ContentHandler and StreamURLConnection, whose names are defined by convention, we can call this class anything we want; the only class that needs to know about the URLConnection is the URLStreamHandler, which we wrote ourselves.

```
class CryptURLConnection extends URLConnection {
    CryptInputStream cis;
    static int defaultPort = 80;

    CryptURLConnection ( URL url, String cryptype )
        throws IOException {
        super( url );
        try {
            String name = "net.www.protocol.crypt." + cryptype
                                   + "CryptInputStream";
            cis = (CryptInputStream)Class.forName(name).newInstance();
        }
        catch ( Exception e ) { }
    }

    synchronized public void connect() throws IOException {
        int port;
        if ( cis == null )
            throw new IOException("Crypt Class Not Found");
        if ( (port = url.getPort()) == -1 )
            port = defaultPort;
        Socket s = new Socket( url.getHost(), port );

        // Send the filename in plaintext
        OutputStream server = s.getOutputStream();
        new PrintStream( server ).println( "GET "+url.getFile() );

        // Initialize the CryptInputStream
        cis.set( s.getInputStream(), server );
        connected = true;
    }

    synchronized public InputStream getInputStream()
       throws IOException {
        if (!connected)
            connect();
        return ( cis );
    }

    public String getContentType() {
        return guessContentTypeFromName( url.getFile() );
    }
}
```

The constructor for our `CryptURLConnection` class takes as arguments the destination `URL` and the name of an encryption type. We pass the `URL` on to the constructor of our superclass, which saves it in a protected `url` instance variable. We could have saved the `URL` ourselves, but calling our parent's constructor shields us from possible changes or enhancements to the base class. We use `cryptype` to construct the name of an encryption class, using the convention that the encryption class is in the same package as the protocol handler (i.e., `net.www.protocol.crypt`); its name is the encryption type followed by the suffix `CryptInputStream`.

Once we have a name, we need to create an instance of the encryption class. To do so, we use the static method `Class.forName()` to turn the name into a `Class` object and `newInstance()` to load and instantiate the class. (This is how Java loads the content and protocol handlers themselves.) `newInstance()` returns an `Object`; we need to cast it to something more specific before we can work with it. Therefore, we cast it to our `CryptInputStream` class, the abstract class that `rot13CryptInputStream` extends. If we implement any additional encryption types as extensions to `CryptInputStream` and name them appropriately, they will fit into our protocol handler without modification.

We do the rest of our setup in the `connect()` method of the `URLConnection`. There, we make sure we have an encryption class and open a `Socket` to the appropriate port on the remote host. `getPort()` returns `-1` if the `URL` doesn't specify a port explicitly; in that case we use the default port for an HTTP connection (port 80). We ask for an `OutputStream` on the socket, assemble a `GET` command using the `getFile()` method to discover the filename specified by the URL, and send our request by writing it into the `OutputStream`. (For convenience, we wrap the `OutputStream` with a `PrintStream` and call `println()` to send the message.) We then initialize the `CryptInputStream` class by calling its `set()` method and passing it an `InputStream` from the `Socket` and the `OutputStream`.

The last thing `connect()` does is set the `boolean` variable `connected` to `true`. `connected` is a `protected` variable inherited from the `URLConnection` class. We need to track the state of our connection because `connect()` is a `public` method. It's called by the `URLConnection`'s `getInputStream()` method, but it could also be called by other classes. Since we don't want to start a connection if one already exists, we use `connected` to tell us if this is so.

In a more sophisticated protocol handler, `connect()` would also be responsible for dealing with any protocol headers that come back from the server. In particular, it would probably stash any important information it can deduce from the headers (e.g., MIME type, content length, time stamp) in instance variables, where it's available to other methods. At a minimum, `connect()` strips the headers from the data so the content handler won't see them. I'm being lazy and assuming that we'll connect to a minimal server, like the modified `TinyHttpd` daemon I discuss below, which doesn't bother with any headers.

The bulk of the work has been done; a few details remain. The `URLConnection`'s `getContent()` method needs to figure out which content handler to invoke for this `URL`. In order to compute the content handler's name, `getContent()` needs to know the resource's MIME type. To find out, it calls the `URLConnection`'s `getContentType()` method, which returns the MIME type as a `String`. Our protocol handler overrides `getContentType()`, providing our own implementation.

The `URLConnection` class provides a number of tools to help determine the MIME type. It's possible that the MIME type is conveyed explicitly in a protocol header; in this case, a more sophisticated version of `connect()` would have stored the MIME type in a convenient location for us. Some servers don't bother to insert the appropriate headers, though, so you can use the method `guessContentTypeFromName()` to examine filename extensions, like *.gif* or *.html*, and map them to MIME types. In the worst case, you can use `guessContentTypeFromStream()` to intuit the MIME type from the raw data. The Java developers call this method "a disgusting hack" that shouldn't be needed, but that is unfortunately necessary "in a world where HTTP servers lie about content types and extensions are often nonstandard." We'll take the easy way out and use the `guessContentTypeFromName()` utility of the `URLConnection` class to determine the MIME type from the filename extension of the URL we are retrieving.

Once the `URLConnection` has found a content handler, it calls the content handler's `getContent()`

method. The content handler then needs to get an `InputStream` from which to read the data. To find an `InputStream`, it calls the `URLConnection`'s `getInputStream()` method. `getInputStream()` returns an `InputStream` from which its caller can read the data after protocol processing is finished. It checks whether a connection is already established; if not, it calls `connect()` to make the connection. Then it returns a reference to our `CryptInputStream`.

A final note on getting the content type: if you read the documentation, it's clear that the Java developers had some ideas about how to find the content type. The `URLConnection`'s default `getContentType()` calls `getHeaderField()`, which is presumably supposed to extract the named field from the protocol headers (it would probably spit back information `connect()` had stored in protected variables). The problem is there's no way to implement `getHeaderField()` if you don't know the protocol, and since the Java developers were designing a general mechanism for working with protocols, they couldn't make any assumptions. Therefore, the default implementation of `getHeaderField()` returns `null`; you have to override it to make it do anything interesting. Why wasn't it an abstract method? I can only guess, but making `getHeaderField()` abstract would have forced everyone building a protocol handler to implement it, whether or not they actually needed it.

The application

We're almost ready to try out a crypt URL! We still need an application (a mini-browser, if you will) to use our protocol handler, and a server to serve data with our protocol. If HotJava were available, we wouldn't need to write the application ourselves; in the meantime, writing this application will teach us a little about how a Java-capable browser works. Our application is similar to the application we wrote to test the `x_tar` content handler.

Because we're working in a standalone application, we have to tell Java how to find our protocol-handler classes. Java relies on a `java.net.URLStreamHandlerFactory` object to take a protocol name and return an instance of the appropriate handler. The `URLStreamHandlerFactory` is very similar to the `ContentHandlerFactory` we saw earlier. We'll provide a trivial implementation that knows only our particular handler. Again, if we were using our protocol handler with HotJava, this step would not be necessary; HotJava has its own stream-handler factory that tells it where to find handlers. To get HotJava to read files with our new protocol, we'd only have to put our protocol handler in the right place. (Note too, that an applet running in HotJava can use any of the methods in the `URL` class and therefore can use the content- and protocol-handler mechanism; applets would also rely on HotJava's stream-handler and content-xhandler factories.)

Here's our `StreamHandlerFactory` and sample application:

```
import java.net.*;

class OurURLStreamHandlerFactory implements URLStreamHandlerFactory {
    public URLStreamHandler createURLStreamHandler(String protocol) {
        if ( protocol.equalsIgnoreCase("crypt") )
            return new net.www.protocol.crypt.Handler();
        else
            return null;
    }
}

class CryptURLTest {
    public static void main( String argv[] ) throws Exception {

        URL.setURLStreamHandlerFactory(
            new OurURLStreamHandlerFactory());

        URL url = new URL("crypt_3Arot13/foo.bar.com_3A1234/myfile.txt");
        System.out.println( url.getContent() );
    }
}
```

The `CryptURLTest` class installs our factory and reads a document via the new "crypt:rot13" URL. (In the example, we have assumed that a *rot13* server is running on port 1234 on the host foo.bar.com.) When the `CryptURLTest` application calls the `URL`'s `getContent()` method, it automatically finds our protocol handler, which decodes the file.

`OurURLStreamHandlerFactory` is really quite simple. It implements the `URLStreamHandlerFactory` interface, which requires a single method called `createURLStreamHandler()`. In our case, this method checks whether the protocol's name is *crypt* ; if so, the method returns an instance of our encryption protocol handler, `net.www.protocol.crypt.Handler`. For any other protocol name, it returns `null`. If we were writing a browser and needed to implement a more general factory, we would compute a class name from the protocol name, check to see if that class exists, and return an instance of that class.

The server

We still need a *rot13* server. Since the *crypt* protocol is nothing more than HTTP with some encryption added, we can make a *rot13* server by modifying one line of the `TinyHttpd` server we developed earlier, so that it spews its files in *rot13*. Just change the line that reads the data from the file:

```
f.read( data );
```

To instead read through a `rot13InputStream`:

```
new example.io.rot13InputStream( f ).read( data );
```

I assume you placed the `rot13InputStream` example in a package called `example.io`, and that it's somewhere in your class path. Now recompile and run the server. It automatically encodes the files before sending them; our sample application decodes them on the other end.

I hope that this example and the rest of this chapter have given you some food for thought. Content and protocol handlers are among the most exciting ideas in Java. It's unfortunate that we have to wait for future releases of HotJava and Netscape to take full advantage of them. In the meantime, you can experiment and implement your own applications.

10.2 Applets

If you've been waiting for a more detailed discussion of the applet class, here it is. For examples of writing applets, please see Chapter 2, *A First Applet* (the tutorial) and the examples in Chapter 11, *Using and Creating GUI Components* and throughout the book.

An `Applet` is something like a `Panel` with a mission. It is a GUI Container that has some extra structure to allow it to be used in an "alien" environment like a Web browser or appletviewer. Applets also have a life-cycle that lets them act more like an application than a static component. Although applets tend to be relatively simple, there's no inherent restriction on their complexity. There's no reason you couldn't write an air traffic control system (well, let's be less ambitious: a word processor) as an applet.

Structurally, an applet is a sort of wrapper for your Java code. In contrast to a standalone graphical Java application, which starts up from a `main()` method and creates a GUI, an applet is itself a Component that expects to be dropped into someone else's GUI. Thus, an applet can't run by itself; it runs in the context of a Web browser or an appletviewer. Instead of having your application create a `Frame` to hold your GUI, you stuff your application inside an `Applet` (which is itself a Container) and let someone else add the applet to their GUI.

Pragmatically, an applet is an intruder into someone else's environment, and therefore has to be treated with suspicion. The Web browsers that run applets impose restrictions on what the applet is allowed to do. The restrictions are enforced by a security manager, which the applet is not allowed to change. The browser also provides an "applet context," which is additional support that helps the applet live within its restrictions.

Aside from that top level structure and the security restrictions, there is no difference between an applet and an application. If your application can live within the restrictions imposed by a browser's security manager, you can easily structure it to function as an applet and a standalone application. (We'll show an example of an Applet that can also be run as a standalone below.) Conversely, if you can supply all of the things that an applet requires from its environment, you can use applets within your stand-alone applications and within other applets (though this requires a bit of work).

As we said a moment ago, an `Applet` expects to be embedded in GUI (perhaps a document) and used in a viewing environment that provides it with special resources. In all other respects, however, applets are just ordinary `Panel` objects. (See Figure 10.8.) Like a `Panel`, an `Applet` can contain user-interface components and implement all the basic drawing and event-handling capabilities of the `Component` class. We draw on an `Applet` by overriding its `paint()` method; we respond to events in the `Applet`'s display area by providing the appropriate event-listeners. The additional structure applets have helps them interact with the viewer environment.

Applet Control

The `Applet` class contains four methods an applet can override to guide it through its life cycle. The `init()`, `start()`, `stop()`, and `destroy()` methods are called by an applet viewer, such as a Web browser, to direct the applet's behavior. `init()` is called once, after the applet is created. The `init()` method is where you perform basic setup like parsing parameters, building a user interface, and loading resources. Given what we've said about objects, you might expect the `Applet`'s constructor would be the right place for such initialization. However, the constructor is meant to be called by the applet's environment, for simple creation of the applet. This might happen before the applet has access to certain resources, like information about its environment. Therefore, an applet doesn't normally do any work in its constructor; it relies on the default constructor for the `Applet` class and does its initialization in the `init()` method.

The `start()` method is called whenever the applet becomes visible; it shouldn't be a surprise then that the `stop()` method is called whenever the applet becomes invisible. `init()` is only called once in the life of an applet, but `start()` and `stop()` can be called any number of times (but always in the logical sequence). For example, `start()` is called when the applet is displayed, such as when it scrolls onto the screen; `stop()` is called if the applet scrolls off the screen or the viewer leaves the document. `start()` tells the applet it should be active. The applet may want to create threads, animate, or otherwise perform useful (or annoying) activity. `stop()` is called to let the applet know it should go dormant. Applets should cease CPU-intensive or wasteful activity when they are stopped and resume it when (and if) they are restarted. However, there's no requirement that an invisible applet stop computing; in some applications, it may be useful for the applet to continue running in the background. Just be considerate of your user, who doesn't want an invisible applet dragging down system performance. And for the users: be aware of the tools that will develop to let you monitor and squash rogue applets in your web browser.

Finally, the `destroy()` method is called to give the applet a last chance to clean up before it's removed--some time after the call to `stop()`. For example, an applet might want to close down suspended communications channels or remove graphics frames. Exactly when `destroy()` is called depends on the applet viewer; Netscape Navigator calls `destroy()` just prior to deleting the applet from its cache. This means that although an applet can cling to life after being told to `stop()`, how long it can go on is unpredictable. If you want to maintain your applet as the user progresses through other activities, consider putting it in an HTML frame (see "Driving the Browser" later in this chapter).

The Applet security Sandbox

Applets are quarantined within the browser by an applet `SecurityManager`. The `SecurityManager` is part of the application that runs the applet, e.g., the web browser or applet viewer. It is installed before the browser loads any applets and implements the basic restrictions that let you run untrusted applets safely. Remember that, aside from basic language robustness, there are no inherent security restrictions on a standalone Java application. It is the browser's responsibility to install a special security manager and limit what applets are allowed to do.

Most browsers impose the following restrictions on untrusted applets:

- Untrusted Applets cannot read or write files on the local host.
- Untrusted Applets can only open network connections (sockets) to the server from which they originated.
- Untrusted Applets cannot start other processes on the local host.
- Untrusted Applets cannot have native methods.

We discuss these restrictions in more detail in the relevant chapters in this book. However, the motivation for these restrictions should be fairly obvious: you clearly wouldn't want a program coming from some random Internet site to access your files, or run arbitrary programs. Although untrusted applets cannot directly read and write files on the client side or talk to arbitrary hosts on the network, applets can work with servers to store data and communicate. For example, an applet can use Java's RMI (Remote Method Invocation) facility to do processing on its server. An applet can communicate with other applets on the Net by proxy through its server.

Trusted Applets

The latest version of Java makes it possible to sign archive files that contain applets. Because a signature identifies the applet's origin unambiguously, we can now distinguish between "trusted" applets (i.e., applets that come from a site or person you trust not to do anything harmful) and run of the mill "untrusted" applets. In web browsers that support signing, trusted applets can be granted permission to "go outside" of the applet security sandbox. Trusted applets can be allowed to do most of the things that standalone Java applications can do: read and write files, open network connections to arbitrary machines, and interact with the local operating system by starting processes. Trusted applets still can't have native methods, but including native methods in an applet would make it unportable, and would therefore be a bad idea.

Chapter 3, *Tools of the Trade* discusses how to package your applet's class files and resources into a JAR file and sign it with your digital signature. Currently, HotJava is the only browser that supports signing, but Netscape Navigator, Internet Explorer, and others will probably catch up soon.

Getting Applet Resources

An applet needs to communicate with its applet viewer. For example, it needs to get its parameters from the HTML document in which it appears. An applet may also need to load images, audio clips, and other items. It may also want to ask the viewer about other applets on the same HTML page in order to communicate with them. To get resources from the applet viewer environment, applets use the `AppletStub` and `AppletContext` interfaces. Unless you're writing a browser or some other application that loads and runs applets, you won't have to implement these interfaces, but you do use them within your applet.

Applet Parameters

An applet gets its parameters from the parameter tags placed inside the `<applet>` tag in the HTML document. For example, the code below reads the "sheep" parameter from its HTML page:

```
String imageName = getParameter( "imageName" );
try  {
    int numberOfSheep = Integer.parseInt(getParameter( "sheep" ));
} catch ( NumberFormatException e ) { // use default }
```

A friendly applet will provide information about the parameters it accepts through its `getParameterInfo()` method. `getParameterInfo()` returns an array of string arrays, listing and describing the applet's parameters. For each parameter, three strings are provided: the parameter name, its possible values or value types, and a verbose description. For example:

```
public String [][] getParameterInfo() {
    String [][] appletInfo =
        {"logo",   "url",   "Main logo image"}
        {"timer", "int",   "Time to wait before becoming annoying"},
        {"flashing", "constant | intermittant",  "Flag for how to flash"},
    return appletInfo;
}
```

Applet Resources

An applet can find where it lives by calling the `getDocumentBase()` and `getCodeBase()` methods. `getDocumentBase()` returns the base URL of the document in which the applet appears; `getCodeBase()` returns the base URL of the `Applet`'s class files. An applet can use these to construct relative URLs from which to load other resources like images, sounds, and other data. The `getImage()` method takes a URL and asks for an image from the viewer environment. The image may be pulled from a cache or loaded asynchronously when later used. The `getAudioClip()` method, similarly, retrieves sound clips. See Chapter 9, *Network Programming* for a full discussion of how to work with URLs, and Chapter 11, *Using and Creating GUI Components* for examples of applets that load images.

The following example uses `getCodeBase()` to construct a URL and load a properties-configuration file, located at the same location as the applet's class file. (See Chapter 7, *Basic Utility Classes* for a discussion of properties.)

```
Properties props = new Properties();
try {
    URL url = new URL(getCodeBase(), "appletConfig.props");
    props.load( url.openStream() );
} catch ( IOException e ) { // failed }
```

A better way to load resources is by calling the `getResource()` and `getResourceAsStream()` methods of the `Class` class, which search the applet's JAR files (if any) as well as its codebase. See Chapter 8, *Input/Output Facilities* for a discussion of resource loading. The following code loads the properties file appletConfig.props:

```
Properties props = new Properties();
try {
    props.load( getClass().getResourceAsStream("appletConfig.props") );
} catch ( IOException e ) { // failed }
```

Driving the Browser

The status line is a blurb of text that usually appears somewhere in the viewer's display, indicating a current activity. An applet can request that some text be placed in the status line with the `showStatus()` method. (The browser isn't required to do anything in response to this call, but most browsers will oblige you.)

An applet can also ask the browser to show a new document. To do this, the applet makes a call to the showDocument(url) method of the `AppletContext`. You can get a reference to the `AppletContext` with the Applet's `getAppletContext()` method. `showDocument()` can take an additional `String` argument to tell the browser where to display the new URL:

```
getAppletContext().showDocument( url, name );
```

The `name` argument can be the name of an existing labeled HTML frame; the document referenced by the URL will be displayed in that frame. You can use this method to create an applet that "drives" the browser to new locations dynamically, but stays active on the screen in a separate frame. If the named frame doesn't exist, the browser will create a new top-level window to hold it. Alternatively, `name` can have one of the following special values:

_self	Show in the current Frame
_parent	Show in the parent of our Frame
_top	Show in outer-most (top level) frame.
_blank	Show in a new top level browser window.

Both `showStatus()` and `showDocument()` requests may be ignored by a cold-hearted viewer or Web browser.

```
    *** Missing Discussion of getApplet() ***
    *** Add a blurb about the upcoming InfoBus stuff ***
```

Applets vs. Standalone Applications

```
    *** Discuss getImage() and image loading from JAR files for applications ***
```

The following list summarizes the methods of the applet API:

```
// from the AppletStub
boolean isActive();
```

```
URL getDocumentBase();
URL getCodeBase();
String getParameter(String name);
AppletContext getAppletContext();
void appletResize(int width, int height);
// from the AppletContext
AudioClip getAudioClip(URL url);
Image getImage(URL url);
Applet getApplet(String name);
Enumeration getApplets();
void showDocument(URL url);
public void showDocument(URL url, String target);
void showStatus(String status);
```

These are the methods that are provided by the applet viewer environment. If your applet doesn't happen to use any of them, or if you can provide alternatives to handle special cases (such as loading images from JAR files), your applet could be made able to function as a standalone application as well as an applet. For example, our `HelloWeb` applet from Chapter 2, *A First Applet* was very simple. We can easily give it a `main()` method to allow it to be run as a standalone application:

```
public class HelloWeb extends Applet {

    public void paint( java.awt.Graphics gc ) {
        gc.drawString( "Hello Web!", 125, 95 );
    }

    public static void main( String [] args ) {
        Frame theFrame = new Frame();
        Applet helloWeb = new HelloWeb();
        theFrame.add("Center", helloWeb);
        theFrame.setSize(200,200);
        helloWeb.init();
        helloWeb.start();
        theFrame.show();
    }
}
```

Here we get to play "appletviewer" for a change. We have created an instance of `HelloWeb` using its constructor - something we don't normally do$mdash;and added it to our own `Frame`. We call its `init()` method to give the applet a chance to wake up and then call its `start()` method. In this example, `HelloWeb` doesn't implement these, `init()` and `start()`, so we're calling methods inherited from the `Applet` class. This is the procedure that an appletviewer would use to run an applet. (If we wanted to go further, we could implement our own `AppletContext` and `AppletStub`, and set them in the `Applet` before startup).

Trying to make your applets into applications as well often doesn't make sense, and is not always trivial. We show this only to get you thinking about the real differences between applets and applications. It is probably best to stay within the applet API until you have a need to go outside it. Remember that trusted applets can do almost all of the things that applications can. It is probably wiser to make an applet that requires trusted permissions than an application.

Events

We've spent a lot of time discussing the different kinds of objects in AWT--components, containers, and a few special containers like applets. But we've neglected communications between different objects. A few times, we've mentioned events, and we have even used them in the occasional program (like our applets in Chapter 2, *A First Applet*), but we have deferred a discussion of events until later. Now is the time to pay that debt.

AWT objects communicate by sending events. The way we talk about "firing" events and "handling" them makes it sound as if they are part of some special Java language feature. But they aren't. An event is simply an ordinary Java object that is delivered to its receiver by invoking an ordinary Java method. Everything else, however interesting, is purely convention. The entire Java event mechanism is really just a set of conventions for the kinds of descriptive objects that should be delivered; these conventions prescribe when, how, and to whom events should be delivered.

Events are sent from a single source object to one or more listeners (or "targets"). A listener implements specific event handling methods that enable it to receive a type of event. It then registers itself with a source of that kind of event. Sometimes there may be an "adapter" object interposed between the event source and the listener, but there is always a connection established before any events are delivered.

An event object is a subclass of `java.util.EventObject` that holds information about "something that's happened" to its source. The `EventObject` class serves mainly to identify event objects; the only information it contains is a reference to the event source (the object that sent the event). Components do not normally send or receive `EventObject`s as such; they work with subclasses that provide more specific information. `AWTEvent` is a subclass of `EventObject` that is used within AWT; further subclasses of `AWTEvent` provide information about specific event types.

For example, events of type `ActionEvent` are fired by buttons when they are pushed. `ActionEvent`s are also sent when a menu item is selected or when a user presses ENTER in a `TextField`. Similarly, `MouseEvent`s are generated when you operate your mouse within a component's area. You can gather the general meaning of these two events from their names; they are relatively self-descriptive. `ActionEvent`s correspond to a decisive "action" that a user has taken with the component--like pressing a button, or pressing ENTER to indicate that he has filled in a text field. An `ActionEvent` thus carries the name of an action to be performed (the "action command") by the program. `MouseEvent`s describe the state of the mouse, and therefore carry information like the x and y coordinates and the state of your mouse buttons at the time it was created. You might hear someone say that `ActionEvent` is at a "higher semantic level" than `MouseEvent`. This means that `ActionEvent` is an interpretation of something that happened and is, therefore, conceptually more powerful than the `MouseEvent`, which carries raw data. An `ActionEvent` lets us know that a component has done its job, while a `MouseEvent` simply confers a lot of information about the mouse at a given time. You could figure out that somebody clicked on a `Button` by examining mouse events, but it is simpler to work with action events. The precise meaning of an event, however, can depend on the context in which it is received. (More on that in a moment.)

Event Receivers and Listener Interfaces

An event is delivered by passing it as an argument to an event handler method in the receiving object. `ActionEvent`s, for example, are always delivered to a method called `actionPerformed()` in the receiver:

```
// Receiver
public void actionPerformed( ActionEvent e ) {
    ...
}
```

For each type of event, there is a corresponding listener interface that describes the methods it must provide to receive those events. In this case, any object that receives `ActionEvent`s must implement the `ActionListener` interface:

```
public interface ActionListener extends java.util.EventListener {
    public void actionPerformed( ActionEvent e );
}
// Reciever implements ActionListener
```

All listener interfaces are subinterfaces of `java.util.EventListener`, but `EventListener` is simply an empty interface. It exists only to help the compiler identify listener interfaces.

Listener interfaces are required for a number of reasons. First, they help to identify objects that are capable of receiving a given type of event. This way we can give the event handler methods friendly, descriptive names and still make it easy for documentation, tools, and humans to recognize them in a class. Next, listener interfaces are useful because there can be several methods specified for an event receiver. For example, the `FocusListener` interface contains two methods:

```
abstract void focusGained( FocusEvent e );
abstract void focusLost( FocusEvent e );
```

Athough these methods both take a `FocusEvent` as an argument, they correspond to different meanings for why the event was fired; in this case, whether the `FocusEvent` means that focus was received or lost. You could figure out what happened by inspecting the event; all `AWTEvent`s contain a constant specifying the event's subtype. By requiring two methods, the `FocusListener` interface saves you the effort: if `focusGained()` is called, you know the event type was `FOCUS_GAINED`. Similarly, the `MouseListener` interface defines five methods for receiving mouse events (and `MouseMotionListener` defines two more), each of which gives you some additional information about why the event occurred. In general, the listener interfaces group sets of related event handler methods; the method called in any given situation provides a context for the information in the event object.

There can be more than one listener interface for dealing with a particular kind of event. For example, the `MouseListener` interface describes methods for receiving `MouseEvent`s when the mouse enters or exits an area, or a mouse button is pressed or released. `MouseMotionListener` is an entirely separate interface that describes methods to get mouse events when the mouse is moved (no buttons pressed) or dragged (buttons pressed). By separating mouse events into these two categories, Java lets you be a little more selective about the circumstances under which you want to recieve `MouseEvent`s. You can register as a listener for mouse events without receiving mouse motion events; since mouse motion events are extremely common, you don't want to handle them if you don't need to.

Finally, we should point out two simple patterns in the naming of AWT event listener interfaces and handler methods:

- Event handler methods are public methods that return type `void` and take a single event object (a subclass of `java.util.EventObject` as an argument).[2]

[2] This rule is not complete. The full Java Beans allows event handler methods to take additional arguments when absolutely necessary and also to throw checked exceptions.

- Listener interfaces are subclasses of `java.util.EventListener` that are named with the suffix "Listener," e.g., FooListener.

These may seem pretty obvious, but they are important because they are our first hint of a *design pattern* governing how to build components that work with events.

Event Sources

The previous section described the machinery that an event receiver uses to accept events. In this section we'll describe how the receiver tells an event source to start sending it events as they occur.

To receive events, an eligible listener must register itself with an event source. It does this by calling an "add listener" method in the event source, and passing a reference (a callback) to itself. For example, the AWT `Button` class is a source of `ActionEvent`s. In order to receive these events, our code might do something like the following:

```
// source of ActionEvents
Button theButton = new Button("Belly");

// receiver of ActionEvents
class TheReceiver implements ActionListener {
   setupReceiver() {
      ...
      theButton.addActionListener( this );
   }
   public void actionPerformed( ActionEvent e ) {
      // Belly Button pushed...
   }
```

The receiver makes a call to `addActionListener()` to complete its setup and become eligible to receive `ActionEvent`s from the button when they occur. It passes the reference `this`, to add itself as the `ActionListener`.

To manage its listeners, an `ActionEvent` source (like the `Button`) always implements two methods:

```
// ActionEvent source
public void addActionListener(ActionListener listener) {
   ...
}
public void removeActionListener(ActionListener listener) {
   ...
}
```

The `removeActionListener()` method complements `addActionListener()` and does what you'd expect: it removes the listener from the list so that it will not receive future events from that source.

Now, you may be expecting an "event source" interface listing these two methods, but there isn't one. There are no event source interfaces in the current conventions. If you are analyzing a class and trying to determine what events it generates, you have to look for the add and remove methods. For example, the presence of the addActionListener() and removeActionListener() methods define the object as a source of ActionEvents. If you happen to be a human being, you can simply look at the documentation; but if the documentation isn't available, or if you're writing a program that needs to analyze a class (a process called "reflection"), you can look for this design pattern:

- A source of events for the FooListener interface must implement a pair of add/remove methods:
    - addFooListener(FooListener listener) (*)
    - removeFooListener(FooListener listener)
- If an event source can only support one event listener (unicast delivery), the add listener method can throw the checked exception java.util.TooManyListenersException.

So, what do all the naming patterns up to this point accomplish? Well, for one thing they make it possible for automated tools and integrated development environments to divine what are sources and what are sinks of particular events. Tools that work with Java Beans will use the Java reflection and introspection APIs to search for these kinds of design patterns and identify the events that can be fired and received by a component.

It also means that event hookups are strongly typed, just like the rest of Java. So, it's not easy to accidentally hook up the wrong kind of components; for example, you can't register to receive ItemEvents from a Button, because a button doesn't have an addItemListener() method. Java knows at compile time what types of events can be delivered to whom.

Event Delivery

AWT events are multicast; every event is associated with a single source, but can be delivered to any number of receivers. Events are registered and distributed using an observer/observable model. When an event listener registers itself with an event source, the event source adds the listener to a list. When an event is fired, it is delivered individually to each listener on the list.

Figure 10.9: Event delivery

There are no guarantees about the order in which events will be delivered. Neither are there any guarantees if you register yourself more than once with an event source; you may get the event more than once, or not. Similarly, you should assume that every listener receives the same event data. Events are "immutable"; they can't be changed by their listeners. There's one important exception to this rule, which we'll discuss later.

To be complete we could say that event delivery is synchronous with respect to the event source, but that follows from the fact that the event delivery is really just the invocation of a normal Java method. The source of the event calls the handler method of each listener. However, listeners shouldn't assume that all of the events will be sent in the same thread. An event source could decide to sent out events to all of the listeners in parallel.

How exactly an event source maintains its set of listeners, constructs, and fires the events is up to it. Often it is sufficient to use a `Vector` to hold the list. We'll show the code for a component that uses a custom event in Chapter 11, *Using and Creating GUI Components*. For efficiency, AWT components all use the `java.awt.AWTEventMulticaster` object, which maintains a linked tree of the listeners for the component. You can use that too, if you are firing standard AWT events. We'll describe the event multicaster in Chapter 11, *Using and Creating GUI Components* as well.

AWTEvents

All of the events used by AWT GUI components are subclasses of `java.awt.AWTEvent`. `AWTEvent` holds some common information that is used by AWT to identify and process events. You can use or subclass any of the `AWTEvent` types for use in your own components.

```
Use the event hierarchy from Java in a Nutshell or AWT Reference.
```

`ComponentEvent` is the base class for events that can be fired by any AWT component. This includes events that provide notification when a component changes its dimensions or visibility, as well as the other event types for mouse operation and key presses. `ContainerEvent`s are fired by AWT containers when components are added or removed.

java.awt.event.InputEvent

`MouseEvent`s, which track the state of the mouse, and `KeyEvent`s, which are fired when the user uses the keyboard, are types of `java.awt.event.InputEvent`. Input events from the mouse and keyboard are a little bit special. They are normally produced by the native Java machinery associated with the peers. When the user touches a key or moves the mouse within a component's area, the events are generated with that component as the source.

Input events and some other AWT events are placed on a special event queue that is managed by the AWT Toolkit. This gives the Toolkit control over how the events are delivered. First, under some circumstances, the Toolkit can decide to "compress" a sequence of the same type of event into a single event. This is done to make some event types more efficient--in particular, mouse events and some special internal events used to control repainting. Perhaps more important to us, input events are delivered with a special arrangement that lets listeners decide if the component itself should act on the event.

Consuming events

Normally, the native peer of a standard AWT component operates by receiving `InputEvent`s telling it about the mouse and keyboard. When you push a `Button`, the native `ButtonPeer` object receives a `MouseEvent` and does its job in native land to accomplish the button-depressing behavior. But for `InputEvent`s, the Toolkit first delivers the event to any listeners registered with the the component and gives those listeners a chance to mark the event as "consumed," effectively telling the peer to ignore it. An `InputEvent` is marked "consumed" by calling the `consume()` method. (Yes, this is a case where an event is not treated as immutable.)

So, we could stop our `Button` from working by registering a listener with it that catches "mouse button depressed" events. When it got one, we could call its `consume()` method to tell the `ButtonPeer` to ignore that event. This is particularly useful if you happen to be building a develoment environment in Java and you want to "turn off" components while the user arranges them.

If you need to, in a trusted application you can get access to the AWT event queue. The Toolkit uses an instance of `java.awt.EventQueue`. With it you can peek at pending AWT events or even to push in new ones.

Mouse and Key Modifiers on InputEvents

`InputEvent`s come with a set of flags for special modifiers. These let you detect if the SHIFT or ALT key was held down during a mouse button or key press, or if the second or third mouse buttons were pressed. The following are the flag values contained in `java.awt.event.InputEvent`:

- SHIFT_MASK
- CTRL_MASK
- META_MASK
- ALT_MASK
- BUTTON1_MASK
- BUTTON2_MASK
- BUTTON3_MASK

To check for these masks, you can simply do a boolean AND of the modifiers, returned by the `InputEvent`'s `getModifiers()` method and the flag or flags you're interested in:

```
public void mousePressed (MouseEvent e) {
    int mods = e.getModifiers();
    if ((mods & InputEvent.SHIFT_MASK) != 0)
        // Shifted Mouse Button press
}
```

In the list you'll notice there are three BUTTON flags. These can be used to detect if a particular mouse button was used in a mouse press on a two or three button mouse. Be warned, if you use these you run the risk that your program won't work on platforms without multibutton mice. Currently, BUTTON2_MASK is equivalent to ALT_MASK, and BUTTON3_MASK is equivalent to META_MASK. This means that pushing the second mouse button is equivalent to pressing the first (or only) button with the ALT key depressed, and the third button is equivalent to the first with the META key depressed. However, if you really want to guarantee portability, you should limit yourself to a single button, possibly in combination with keyboard modifiers, rather than relying on the button masks.

Key events provide one other situation in which events aren't immutable. You can change the character that the user typed by calling `setKeyChar()`, `setKeyCode()`, or `setKeyModifiers()`. A user's keystroke isn't displayed until the `KeyEvent` is delivered to the peer. Therefore, by changing the character in the `KeyEvent`, you can change the character displayed on the screen. This is a good way to implement a field that only displays uppercase characters, regardless of what the user types.

AWT Event Reference

The following tables summarize the AWT Events, which components fire them, and the methods of the listener interfaces that receive them:

AWT Component and Container Events

Event	**Fired by**	**Listener interface(s)**	**Handler Method(s)**

ComponentEvent	*All Components (*)*	ComponentListener	componentResized()
			componentMoved()
			componentShown()
			componentHidden()

FocusEvent		FocusListener	focusGained()
			focusLost()

KeyEvent		KeyListener	keyTyped()
			keyPressed()
			keyReleased()

MouseEvent		MouseListener	mouseClicked()
			mousePressed()
			mouseReleased()
			mouseEntered()
			mouseExited()

		MouseMotionListener	mouseDragged()
			mouseMoved()

ContainerEvent	*All Containers*	ContainerListener	componentAdded()
			componentRemoved()

Component specific AWT Events

Event	**Fired by**	**Listener interface(s)**	**Handler Method(s)**
ActionEvent	TextField MenuItem List Button	ActionListener	actionPerformed()

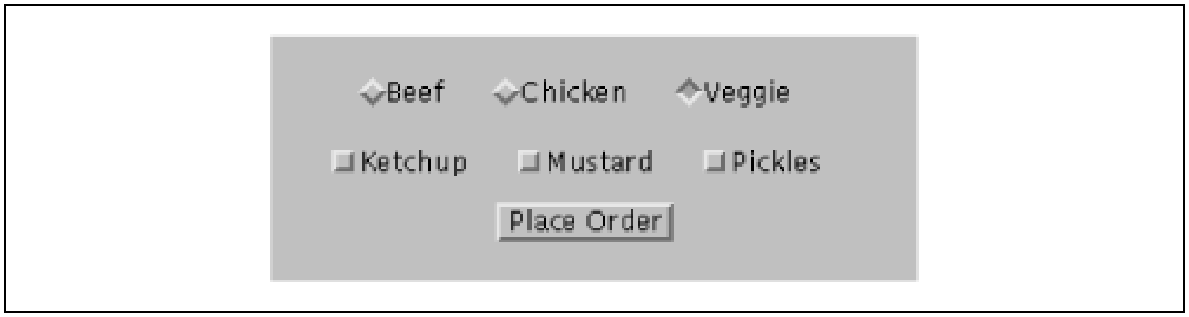
ItemEvent	List Checkbox Choice CheckboxMenuItem	ItemListener	itemStateChanged()
AdjustmentEvent	ScrollPane Scrollbar	AdjustmentListener	adjustmentValueChanged()
TextEvent	TextArea TextField	TextListener	textValueChanged()

WindowEvent	Frame, Dialog	WindowListener	windowOpened()
			windowClosing()
			windowClosed()
			windowIconified()
			windowDeiconified()
			windowActivated()
			windowDeactivated()

Adapter Classes

It's not ideal to have your application components implement a listener interface and receive events directly. Sometimes it's not even possible. Being an event receiver forces you to modify or subclass your objects to implement the appropriate event listener interfaces and add the code necessary to handle the events. A more subtle issue is that, since we are talking about AWT events here, you are, of necessity, building GUI logic into parts of your application that shouldn't have to know anything about the GUI. Let's look at an example:

Figure 10.10: Implementing the ActionListener interface



In Figure 10.10 we have drawn the plans for our Vegomatic food processor. Here we have made our Vegomatic object implement the `ActionListener` interface so that it can receive events directly from the three `Button` components: "Chop," "Puree," and "Frappe." The problem is that our Vegomatic object now has to know more than how to mangle food. It also has to be aware that it will be driven by three controls, specifically buttons that send action commands, and be aware of which methods in itself it should invoke for those commands. Our boxes labeling the GUI and Application code overlap in an unwholesome way. If the marketing people should later want to add or remove buttons, or perhaps just change the names, we have to be careful. We may have to modify the logic in our Vegomatic Object. All is not well.

An alternative is to place an "adapter" class between our event source and receiver. An adapter is a simple object whose sole purpose is to map an incoming event to an outgoing method.

Figure 10.11: A design using adapter classes

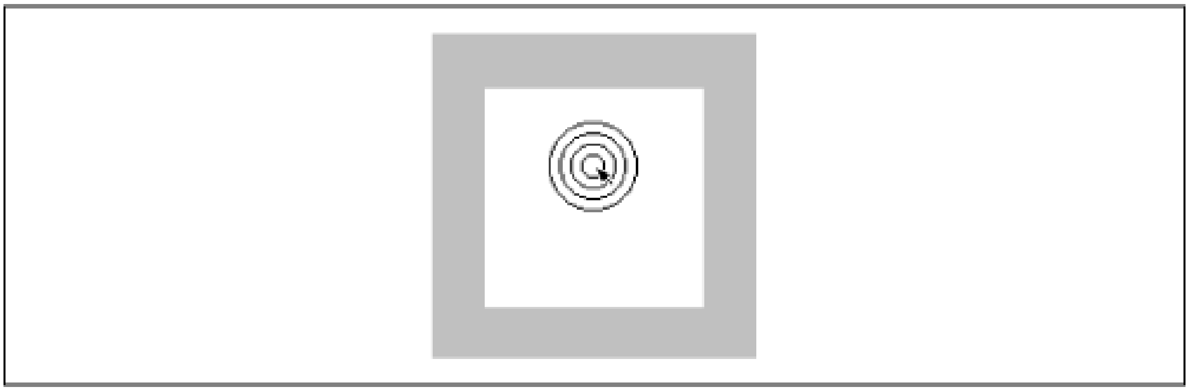


Figure 10.11 shows a better design that uses three adapter classes, one for each button. The implementation of the first adapter might look like:

```
class VegomaticAdapter1 implements actionListener {
    Vegotmatic vegomatic;
    VegomaticAdapter1 ( Vegotmatic vegomatic ) {
        this.vegomatic = vegomatic;
    }
    public void actionPerformed( ActionEvent e ) {
        vegomatic.chopFood();
    }
}
```

So somewhere in the code where we build our GUI, we could register our listener like so:

```
// building GUI for our Vegomatic
Vegomatic theVegomatic = ...;
Button chopButton = ...;
// make the hookup
chopButton.addActionListener( new VegomaticAdapter1(theVegomatic) );
```

We have completely separated the messiness of our GUI from the application code. However, we have added three new classes to our application, none of which does very much. Is that good? That depends on your vantage point.

Under different circumstances our buttons may have been able to share a common adapter class that was simply instantiated with different parameters. There are various trade-off that can be made between size, efficiency, and elegance of code. Often, adapter classes will be generated automatically by development tools. The way we have named our adapter classes "VegomaticAdapter1," "VegomaticAdapter2," and "VegomaticAdapter3" hints at this. More often, when hand coding, you'll use an inner class. At the other extreme, we can forsake Java's strong typing and use the reflection API to create a completely dynamic hookup betwen an event source and listener.

AWT Dummy Adapters

Many listener interfaces contain more than one event handler method. Unfortunately, this means that to register yourself as interested in any one of those events, you must implement the whole listener interface. And to accomplish this you might find yourself typing in dummy "stubbed out" methods, simply to complete the interface. There is really nothing wrong with this, but it is a bit tedious. To save you some trouble, AWT provides some helper classes that implement these dummy methods for you. For each listener interface containing more than one method there is an adapter class containing the stubbed methods. The adapter class serves as a base class for your own adapters. So, when you need a class to patch together your event source and listener, you can simply subclass the adapter and override only the methods you want.

For example, the `MouseAdapter` class implements the `MouseListener` interface and provides the following implementation:

```
public void mouseClicked(MouseEvent e) {};
public void mousePressed(MouseEvent e) {};
public void mouseReleased(MouseEvent e) {};
public void mouseEntered(MouseEvent e) {};
public void mouseExited(MouseEvent e) {};
```

This may not look like a tremendous time saver, and you're right. It's simply a bit of sugar. The primary advantage comes into play when we use the `MouseAdapter` as the base for your own adapter in an anonymous inner class. For example, suppose we want to catch a `mousePressed()` event in some component and blow up a building. We can use the following to make the hookup:

```
someComponent.addMouseListener( new MouseAdapter() {
    public void MousePressed(MouseEvent e) {
        building.blowUp();
    }
} );
```

We've taken artistic liberties with the formatting, but I think it's very readable, and I like it. It's a common enough activity that it's nice to avoid typing those extra few lines and perhaps stave off the onset of carpal tunnel syndrome for a few more hours. Remember that any time you use an inner class, the compiler is generating a class for you, so the messiness you've saved in your source still exists in the output classes.

Old Style and New Style Event Processing

Although Java is still a youngster, it has a bit of a legacy. Versions of Java before 1.1 used a different style of event delivery. Back in the old days (a few months ago) event types were limited and events were only delivered to the `Component` that generated it, or one of its parent containers. The old style component event handler methods (now deprecated) returned a boolean value declaring whether or not they had "handled" the event.

```
boolean handleEvent( Event e ) {
    ...
}
```

If the method returns false, the event is automatically redelivered to the component's container to give it a chance. If the container does not handle it, it is passed on to its parent container and so on. In this way, events were propogated up the containment hierarchy until they were either consumed or passed over to the component peer, just as current

InputEvents are ultimately interpreted used the peer if no registered event listeners have consumed them.

Although this style of event delivery was convenient for some simple applications, it is not very flexible. Events could only be handled by components, which meant that you always had to subclass a Component or Container type to handle events. This was a degenerate use of inheritance (bad design) that led to the creation of lots of unnecessary classes.

We could, alternatively, receive the events for many embedded components in a single parent container, but that would often lead to very convoluted logic in the container's event handling methods. It is also very costly to run every single AWT event through a guantlet of (often empty) tests as it traverses its way up the tree of containers. This is why Java now provides the more dynamic and general event source/listener model that we have described in this chapter. The old style events and event handler methods are, however, still with us.

Java is not allowed to simply change and break an established API. Instead, as we described in Chapter 1, *Yet Another Language?*, older ways of doing things are simply "deprecated" in favor of the new ones. This means that code using the old style event handler methods will still work; you may see old-style code around for a long time. The problem with relying on old-style event delivery, however, is that the old and new ways of doing things cannot be mixed.

By default, Java is obligated to perform the old behavior--offering events to the component and each of its parent containers. However, Java turns off the old style delivery whenever it thinks that we have elected to use the new style. Java determines whether a Component should recieve old style or new style events based on whether any event listeners are registered, or whether new style events have been explicitly enabled. When an AWT event listener is registered with a Component, new style events are implicitly turned on (a flag is set). Additionally, a mask is set telling the component the types of AWT events it should process. The mask allows components to be more selective about which events they process.

processEvent()

When new style events are enabled, all events are first routed to the dispatchEvent() method of the Component class. The dispatchEvent() method examines the component's event mask and decides whether the event should be processed or ignored. Events that have been "enabled" are sent to the processEvent() method, which simply looks at the event's type and delegates it to a "helper" processing method named for its type. The helper processing method finally dispatches the event to the set of registered listeners for its type.

This process closely parallels the way in which old style events are processed, and the way in which events are first directed to a single handleEvent() method that dispatches them to more specific handler methods in the Component class. The differences are that new style events are not delivered unless someone is listening for them, and the listener registration mechanism means that we don't have to subclass the component in order to override its event handler methods and insert our own code.

Enabling New Style Events Explicitly

Still, if you are subclassing a Component type for other reasons, or you really want to process all events in a single method, you should be aware that it is possible to emulate the old style event handling and override your component's event processing methods. You simply have to call the Component's enableEvents() method with the appropriate mask value to turn on processing for the given type of event. You can then override the corresponding method and insert your code. The mask values are found in the java.awt.AWTEvent class:

java.awt.AWTEvent mask	method
COMPONENT_EVENT_MASK	processComponentEvent()
FOCUS_EVENT_MASK	processFocusEvent()
KEY_EVENT_MASK	processKeyEvent()
MOUSE_EVENT_MASK	processMouseEvent()
MOUSE_MOTION_EVENT_MASK	processMouseMotionEvent()

For example:

```
    public void init() {
        ...
        enableEvent( AWTEvent.KEY_EVENT_MASK ):
    }
    public void processKeyEvent(KeyEvent e) {
        if ( e.getID() == KeyEvent.KEY_TYPED )
            // do work
        super.processKeyEvent(e);
    }
```

If you do this it is vital that you remember to make a call to `super.process...Event()` in order to allow normal event delegation to continue. Of course, by emulating old-style event handling, we're giving up the virtues of the new style; in particular, this code is a lot less flexible than the code we could write with the new event model. As we've seen, the user interface is hopelessly tangled with the actual work your program does. A compromise solution would be to have your subclass declare that it implements the appropriate listener interface and register itself, as we have done in the simpler examples in this book:

```
class MyApplet implements KeyListener ...

    public void init() {
        addKeyListener( this ):
        ...
    }
    public void keyTyped(KeyEvent e) {
        // do work
    }
```

11.2 Text Components

AWT gives us two basic text components: TextArea is a multiline text editor with vertical and horizontal scrollbars; TextField is a simple, single-line text editor. Both TextField and TextArea derive from the TextComponent class, which provides the functionality they have in common. This includes methods for setting and retrieving the displayed text, specifying whether the text is "editable" or read-only, manipulating the caret (cursor) position in the display, and manipulating the "selection text."

Both TextAreas and TextFields send TextEvents to listeners when their text is modified. To receive these events, you must implement the java.awt.TextListener interface and register by calling the component's addTextListener() method. In addition, TextField components generate an ActionEvent whenever the user presses the RETURN key within the field. To get these events, implement the ActionListener interface and call addActionListener() to register.

Here are a couple of simple applets that show you how to work with text areas and fields.

A TextEntryBox

Our first example, TextEntryBox, creates a TextArea and ties it to a TextField, as you can see in Figure 11.1.

When the user hits RETURN in the TextField, we receive an ActionEvent and add the line to the TextArea's display.

Try it out. You may have to click your mouse in the TextField to give it focus before typing in it. If you fill up the display with lines, you can test drive the scrollbar.

Figure 11.1: The TextEntryBox applet

[Graphic: Figure 11-1]

```
import java.awt.*;
import java.awt.event.*;
public class TextEntryBox extends java.applet.Applet
implements ActionListener {
    TextArea area;
    TextField field;

    public void init() {
        setLayout( new BorderLayout() );
        add( "Center", area = new TextArea() );
        area.setFont( new Font("TimesRoman",Font.BOLD,18) );
        area.setText("Howdy!\n");
        add( "South", field = new TextField() );
        field.addActionListener ( this );
    }
    public void actionPerformed(ActionEvent e) {
        area.append( field.getText() + '\n' );
        field.setText("");
    }
}
```

`TextEntryBox` is exceedingly simple; we've done a few things to make it more interesting. First, we set the applet's layout manager to `BorderLayout`. We use `BorderLayout` to position the `TextArea` above the `TextField`; the text area goes in the "North" region of the layout, and the text field is in the "South" region. We give the text area a bigger font using `Component`'s `setFont()` method; fonts are discussed in Chapter 11, *Using and Creating GUI Components*. Finally, we want to be notified whenever the user types RETURN in the text field, so we register our applet (`this`) as a listener for action events by calling `field.addActionListener(this)`.

Hitting RETURN in the `TextField` generates an action event, and that's where the fun begins. We handle the event in the `actionPerformed()` method of our container, the `TextEntryBox` applet. Then we use the `getText()` and `setText()` methods to manipulate the text the user has typed. These methods can be used for both `TextField` and `TextArea`, because these components are derived from the `TextComponent` class, and therefore have some common functionality.

Our event handler is called `actionPerformed()`, as required by the `ActionListener` interface. First, `actionPerformed()` calls `field.getText()` to read the text that the user typed into our `TextField`. It then adds this text to the `TextArea` by calling `area.append()`. Finally, we clear the text field by calling `field.setText("")`, preparing it for more input.

By default, `TextField` and `TextArea` are editable; you can type and edit in both text components. They can be changed to output-only areas with the `setEditable()` method. Both text components also support *selections*. A selection is a subset of text that is highlighted for copying and pasting in your windowing system. You select text by dragging the mouse over it; you can then copy and paste it into other text windows. You can get the selected text explicitly with `getSelectedText()`.

TextWatcher Applet

Our next example is a `TextWatcher` that consists of two linked text areas. Anything the user types into either area is reflected in both. It demonstrates how to handle a `TextEvent`, which is generated whenever the text changes in a `TextComponent`. It also demonstrates how to use an adapter class, which is a more realistic way of setting up event listeners. Registering the applet as a listener is okay for simple programs, but the technique shown here will serve you better in more complex situations.

Figure 11.2: The TextWatcher applet

[Graphic: Figure 11-2]

```
import java.awt.*;
import java.awt.event.*;
public class TextWatcher extends java.applet.Applet {
    TextArea area1, area2;

    public void init() {
        setLayout( new GridLayout(2,1) );
        add( area1 = new TextArea() );
        add( area2 = new TextArea() );
        area1.addTextListener ( new TextSyncAdapter( area2 ));
        area2.addTextListener ( new TextSyncAdapter( area1 ));
    }
    class TextSyncAdapter implements TextListener {
        TextArea targetArea;
        TextSyncAdapter( TextArea targetArea ) {
            this.targetArea = targetArea;
        }
        public void textValueChanged(TextEvent e) {
            TextArea sourceArea = (TextArea)e.getSource();
            if ( ! targetArea.getText().equals( sourceArea.getText() ) )
                targetArea.setText( sourceArea.getText() );
        }
    }
}
```

Setting up the display is simple. We use a `GridLayout` and add two text areas to the layout. Then we add our listeners for text events, which are generated whenever the text in a `TextComponent` is changed. There is one listener for each text area; both are `TextSyncAdapter` objects. One listens to events from `area1` and modifies the text in `area2`; the other listens to events from `area2` and modifies the text in `area1`.

All the real work is done by the `TextSyncAdapter`. This is an inner class; its definition is contained within `TextWatcher` and can't be referenced by classes outside of our `TextWatcher`. The adapter implements the `TextListener` interface, and therefore includes a `textValueChanged()` method.

`textValueChanged()` is the heart of the listener. First, it extracts the source area from the incoming event; this is the area that generated the event. The area whose text the listener is changing (the target area) was stored by the constructor. Then it tests whether or not the texts in both areas are the same. If they aren't, it calls the target area's `setText()` method to set its text equal to the source area's.

The one mysterious feature of this method is the test for equality. Why is it necessary? Why can't we just say "the text in one area changed, so set the text in the other?" A `TextEvent` is generated whenever a `TextComponent` is modified for any reason; this includes changes caused by software, not just changes that occur when a user types. So think about what happens when the user types into `area1`. Typing generates a `TextEvent`, which causes the adapter to change the text in `area2`. This generates another `TextEvent`, which if we didn't do any testing, would cause us to change area1 again, which would generate another `TextEvent`, ad infinitum. By checking whether or not the texts in our two areas are equivalent, we prevent an infinite loop in which text events ping-pong back and forth between the two areas.

Managing Text Yourself

Text areas and text fields do the work of handling keystrokes for you, but they're certainly not your only options for dealing with keyboard input. Any `Component` can register `KeyListener`s to recieve `KeyEvent`s that occur when their component has focus Chapter 10, *Understand the Abstract Windowing Toolkit*. We will provide an example here that shows how you might use these to make your own text gadgets.

Figure 11.3: The KeyWatcher applet

[Graphic: Figure 11-3]

```
import java.awt.*;
import java.awt.event.*;
public class KeyWatcher extends java.applet.Applet {
    StringBuffer text = new StringBuffer();
    public void init () {
        setFont( new Font("TimesRoman",Font.BOLD,18) );
        addKeyListener ( new KeyAdapter() {
            public void keyPressed( KeyEvent e ) {
                System.out.println(e);
                type( e.getKeyCode(), e.getKeyChar() );
            }
        } );
        requestFocus();
    }
    public void type(int code, char ch ) {
        switch ( code ) {
            case ( KeyEvent.VK_BACK_SPACE ):
                if (text.length() > 0)
                    text.setLength( text.length() - 1 );
                break;
            case ( KeyEvent.VK_ENTER ):
                    System.out.println( text );  // Process line
                    text.setLength( 0 );
                break;
            default:
                if ( (ch >= ' ') && (ch <= '~') )
                    text.append( ch );
        }
        repaint();
    }

    public void paint(Graphics g) {
        g.drawString(text.toString() + "_", 20, 20);
    }
}
```

Fundamentally, all we are doing is collecting text in a `StringBuffer` and using the `drawString()` method to display it on the screen. As you'd expect, paint() is responsible for managing the display.

In this applet, we're interested in receiving `KeyEvent`s, which occur whenever the user presses any key. To get these events, the applet calls its own `addKeyListener()` method. The `KeyListener` itself is an anonymous class. It doesn't have a name and can't be used anywhere else. We create this class by getting a new `KeyAdapter()`, and overriding its `keyPressed()` method. (Remember that `KeyAdapter` contains do-nothing implementations of the methods in the `KeyListener` interface.) All `keyPressed()` does is call our private method type(), with two arguments: the key code of the key that was pressed, and the logical character represented by the keystroke.

`type()` shows you how to deal with keystrokes. Each key event is identified with a code, which identifies the actual key typed, and a character, which identifies what the user meant to type. This sounds confusing, but it isn't. Basically, there is a constant for each key on the keyboard: `VK_ENTER` for the ENTER (return) key, `VK_A` for the letter A, and so on. However, the physical keystroke isn't usually the same as what the user types: the character capital A is made up of two keystrokes, while lower case a is made up of one.

Therefore, you can expect events for both physical keystrokes and typed characters. The `int` constant `VK_UNDEFINED` is used for the physical key code when the event doesn't correspond to a single keystroke. The `char` constant `CHAR_UNDEFINED` indicates that the event corresponds to a physical keystroke, but not a typed character.

The `type()` method is called with both the key constant and the character as arguments. The way we use them is relatively simple and would need more work for an industrial strength program. Simply, if the physical key is `VK_BACK_SPACE`, we delete the last character from the `StringBuffer` we're building. If it's `VK_ENTER`, we clear the `StringBuffer`. If the physical key has any other value, we look at the character the user typed. If this is a printable character, we add it to the `StringBuffer`. Anything else we ignore. Once we've handled the event, we call `repaint()` to update the screen. Using key codes to handle operations like "Backspace" or "Enter" is easier and less bug-prone than working with odd "Control" characters.

A final note on our anonymous adapter class: in essence our adapter is letting us write a "callback," by calling `type()` whenever `keyPressed()` is called. That's one important use for adapters: to map methods in the various listener interfaces into the methods that make sense for your class. Unlike C or C++, Java won't let us pass a method pointer as an argument, but it will let us create an anonymous class that calls our method and passes an instance of that class.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

11.3 Lists

A List is a step up on the evolutionary chain. Lists let the user choose from a group of alternatives. They can be configured to force the user to choose a single selection or to allow multiple choices. Usually, only a small group of choices are displayed at a time; a built-in scrollbar lets you move to the choices that aren't visible.

A List generates two kinds of events. If the user single clicks on a selection, the List generates an ItemEvent. If the user double-clicks, a List generates an ActionEvent. Therefore, a List can register both ItemListeners and ActionListeners. In either case, the listener can use the event to figure out what the user selected.

The applet below, SearchableListApplet, contains a List and a text field. Several of the items in the list aren't visible, because the list is too long for the space we've allotted for it (enough to display three items). When you type the name of an item into the text field, the applet displays the item you want and selects it. Of course, you could do this with a scrollbar, but then we wouldn't have the opportunity to demonstrate how to work with lists.

Figure 11.4: The SearchableList applet

[Graphic: Figure 11-4]

```
import java.awt.*;
import java.awt.event.*;
public class SearchableListApplet extends java.applet.Applet {
    public void init() {
        String [] items = { "One", "Two", "Three", "Four", "Five", "Six" };
        add( new SearchableList( items ) );
    }
}
class SearchableList extends Container implements ActionListener {
    List list;
    TextField field;
    SearchableList( String [] items ) {
        list = new List( 3 );  // Let some scroll for this example
        for(int i=0; i< items.length; i++)
            list.addItem( items[i] );
        field = new TextField();
        field.addActionListener( this );
        setLayout( new BorderLayout() );
        add("Center", list);
        add("South", field);
    }
    public void actionPerformed( ActionEvent e ) {
        String search = field.getText();
        for (int i=0; i< list.getItemCount(); i++)
            if ( list.getItem( i ).equals( search ) ) {
                list.select( i );
                list.makeVisible( i );  // Scroll it into view
                break;
            }
        field.setText(""); // clear the text field
    }
}
```

We create the `List` and the `TextField` in a new class, `SearchableList`; the applet itself only displays the `SearchableList`. `SearchableList` itself is a new kind of animal; it is a lightweight component that subclasses `Container` directly. We'll talk a little more about lightweight components later in the chapter.

In the constructor for `SearchableList`, we create our `List` by calling its constructor, setting it to display at most three components. We then call the `addItem()` method to add the possible selections to the list; these are the numbers "One" through "Six," passed to us in an array.

We then create our `TextField`, and register ourselves (i.e., the `SearchableList`) as an `ActionListener` for the field's events. Finally, we set the layout for `SearchableList` to a border layout, put the `List` in the center of the layout, and the `TextField` at the bottom.

The actionPerformed() method is called whenever the user presses RETURN in our TextField. In this method, we call getText() to extract the text the user typed. Then we loop through all the items in the list to see if there's a match. getItemCount() tells us the number of items in the list; getItem() gives us the text associated with any particular item. When we find a match, we call select() to make the matching item the selected item, and we call makeVisible() to make sure that this item is displayed.

By default, a List only allows a single selection. We've done nothing in this example to allow multiple selections, so whenever a user chooses an item, the previous selection is automatically dropped. If you want a list that supports multiple selections, call setMultipleMode(true). In this case, you must use the deselect() method to clear the user's selections.

11.4 Menus and Choices

A Menu is a standard, pull-down menu with a fixed name. Menus can hold other menus as submenu items, letting you implement complex menu structures. Menus come with several restrictions; they must be attached to a menu bar, and the menu bar can be attached only to a Frame (or another menu). You can't stick a Menu at an arbitrary position within a container. A top-level Menu has a name that is always visible in the menu bar. (An important exception to these rules is the PopupMenu, which we'll describe in the next section.)

A Choice is an item that lets you choose from a selection of alternatives. If this sounds like a menu, you're right. Choices are free-spirited relatives of menus. A Choice item can be positioned anywhere, in any kind of container. It looks something like a button, with the current selection as its label. When you press the mouse button on a choice, it unfurls to show possible selections.

Both menus and choices send action events when an item is selected. We'll create a little example that illustrates choices and menus and demonstrates how to work with the events they generate. Since a Menu has to be placed in the menu bar of a Frame, we'll take this opportunity to show off a Frame object as well. DinnerMenu pops up a window containing a **Food** choice and a menu of **Utensils**, as shown in Figure 11.2. DinnerMenu prints a message for each selection; choosing **Quit** from the menu removes the window. Give it a try.

Figure 11.5: The DinnerMenu applet

[Graphic: Figure 11-5]

```
import java.awt.*;
import java.awt.event.*;
import java.util.EventListener;
public class DinnerMenu extends java.applet.Applet {
    public void init() {
        new DinnerFrame().show();
    }
}
class DinnerFrame extends Frame implements ActionListener, ItemListener {
    DinnerFrame() {
        setTitle("Dinner Helper");
        setLayout( new FlowLayout() );
        add( new Label("Food") );
        Choice c = new Choice ();
        c.addItem("Chinese");
        c.addItem("Italian");
        c.addItem("American");
        c.addItemListener( this );
        add( c );
        Menu menu = new Menu("Utensils");
        menu.add( makeMenuItem("Fork") );
        menu.add( makeMenuItem("Knife") );
        menu.add( makeMenuItem("Spoon") );
        Menu subMenu = new Menu("Hybrid");
        subMenu.add( makeMenuItem("Spork") );
        subMenu.add( makeMenuItem("Spife") );
        subMenu.add( makeMenuItem("Knork") );
        menu.add( subMenu);
        menu.add( makeMenuItem("Quit") );
        MenuBar menuBar = new MenuBar();
        menuBar.add(menu);
        setMenuBar(menuBar);
        pack();
    }
    public void itemStateChanged(ItemEvent e) {
        System.out.println( "Choice set to: " + e.getItem() );
    }
    public void actionPerformed(ActionEvent e) {
        String command = e.getActionCommand();
        if ( command.equals( "Quit" ) )
            dispose();
        else
            System.out.println( "Menu selected: " + e.getActionCommand() );
    }
    private MenuItem makeMenuItem( String name ) {
        MenuItem m = new MenuItem( name );
        m.addActionListener( this );
        return m;
    }
}
```

Yes, I know. **Quit** doesn't belong in the **Utensils** menu. If it's driving you crazy, you can go back and add a **File** menu as an exercise when we're through.

So what do we have? Well, we've created a new kind of component called `DinnerFrame` that implements our palette of dinner options. We do our set-up work in the `DinnerFrame` constructor. `DinnerFrame` sets the name on its titlebar with `setTitle()`. The constructor also handles a few other miscellaneous details, such as setting the layout manager that places things side by side in the display area and later, resizing itself by calling `pack()`.

We make an instance of `Choice` and add three options to it with its `addItem()` method. `Choice` options are simple `String` objects. When one is picked, we get an action event with an argument that specifies the selected option name. We can also examine the currently selected item at any time with the `Choice`'s `getSelectedItem()` method. A `Choice` generates an `ItemEvent` when a user makes a selection, so we register the `DinnerFrame` as an `ItemEvent` listener by calling `addItemListener()`. (This means we must also implement the `ItemListener` interface and provide an `itemStateChanged()` method.) As with any component, we display the `Choice` by adding it to our applet's layout with `add()`.

The `Menu` has a few more moving parts. A `Menu` holds `MenuItem` objects. A simple `MenuItem` just has a `String` as a label. It sends this as an argument in an action event when it's selected. We can set its font with `setFont()`. We can also turn it on or off with `setEnabled()`; this method controls whether the `MenuItem` is available or not. A `Menu` object is itself a kind of `MenuItem`, and this allows us to use a menu as a submenu in another menu.

We construct the `Menu` with its name and call its `add()` method to give it three new `MenuItem` objects. To create the menu items, we call our own `makeMenuItem()` helper method. Next, we repeat this process to make a new `Menu` object, `subMenu`, and add it as the fourth option. Its name appears as the menu item along with a little arrow, indicating it's a submenu. When it's selected, the `subMenu` menu pops up to the side and we can select from it. Finally, we add one last simple menu item, to serve as a **Quit** option.

We use a private method, `makeMenuItem()`, to create our menu items for us. This method is convenient because, with menus, every item generates its own events. Therefore, we must register an `ActionListener` for every selection on the menu. Rather than write lots of code, we use a helper method to register our `DinnerFrame` (`this`) as the listener for every item. It should be no surprise then, that `DinnerFrame` must implement `ActionListener` and provide an `actionPerformed()` method.

Now we have the menu; to use it, we have to insert it in a menu bar. A `MenuBar` holds `Menu` objects. We create a `MenuBar` and set it as the menu bar for `DinnerFrame` with the `Frame.setMenuBar()` method. We can then add our menu to it with `menuBar.add()`:

```
MenuBar menuBar = new MenuBar();
menuBar.add(menu);
setMenuBar(menuBar);
```

Suppose our applet didn't have its own frame? Where could we put our menu? Ideally, you'd like the applet to be able to add a menu to the top-level menu bar of the Web browser or applet viewer. Unfortunately, as of Java 1.1, there is no standard for doing so. (There are obvious security considerations in allowing an applet to modify its viewer.) There has been talk of adding this ability as part of Java Beans, but so far, it's not possible.

One final note about the `DinnerMenu` example. As we said in the previous chapter, any time you use a `Frame`, and thus create a new top-level window, you should add code to destroy your frame whenever the user closes the window with his native window manager. To do so, you register your frame as a `WindowListener`, implement the `WindowListener` interface, and provide a `windowClosing()` method that calls `dispose()`. By calling `dispose()`, we indicate the window is no longer needed, so that it can release its window-system resources.

11.5 PopupMenus

One of the new components in Java 1.1 is the `PopupMenu`: a menu that automatically appears when you press the appropriate mouse button inside of a component. Which button you press depends on the platform you're using; fortunately you don't have to care.

The care and feeding of a `PopupMenu` is basically the same as any other menu. You use a different constructor (`PopupMenu()`) to create it, but otherwise, you build a menu and add elements to it the same way. The big difference is that you don't need to attach it to a `MenuBar`, and consequently don't need to worry about putting the `MenuBar` in a `Frame`. Instead, you call `add()` to add the `PopupMenu` to any component.

The `PopupColorMenu` applet contains three buttons. You can use a `PopupMenu` to set the color of each button or the applet itself, depending on where you press the mouse. (Setting the color of the applet also sets the buttons' colors). Figure 11.3 shows the applet in action; the user is preparing to change the color of the right-most button.

Figure 11.6: The PopupColorMenu Applet

[Graphic: Figure 11-6]

```
import java.awt.*;
import java.awt.event.*;
public class PopUpColorMenu extends java.applet.Applet
```

```
implements ActionListener {
    PopupMenu colorMenu;
    Component selectedComponent;
    public void init() {
        add( new Button("One") );
        add( new Button("Two") );
        add( new Button("Three") );

        colorMenu = new PopupMenu("Color");
        colorMenu.add( makeMenuItem("Red") );
        colorMenu.add( makeMenuItem("Green") );
        colorMenu.add( makeMenuItem("Blue") );
        addMouseListener( new MouseAdapter() {
            public void mousePressed(MouseEvent e) {
                if ( e.isPopupTrigger() ) {
                    selectedComponent = getComponentAt( e.getX(), e.getY() );
                    colorMenu.show(e.getComponent(), e.getX(), e.getY());
                }
            }
        } );
        add(colorMenu);
    }
    public void actionPerformed(ActionEvent e) {
        String color = e.getActionCommand();
        if ( color.equals("Red") )
            selectedComponent.setBackground( Color.red );
        else if ( color.equals("Green") )
            selectedComponent.setBackground( Color.green );
        else if ( color.equals("Blue") )
            selectedComponent.setBackground( Color.blue );
    }
    private MenuItem makeMenuItem(String label) {
        MenuItem item = new MenuItem(label);
        item.addActionListener( this );
        return item;
    }
}
```

Because the popup menu is triggered by mouse events, we need to register a `MouseListener`. In our call to `addMouseListener()`, we create an anonymous inner class based on the `MouseAdapter`. In this class, we override the `mousePressed()` method to display the popup menu when we get an appropriate event. How do we know what an "appropriate event" is? Fortunately, we don't need to worry about the specifics of our user's platform; we just need to call the event's `isPopupTrigger()` method. If this method returns `true`, we know the user has done whatever normally displays a popup menu on his system.

Once we know that the user wants to raise a popup menu, we figure out which component the mouse is over by calling `getComponentAt()`, with the coordinates of the mouse click (given by `e.getX()` and `e.getY()`).

Then we display the popup menu by calling its `show()` method, again with the mouse coordinates as arguments.

If we wanted to provide different menus for different types of components or the background, we could add a test within the check for the popup trigger:

```
if ( e.isPopupTrigger() ) {
    selectedComponent = getComponentAt( e.getX(), e.getY() );

    if ( selectedComponent instanceof Button )
         colorMenu.show(e.getComponent(),
                        e.getX(), e.getY());
    else if ( selectedComponent instanceof Applet )
            // show a menu for the background
    else if ( selectedComponent instanceof someOtherComponent )
            // show another menu
}
```

The only thing left is to handle the action events from the popup menu items. As in our earlier example, we use a helper method called `makeMenuItem()` to register the applet as an action listener for every item we add. The applet implements `ActionListener` and has the required `actionPerformed()` method. This method reads the action command from the event, which is equal to the selected menu item's label by default. It then sets the background color of the selected component appropriately.

11.6 Checkboxes and CheckboxGroups

A `Checkbox` is a labeled toggle button. A group of such toggle buttons can be made mutually exclusive by tethering them together with a `CheckboxGroup` object. By now you're probably well into the swing of things and could easily master the `Checkbox` on your own. We'll throw out an example to illustrate a different way of dealing with the state of components and to show off a few more things about containers.

A `Checkbox` sends item events when it's pushed, just like a `List`, a `Menu`, or a `Choice`. In our last example, we caught the action events from our choice and menu selections and worked with them when they happened. For something like a checkbox, we might want to be lazy and check on the state of the buttons only at some later time, such as when the user commits an action. It's like filling out a form; you can change your choices until you submit the form.

The following applet, `DriveThrough`, lets us check off selections on a fast food menu, as shown in Figure 11.4. `DriveThrough` prints the results when we press the **Place Order** button. Therefore, we can ignore all the item events generated by our checkboxes and listen only for the action events generated by the button.

Figure 11.7: The DriveThrough applet

[Graphic: Figure 11-7]

```
import java.awt.*;
import java.awt.event.*;
public class OrderForm extends java.applet.Applet implements ActionListener {
    Panel condimentsPanel = new Panel();
    CheckboxGroup entreeGroup = new CheckboxGroup();
    public void init() {
        condimentsPanel.add( new Checkbox("Ketchup"));
        condimentsPanel.add( new Checkbox("Mustard"));
        condimentsPanel.add( new Checkbox("Pickles"));
        Checkbox c;
        Panel entreePanel = new Panel();
        entreePanel.add( c = new Checkbox("Beef") );
        c.setCheckboxGroup( entreeGroup );
        entreePanel.add( c = new Checkbox("Chicken") );
        c.setCheckboxGroup( entreeGroup );
        entreePanel.add( c = new Checkbox("Veggie") );
        c.setCheckboxGroup( entreeGroup );
        entreeGroup.setCurrent( c );
        Panel orderPanel = new Panel();
        Button orderButton = new Button("Place Order");
        orderButton.addActionListener( this );
        orderPanel.add( orderButton );
        setLayout( new GridLayout(3, 1) );
        add( entreePanel );
        add( condimentsPanel );
        add( orderPanel );
    }
    public void actionPerformed(ActionEvent e) {
        takeOrder();
    }
    void takeOrder() {
        Checkbox c = entreeGroup.getCurrent();
            System.out.println( c.getLabel() + " sandwich" );
        Component [] components = condimentsPanel.getComponents();
        for (int i=0; i< components.length; i++)
            if ( (c = (Checkbox)components[i]).getState() )
                System.out.println( "With " + c.getLabel() );
        System.out.println("Thank you, drive through...");
    }
}
```

DriveThrough lays out two panels, each containing three checkboxes. The checkboxes in the entreePanel are tied together through a single CheckboxGroup object. We call their setCheckboxGroup() methods to put them in a single CheckboxGroup that makes the checkboxes mutually exclusive. The CheckboxGroup object is an odd animal. One expects it to be a container or a component, but it isn't; it's simply a helper object that coordinates the functionality of the Checkbox objects. Because a CheckboxGroup isn't a container, it doesn't have an add() method. To put a checkbox into a group, you call the setCheckboxGroup() method of the Checkbox class.

Once a set of checkboxes have been placed in a checkbox group, only one of the boxes may be checked at a time. In this applet, the checkbox group forces you to choose a beef, chicken, or veggie entree, but not more than one.

The condiment choices, however, aren't in a checkbox group, so you can request ketchup, mustard, and pickles on your chicken sandwich.

When the **Place Order** button is pushed, we receive an `ActionEvent` via our `actionPerformed()` method. At this point, we gather the information in the checkboxes and print it. `actionPerformed()` simply calls our `takeOrder()` method, which reads the checkboxes. We could have saved references to the checkboxes in a number of ways; this example demonstrates two. First, we find out which entree was selected. To do so, we call the `CheckboxGroup`'s `getCurrent()` method. `getCurrent()` returns the selected `Checkbox`; we use `getLabel()` to extract the entree's name.

To find out which condiments were selected, we use a more complicated procedure. The problem is that condiments aren't mutually exclusive, so we don't have the convenience of a `CheckboxGroup`. Instead, we ask the condiments `Panel` for a list of its components. The `getComponent()` method returns an array of references to the container's child components. We'll use this to loop over the components and print the results. We cast each element of the array back to `Checkbox` and call its `getState()` method to see if the checkbox is on or off. Remember that if we were dealing with different types of components, we could determine what kind of component we had with the `instanceof` operator.

11.7 ScrollPane and Scrollbars

One of the big advantages of Java 1.1 is the addition of a ScrollPane container. Previously, unless you were working with a text component, you had to manage scrolling yourself. It wasn't terribly difficult, but it was a pain: you had to create Scrollbar objects, attach them to whatever you were scrolling, and redisplay everything with new positions whenever the user made an adjustment. ScrollPane does it all for you. About the only time you absolutely need a Scrollbar is when you want to create a "volume control-type" object. For example, you might want to create a paint mixer that blended different amounts of red, blue, and green, depending on some scrollbar settings.

The unifying theme behind both ScrollPane and Scrollbar is the Adjustable interface, which defines the responsibilities of scrollable objects. An object that implements Adjustable lets you modify an integer value through some fixed range. When a user changes the value, the object generates an AdjustmentEvent; as you might expect, to get an AdjustmentEvent, you must implement AdjustmentListener and register by calling addAdjustmentListener(). Scrollbars implement Adjustable, and a ScrollPane can return Adjustable objects for each of its scrollbars.[2]

In this section, we'll demonstrate both the ScrollPane and Scrollbar classes. We'll start with a ScrollPane.

Working With A ScrollPane

Technically, a ScrollPane is a Container, but it's a funny one. It has its own layout manager, which can't be changed. It can only accomodate one component at a time. This seems like a big limitation, but it isn't. If you want to put a lot of stuff in a ScrollPane, just put your components into a Panel, with whatever layout manager you like, and put that panel into the ScrollPane.

When you create a ScrollPane, you can specify the conditions under which its srollbars will be displayed. This is called the scrollbar display policy; you can specify the policy by using one of the three constants below as an argument to the ScrollPane constructor.

SCROLLBARS_AS_NEEDED

> Only displays scrollbars if the object in the ScrollPane doesn't fit.

> [2] There may be a bug in the Adjustable objects you get from a ScrollPane. Although you can read their settings, you can't change them; methods like setMinimum() and setMaximum() (which should set the object's minimum and maximum values) throw an AWTError.

SCROLLBARS_ALWAYS

Always displays scrollbars, regardless of the object's size.

SCROLLBARS_NEVER

Never displays scrollbars, even if the object is too big. If you use this policy, you should provide some other way for the user to manipulate the ScrollPane.

By default, the policy is SCROLLBARS_AS_NEEDED.

Here's an applet that uses a ScrollPane to display a large image. As you'll see, the applet itself is very simple; all we do is get the image, set the applet's layout manager, create a ScrollPane, put the image in our pane, and add the ScrollPane to the applet. To make the program slightly cleaner, we create an ImageComponent component to hold the image, rather than placing the image directly into the ScrollPane. Here's the applet itself:

```
import java.awt.*;
public class ScrollPaneApplet extends java.applet.Applet {
    public void init() {
        Image image = getImage( getClass().getResource(getParameter("image")) );
        setLayout(  new BorderLayout() );
        ScrollPane scrollPane = new ScrollPane();
        scrollPane.add( new ImageComponent(image) );
        add( "Center", scrollPane );
    }
}
```

And here's the ImageComponent. It waits for the image to load, using a MediaTracker, and sets its size to the size of the image. It also provides a paint() method to draw the image. This takes a single call to drawImage(). The first argument is the image itself; the next two are the coordinates of the image relative to the ImageComponent; and the last is a reference to the ImageComponent itself (this), which serves as an image observer. (We'll discuss image observers in Chapter 14, *Working With Images*; for the time being, take this on faith.)

We also supply an update() method that calls paint(). As we'll see later, the default version of update() automatically clears the screen, which wastes time if we already know that our image will cover the entire screen. Therefore, we override update() so that it doesn't bother clearing the screen first.

Finally, ImageComponent provides a getPreferredSize() method, overriding the method it inherits from Component. This method simply returns the image's size, which is a Dimension object. When you're using a ScrollPane, it's important for the object you're scrolling to provide a reliable indication of its size, particularly if the object is a lightweight component.

```
import java.awt.*;
class ImageComponent extends Component {
    Image image;
    Dimension size;
    ImageComponent ( Image image ) {
        this.image = image;
        MediaTracker mt = new MediaTracker(this);
        mt.addImage( image, 0 );
        try { mt.waitForAll(); } catch (InterruptedException e) { /* error */ };
        size = new Dimension ( image.getWidth(null), image.getHeight(null) );
        setSize( size );
    }
    public void update( Graphics g ) {
        paint(g);
    }
    public void paint( Graphics g ) {
        g.drawImage( image, 0, 0, this );
    }
    public Dimension getPreferredSize() {
        return size;
    }
}
```

Using Scrollbars

Our next example is basically the same as the previous, except that it doesn't use the `ScrollPane`; it implements its own scroller using scrollbars. With Java 1.1, you'd never write code like this, but it does show how much work the `ScrollPane` saves, and also demonstrates how to use scrollbars in other situations.

Figure 11.8: The ComponentScrollerApplet

[Graphic: Figure 11-8]

Our applet is called `ComponentScrollerApplet`; it uses a homegrown scroll pane called `ComponentScroller`. The component that we scroll is the `ImageComponent` we developed in the previous example.

Now let's dive into the code for `ComponentScrollerApplet`:

```
import java.awt.*;
import java.awt.event.*;
public class ComponentScrollerApplet extends java.applet.Applet {
    public void init() {
        Image image = getImage( getClass().getResource(getParameter("image")) );
        ImageComponent canvas = new ImageComponent( image );
        setLayout(  new BorderLayout() );
        add( "Center", new ComponentScroller(canvas) );
    }
}
class ComponentScroller extends Container {
    Scrollbar horizontal, vertical;
    Panel scrollarea = new Panel();
    Component component;
    int orgX, orgY;
    ComponentScroller( Component comp ) {
        scrollarea.setLayout( null );  // We'll handle the layout
        scrollarea.add( component = comp );
        horizontal = new Scrollbar( Scrollbar.HORIZONTAL );
        horizontal.setMaximum( component.getSize().width );
        horizontal.addAdjustmentListener( new AdjustmentListener() {
            public void adjustmentValueChanged(AdjustmentEvent e) {
                component.setLocation( orgX = -e.getValue(), orgY );
            }
        } );
        vertical = new Scrollbar( Scrollbar.VERTICAL );
        vertical.setMaximum( component.getSize().height);
        vertical.addAdjustmentListener( new AdjustmentListener() {
            public void adjustmentValueChanged(AdjustmentEvent e) {
                component.setLocation( orgX, orgY = -e.getValue() );
            }
        } );
        setLayout( new BorderLayout() );
        add( "Center", scrollarea );
        add( "South", horizontal );
        add( "East", vertical );
    }
    public void doLayout() {
        super.doLayout();
        horizontal.setVisibleAmount( scrollarea.getSize().width );
        vertical.setVisibleAmount( scrollarea.getSize().height );
    }
}
```

So, what do our new components do? Let's start at the top and work our way down. The applet itself is very simple; it does all of its work in `init()`. First it sets its layout manager to `BorderLayout`. Then it acquires an `Image` object with a call to `getImage()`. Finally, the applet creates an `ImageComponent` to hold our image, creates a

`ComponentScroller` to hold the `ImageComponent`, and adds the scroller to the "Center" region of the layout. I chose `BorderLayout` because it resizes its central component to fill the entire area available.

Next comes the `ComponentScroller` itself. `ComponentScroller` takes a reference to our `ImageComponent` in its constructor. It adds the component it will be scrolling to a `Panel` with no layout manager. It then creates horizontal and vertical `Scrollbar` objects (`HORIZONTAL` and `VERTICAL` are constants of the `Scrollbar` class, used to specify a scrollbar's direction), sets their maximum values using the height and width of the `Panel`, and registers an `AdjustmentListener` for each scrollbar. The `AdjustmentListener` is an anonymous inner class that implements the `adjustmentValueChanged()` method. This method is called whenever the user moves the scrollbar. It extracts the new scrollbar setting from an `AdjustmentEvent` and uses this to move the component we're scrolling to its new location. We have a separate listener for each scrollbar, so we don't have to figure out which scrollbar generated the event. The listener for the horizontal scrollbar adjusts the component's x coordinate (`orgX`) and leaves its y coordinate unchanged; likewise, the listener for the vertical scrollbar adjusts the component's y coordinate. By adjusting the location of the `ImageComponent`, we control how much of the image is displayed; anything that falls outside of the scroller's `Panel` (`scrollarea`) isn't displayed.

The `ComponentScroller` overrides the `doLayout()` method of the `Container` class. This gives us an opportunity to change the size of the scrollbar "handles" whenever the scroller is resized. To do so, we call `super.doLayout()` first, to make sure that the container gets arranged properly; although we're overriding this method, we need to make sure that it does its work. Then we call the `setVisibleAmount()` method of each scrollbar with the new width and height of the scrolling area.

So in review: we call `setMaximum()` to set the vertical scrollbar's maximum value to the image's height; we call `setVisibleAmount()` to tell the vertical scrollbar how much area we have available; and it sets the size of its "handle" accordingly. For example, if the image is 200 pixels high, and the visible amount is 100 pixels, the scrollbar sets its handle to be roughly half its length. We do similar things to the horizontal scrollbar. As a result, the handles grow or shrink as we change the size of the viewing area and indicate how much of the image is visible.

The `setMaximum()` and `setVisibleAmount()` are both part of the `Adjustable` interface, which scrollbars implement. Other methods of this interface are:

`getOrientation()`	Tells you whether the scrollbar is HORIZONTAL or VERTICAL. There is no `setOrientation()` method in the interface, but the `Scrollbar` class does support `setOrientation()`.
`getVisibleAmount()` and `setVisibleAmount()`	Lets you control the size of the scrollbar's handle (slider). As we saw above, this is a convenient way to give the user a feel for the size of the object you're scrolling.
`getValue()` and `setValue()`	Lets you retrieve or change the scrollbar's current setting.
`getMinimum()` and `setMinimum()`	Lets you control the scrollbar's minimum value.
`getMaximum()` and `setMaximum()`	Lets you control the scrollbar's maximum value.

`getUnitIncrement()` and `setUnitIncrement()`	Lets you control the amount the scrollbar will move if the user clicks on the scrollbar's arrows; in many environments, this means the user wants to move up or down one line.
`getBlockIncrement()` and `setBlockIncrement()`	Lets you control the amount the scrollbar will move if the user clicks between an arrow and the slider; in many environments, this means the user wants to move up or down one page.
`addAdjustmentListener()` and `removeAdjustmentListener()`	Adds or removes listeners for the scrollbar's events.

It's worth asking why we put our image in a `Canvas`, which we then put into a `Panel`, which we put into another `Panel`, which we put into the applet. Surely there's a more efficient way. Yes there is, but we wanted to make as many reusable components as possible. With this design, you can use `ImageComponent` wherever you need to display an image and check that it is loaded first; you can use `ComponentScroller` wherever you need to scroll any kind of component, not just an image or a `Canvas`. Making resuable components is one of the big advantages of object oriented design; it's something you should always keep in mind.

11.8 Dialogs

A `Dialog` is another standard feature of user interfaces. In Java, a `Dialog` is a kind of `Window`, which means that it's really a container into which you put other components. A `Dialog` can be either *modal* or *nonmodal*. A modal dialog seizes the attention of the user by staying in the foreground and grabbing all input until it is satisfied. A non-modal dialog isn't quite so insistent; you're allowed to do other things before dealing with the dialog. `Dialog` objects are useful for pop-up messages and queries or important user-driven decisions.

Most of the components we've seen so far have some special kinds of events associated with them. A `Dialog` doesn't have any special events. Of course, this doesn't mean that a dialog doesn't generate events. Since a dialog is a `Window`, it can generate any event that a `Window` can. However, there aren't any special events, like action events or item events, to worry about. When you're dealing with a `Dialog`, your primary concern will be events generated by the components that you put into the `Dialog`.

We'll do a quick example of a `Dialog` window and then take a look at `FileDialog`, a subclass of `Dialog` that provides an easy-to-use file-selector component. Our example will be a modal dialog that asks a simple question:

A Simple Query Dialog

```
import java.awt.*;
import java.awt.event.*;
class ModalYesNoDialog extends Dialog implements ActionListener {
    private boolean isYes = false;
    ModalYesNoDialog( Frame frame, String question ) {
        super(frame, true /* modal */);
        Label label = new Label(question);
        label.setFont( new Font("Dialog",Font.PLAIN,20) );
        add( "Center", label );
        Panel yn = new Panel();
        Button button = new Button("Yes");
        button.addActionListener( this );
        yn.add( button );
        button = new Button("No");
        button.addActionListener( this );
        yn.add( button );
        add("South", yn);
        pack();
    }
    synchronized public boolean answer() {
        return isYes;
    }
    synchronized public void actionPerformed ( ActionEvent e ) {
        isYes = e.getActionCommand().equals("Yes");
        dispose();
    }
    public static void main(String[] s) {
        Frame f = new Frame();
        f.add( "Center", new Label("I'm the application") );
        f.add( "South", new Button("Can you press me?") );
        f.pack();
        f.show();
        ModalYesNoDialog query = new ModalYesNoDialog( f, "Do you love me?");
        query.show();
        if ( query.answer() == true )
            System.out.println("She loves me...");
        else
            System.out.println("She loves me not...");
    }
}
```

The heart of this example is a class called `ModalYesNoDialog` that implements a simple form with a question and two buttons. To create the `Dialog`, our class's constructor calls its superclass's constructor (`super()`), which is `Dialog()`. When we create the dialog, we must supply a parent `Frame`; we also specify that the `Dialog` is modal.

The rest of the constructor--for that matter, the rest of the class--doesn't have any surprises. We use a `Label` to display the question; we add a pair of buttons, labeled "Yes" and "No," for the user to give his answer. We provide an `answer()` method so we can ask the dialog which button the user pushed; and we provide an `actionPerformed()` method to receive the button events.

The rest of our program is an application that uses the `ModalYesNoDialog`. It creates a `Frame`, creates the `ModalYesNoDialog`, displays the dialog by calling its `show()` method, and reads the answer.

We used an application rather than an applet to demonstrate the `Dialog` because dialogs are somewhat unweildy in applets. You need to have a `Frame` to serve as the dialog's parent, and most applets don't need Frames. However, there's a simple workaround. There's no reason an applet can't use an invisible frame: just create a `Frame`, call its `pack()` method, but never call its `show()` method. The `Frame` won't be displayed, but will be able to serve as the parent to a dialog box.

Now let's talk briefly about nonmodal dialogs. The most obvious change is in the constructor: now you call

```
new Dialog(myFrame, false);
```

But there are a few other issues to think about. Using a nonmodal dialog is slightly more complex because it's asynchronous: the program doesn't wait until the user responds. Therefore, you might want to modify the `answer()` method so that it calls `wait()` to wait until the user replies. The code would look like this:

```
// add a new boolean for the answer() method
private boolean isAnswered = false;
// add a wait() in the answer() method
synchronized public boolean answer() {
    while ( !isAnswered )
        try { wait(); } catch (InterruptedException e) { /* error */ }
    return isYes;
}
```

If you do this, you also need to modify `actionPerformed()` to call `notifyAll()` and terminate the `wait()`:

```
    // add a notify() in the actionPeformed() method
    synchronized public void actionPerformed ( ActionEvent e ) {
        isYes = e.getActionCommand().equals("Yes");
        isAnswered = true;
        notifyAll();
        dispose();
    }
}
```

File Selection Dialog

A `FileDialog` is a standard file-selection box. As with other AWT components, most of `FileDialog` is implemented in the native part of the AWT toolkit, so it looks and acts like a standard file selector on your platform.

Now selecting files all day can be pretty boring without a greater purpose, so we'll exercise the `FileDialog` in a mini-editor application. `Editor` provides a text area in which we can load and work with files. We'll stop just shy of the capability to save and let you fill in the blanks (with a few caveats). The `FileDialog` created by `Editor` is shown in Figure 11.6.

Figure 11.9: A FileDialog

[Graphic: Figure 11-9]

```
import java.awt.*;
import java.awt.event.*;
import java.io.*;
class Editor extends Frame implements ActionListener {
    TextArea textArea = new TextArea();
    Editor() {
        super("Editor");
        setLayout( new BorderLayout() );
        add("Center", textArea);
        Menu menu = new Menu ("File");
        menu.add ( makeMenuItem ("Load") );
        menu.add ( makeMenuItem ("Save") );
        menu.add ( makeMenuItem ("Quit") );
        MenuBar menuBar = new MenuBar();
        menuBar.add ( menu );
        setMenuBar( menuBar );
        pack();
    }
    public void actionPerformed( ActionEvent e ) {
        String command = e.getActionCommand();
        if ( command.equals("Quit") )
            dispose();
        else if ( command.equals("Load") )
            loadFile();
        else if ( command.equals("Save") )
            saveFile();
    }
    private void loadFile () {
        FileDialog fd = new FileDialog( this, "Load File", FileDialog.LOAD );
        fd.show();
        String file = fd.getFile();
        if ( file == null ) // Cancel
            return;
        try {
            FileInputStream fis = new FileInputStream ( fd.getFile() );
            byte [] data = new byte [ fis.available() ];
            fis.read( data );
            textArea.setText( new String( data ) );
        } catch ( IOException e ) {
            textArea.setText( "Could not load file..." );
        }
    }
    private void saveFile() {
        FileDialog fd = new FileDialog( this, "Save File", FileDialog.SAVE );
        fd.show();
        // Save file data...
    }
    private MenuItem makeMenuItem( String name ) {
        MenuItem m = new MenuItem( name );
        m.addActionListener( this );
        return m;
    }
    public static void main(String[] s) {
        new Editor().show();
    }
}
```

`Editor` is a `Frame` that lays itself out with a `TextArea` and a pull-down menu. From the pull-down **File** menu, we can opt to **Load**, **Save**, or **Quit**. The `action()` method catches the events associated with these menu selections and takes the appropriate action.

The interesting parts of `Editor` are the `private` methods `loadFile()` and `saveFile()`. `loadFile()` creates a new `FileDialog` with three parameters: a parent frame (just as in the previous `Dialog` example), a title, and a directive. This parameter should be one of the `FileDialog` class's `static` identifiers `LOAD` or `SAVE`, which tell the dialog whether to load or save a file.

A `FileDialog` does its work when the `show()` method is called. Unlike most components, its `show()` method blocks the caller until it completes its job; the file selector then disappears. After that, we can retrieve the designated filename with the `FileDialog`'s `getFile()` method. In `loadFile()`, we use a fragment of code from Chapter 8, *Input/Output Facilities* to get the contents of the named file. We then add the contents to the `TextArea` with `setText()`. You can use `loadFile()` as a roadmap for the unfinished `saveFile()`

method, but it would be prudent to add the standard safety precautions. For example, you could use the previous `YesNo` example to prompt the user before overwriting an existing file.

11.9 Creating custom components

In the previous sections, we've worked with many different user interface objects, and made a lot of new classes that are sort of like components. Our new classes do one particular thing well; a number of them can be added to applets or other containers just like the standard AWT components; and several of them are lightweight components that use system resources efficiently because they don't rely on a peer.

But these new classes still aren't really components. If you think about it, all our classes have been fairly self-contained; they know everything about what to do, and don't rely on other parts of the program to do much processing. Therefore, they are overly specialized. Our menu example created a `DinnerFrame` class that had a menu of dinner options, but it included all the processing needed to handle the user's selections. If we wanted to process the selections differently, we'd have to modify the class. That's not what we want; we'd like to separate registering the user's choices from processing those choices. In contrast, true components don't do any processing. They let the user take some action, and then inform some other part of the program, which processes the action.

So we need a way for our new classes to communicate with other parts of the program. Since we want our new classes to be components, they should communicate the way components communicate: that is, by generating events and sending those events to listeners. So far, we've written a lot of code that listened for events, but haven't seen any examples that generated events.

Generating events sounds like it ought to be difficult, but it isn't. You can either create new kinds of events, by subclassing `AWTEvent`, or use one of the standard event types. In either case, you need to register listeners for your events, and provide a means to deliver events to your listeners. If you are using the standard events, AWT provides an `AWTEventMulticaster` class that handles most of the machinery. We'll focus on that option in this section; at the end, we'll make some comments on how you might manage events on your own.

The `AWTEventMulticaster` is one of those things that looks a lot more complicated than it is. It is confusing, but most of the confusion occurs because it's hard to believe it's so simple. Its job is to maintain a linked list of event listeners and to propagate events to all the listeners on that linked list. So we can use a multicaster to register (and unregister) event listeners and to send any events we generate to all registered listeners.

The best way to show you how to use the multicaster is through an example. The following example creates a new component called `PictureButton`. `PictureButton` looks at least somewhat button-like and responds to mouse clicks (`MOUSE_RELEASED` events) by generating action events. (Figure 11.7 shows a `PictureButton` in both depressed and raised modes.) The `PictureButtonApplet` is passed the events in its `actionPerformed()` method, just as with any other button, and prints a message each time it's pressed.

Figure 11.10: The PictureButtonApplet

[Graphic: Figure 11-10]

```
import java.awt.*;
import java.awt.event.*;
public class PictureButtonApplet extends java.applet.Applet implements ActionListener
{
    Image image;
    public void init() {
        image = getImage( getClass().getResource(getParameter("image")) );
        PictureButton pictureButton = new PictureButton( image );
        add ( pictureButton );
        pictureButton.setActionCommand("Aaargh!");
        pictureButton.addActionListener( this );
    }

    public void actionPerformed( ActionEvent e ) {
        System.out.println( e );
    }
}
class PictureButton extends Component {
    private Image image;
    boolean pressed = false;
    ActionListener actionListener;
    String actionCommand;
    PictureButton(Image image) {
        this.image = image;
        MediaTracker mt = new MediaTracker(this);
        mt.addImage( image, 0 );
        try { mt.waitForAll(); } catch (InterruptedException e) { /* error */ };
        setSize( image.getWidth(null), image.getHeight(null) );
        enableEvents( AWTEvent.MOUSE_EVENT_MASK );
    }
    public void paint( Graphics g ) {
        g.setColor(Color.white);
        int width = getSize().width, height = getSize().height;
        int offset = pressed ? -2 : 0;  // fake depth
        g.drawImage( image, offset, offset, width, height, this );
        g.draw3DRect(0, 0, width-1, height-1, !pressed);
        g.draw3DRect(1, 1, width-3, height-3, !pressed);
    }
    public Dimension getPreferredSize() {
        return getSize();
    }
    public void processEvent( AWTEvent e ) {
        if ( e.getID() == MouseEvent.MOUSE_PRESSED ) {
            pressed = true;
            repaint();
        } else
        if ( e.getID() == MouseEvent.MOUSE_RELEASED ) {
            pressed = false;
            repaint();
            fireEvent();
        }
        super.processEvent(e);
    }
    public void setActionCommand( String actionCommand ) {
        this.actionCommand = actionCommand;
    }
    public void addActionListener(ActionListener l) {
        actionListener = AWTEventMulticaster.add(actionListener, l);
    }
    public void removeActionListener(ActionListener l) {
        actionListener = AWTEventMulticaster.remove(actionListener, l);
    }
    private void fireEvent() {
        if (actionListener != null) {
            ActionEvent event = new ActionEvent( this,
                                ActionEvent.ACTION_PERFORMED, actionCommand );
            actionListener.actionPerformed( event );
        }
    }
}
```

Before diving into the event multicaster, here are a few notes about the applet and the `PictureButton`. The applet is an `ActionListener` because it is looking for events coming from the button. Therefore it registers itself as a listener and contains an `actionPerformed()` method. The `PictureButton` doesn't have a label, so the applet explicitly sets the button's action command by calling `setActionCommand()`.

The button itself is concerned mostly with being pretty. It uses a media tracker to make sure that the image has loaded before displaying itself. The `paint()` method, which we won't discuss in detail, is devoted to making the button appear "pressed" (i.e., recessed) when the mouse is pressed. The `getPreferredSize()` method lets layout managers size the button appropriately.

Now we'll start with the button's machinery. The button needs to receive mouse events. It could register as a mouse listener, but in this case, it seems more appropriate to override `processEvent()`. `processEvent()` receives all incoming events. It first checks whether we have a `MOUSE_PRESSED` event; if so, it tells the button to repaint itself in its "pressed" mode. If the event is a `MOUSE_RELEASED` event, it tells the button to paint itself in its "unpressed" mode and calls the private `fireEvent()` method, which sends an action event to all listeners. Finally, `processEvent()` calls `super.processEvent()` to make sure normal event processing occurs; this is a good practice whenever you override a method that performs a significant task.

However, `processEvent()` doesn't receive events if they aren't generated; and normally, events aren't generated if there are no listeners. Therefore, the button's constructor calls `enableEvents()` with the argument `MOUSE_EVENT_MASK` to turn on mouse event processing.

Now we're ready to talk about how to generate events. The picture button has `addActionListener()` and `removeActionListener()` methods, for registering listeners. These just call the static methods `add()` and `remove()` of the `AWTEventMulticaster` class. Here's the `addActionListener()` method:

```
public void addActionListener(ActionListener l) {
    actionListener = AWTEventMulticaster.add(actionListener, l);
}
```

If you look back to see how the instance variable `actionListener` is declared, you'll see that it is an `ActionListener`. No big surprise--except that this code doesn't appear to make sense. It's saying "add an action listener to an action listener and store the result back in the original action listener."

There are a couple of tricks here. First, an `AWTEventMulticaster` implements all of the listener interfaces. Therefore, a multicaster can appear wherever an `ActionListener` (or any other listener) is required. In this case, the `actionListener` object will be a multicaster--perhaps not what you expected, and certainly not what's being passed in the argument `l`. Now the code is starting to make sense: earlier, I said that multicasters maintained linked lists of listeners. So this method really adds `l` to the linked list of action listeners that a multicaster is managing, and saved the new list.

But that begs the question: where does the multicaster come from? The linked list has to start somewhere. This is where the second trick comes in. `add()` is a static method, so we don't need a multicaster to call it. But we still need some way to start the linked list. The class's constructor is never called--in fact, it's protected, so you can't call it. The answer lies in the `add()` method, which creates an `AWTEventMulticaster` when you need it--that is, as soon as you add the second listener to the list. The arguments to `add()` may be `null`; one of them probably is `null` when you register your first action listener.

Removing action listeners works the same way. We use the `AWTEventMulticaster`'s `remove()` method. After the last listener is taken off the linked list, `remove()` returns `null`.

With this machinery in place, sending an event to all registered listeners is very simple. You just create an event by calling its constructor, and then call the appropriate method in the listener interface to deliver it. The `AWTEventMulticaster` makes sure that the event gets to all the listeners. In this example, we create an `ActionEvent` and deliver the event to the listeners' `actionPerformed()` methods by calling `actionListener.actionPerformed(event)`.

The code to generate other kinds of events is almost exactly the same. Remember the multicaster implements all the listener interfaces and has overloaded `add()` and `remove()` methods for every standard listener type. Therefore, it can be used for any kind of `AWTEvent`. It shouldn't be hard to adapt this example to other situations.

What if you want to generate your own event type by subclassing `AWTEvent`? To make things concrete, let's say you want to create an `ExplosionEvent` that you generate whenever your monitor catches fire. In this case, you should define your own `ExplosionListener` interface, and (possibly) your own `ExplosionAdapter` class. You can't use the `AWTEventMulticaster` unless your new event is a subclass of a standard event; extending the multicaster to support new event types probably isn't worth the effort. It's easier to write an `addExplosionListener()` method that maintains a `Vector` of listeners and to deliver events by calling the appropriate method of each listener in the `Vector`. We'll demonstrate this approach in the next section, where we implement another new component: a `Dial`.

A Dial Component

```
    Things to mention in widgets Dial event example:
        synchronization issues in add/remove/fire.
        You should sync add/remove... but be wary of syncing fire,
        deadlocks
```

The standard AWT classes don't have a component that's similar to an old fashioned dial--for example, the volume control on your radio. Such a component is something of a rarity; I don't remember seeing one in any application I've used. But there's no reason we can't build one. In this section, we implement a `Dial` class. We also define a new event type, `DialEvent`, and a new listener interface, `DialListener`. The dial can be used just like any other Java component. It is built entirely in Java and, therefore, is a lightweight component; it extends `Component` directly and doesn't have a peer.

By defining a new event type, I'm stretching the point slightly. There's no reason our dial couldn't use the standard `AdjustmentEvent`. However, this gives us a chance to show how to handle event listeners without using the event multicaster. There are many situations in which defining a new event type will be the only appropriate solution.

Figure 11.11 shows what the dial looks like; it is followed by the code.

Figure 11.11: The Dial Applet

[Graphic: Figure 11-11]

```
import java.awt.*;
import java.awt.event.*;
import java.util.*;
public interface DialListener {
    void dialAdjusted( DialEvent e );
}
public class DialEvent extends AWTEvent {
    int value;
    public static final int DIAL_ADJUSTED = RESERVED_ID_MAX + 1;
    DialEvent( Dial source, int id, int value ) {
        super( source, id );
        this.value = value;
    }
    public int getValue() {
        return value;
    }
}
public class Dial extends Component {
    int minValue = 0, value, maxValue = 100, radius;
    Vector dialListeners;
    Dial( int maxValue ) {
        this.maxValue = maxValue;
        enableEvents( AWTEvent.MOUSE_MOTION_EVENT_MASK );
    }
    public void paint( Graphics g ) {
        int tick = 10;
        radius = getSize().width/2 - tick;
        g.drawLine(radius*2+tick/2, radius, radius*2+tick, radius); // the tick
        draw3DCircle( g, 0, 0, radius, true );
        draw3DCircle( g, 1, 1, radius-1, true );
        int knobRadius = radius/7;
        double th = value*(2*Math.PI)/(maxValue-minValue);
        int x = (int)(Math.cos(th)*(radius-knobRadius*3)),
            y = (int)(Math.sin(th)*(radius-knobRadius*3));
        draw3DCircle( g, x+radius-knobRadius, y+radius-knobRadius, knobRadius, false
);
    }
    private void draw3DCircle( Graphics g, int x, int y, int radius, boolean raised )
{
        g.setColor( raised ? Color.white : Color.black );
        g.drawArc( x, y, radius*2, radius*2, 45, 180);
        g.setColor( raised ? Color.black : Color.white);
        g.drawArc( x, y, radius*2, radius*2, 225, 180);
    }
    public void processEvent( AWTEvent e ) {
        if ( e.getID() == MouseEvent.MOUSE_DRAGGED ) {
            int y=((MouseEvent)e).getY();
            int x=((MouseEvent)e).getX();
            double th = Math.atan( (1.0*y-radius)/(x-radius) );
            int value = ( (int)(th/(2*Math.PI) * (maxValue-minValue)) );
            if ( x < radius )
                setValue( value + maxValue/2 );
            else if ( y < radius )
                setValue( value + maxValue );
            else
                setValue( value );
            fireEvent();
        }
        super.processEvent( e );
    }
    public void setValue(int value) {
        this.value = value;
        repaint();
    }
    public int getValue()  { return value; }
    public void setMinimum(int minValue )  { this.minValue = this.minValue; }
    public int getMinimum()  { return minValue; }
    public void setMaximum(int maxValue )  { this.maxValue = maxValue; }
    public int getMaximum()  { return maxValue; }
    public void addDialListener(DialListener listener) {
        if ( dialListeners == null )
            dialListeners = new Vector();
        dialListeners.addElement( listener );
    }
    public void removeDialListener(DialListener listener) {
        if ( dialListeners != null )
            dialListeners.removeElement( listener );
    }
    private void fireEvent() {
        if ( dialListeners == null )
            return;
        DialEvent event = new DialEvent(this, DialEvent.DIAL_ADJUSTED, value);
        for (Enumeration e = dialListeners.elements(); e.hasMoreElements(); )
            ((DialListener)e.nextElement()).dialAdjusted( event );
    }
}
public class DialApplet extends java.applet.Applet
                                implements DialListener, AdjustmentListener {
    final int max = 100;
    Scrollbar scrollbar = new Scrollbar( Scrollbar.HORIZONTAL, 0, 1, 0, max );
    Dial dial = new Dial( max );
    public void init() {
        setLayout( new BorderLayout() );
        dial.addDialListener( this );
        add( "Center", dial );
        scrollbar.addAdjustmentListener( this );
        add( "South", scrollbar );
    }
    public void dialAdjusted( DialEvent e ) {
        scrollbar.setValue( e.getValue() );
    }
    public void adjustmentValueChanged( AdjustmentEvent e ) {
        dial.setValue( e.getValue() );
    }
}
```

Let's start from the top. We'll focus on the event handling and leave you to figure out the trigonometry on your own. The DialListener interface contains a single method, dialAdjusted(), which is called when a DialEvent occurs. The DialEvent itself is simple. It defines a new event ID, DIAL_ADJUSTED, that identifies dial events. This constant is defined so that it won't conflict with the ID numbers reserved for standard AWT events. The event itself only carries one item of data: the dial's new value. It has a single method that returns this value.

The constructor for the Dial class stores the dial's maximum value; its minimum value is 0. It then enables mouse motion events, which the Dial needs to tell how it is being manipulated.

paint(), draw3DCircle(), and processEvent() do a lot of trigonometry to figure out how to display the dial. draw3DCircle() is a private helper method that draws a circle that appears either raised or depressed; we use this to make the dial look three dimensional. processEvent() is called whenever any event occurs within the component's area. We only expect to receive mouse motion events, because these are the only events we enabled. processEvent() first checks the event's ID; if it is MOUSE_DRAGGED, the user has changed the dial's setting. We respond by computing a new value for the dial, repainting the dial in its new position and firing a DialEvent. Any other events (in particular, MOUSE_MOVED) are ignored. However, we call the superclass's processEvent() method to make sure that any other processing needed for this event occurs.

The next group of methods provide ways to retrieve or change the dial's current setting, minimum, and maximum values. They are similar to the methods in the Adjustable interface; you could argue that Dial really ought to implement Adjustable.

Finally, we reach the methods that work with listeners. addDialListener() adds a new listener to a Vector of listeners by calling addElement(). If the vector doesn't already exist, addDialListener() creates it. removeDialListener() simply takes a listener off the list, so that it won't receive any further events. fireEvent() is a private method that creates a DialEvent and sends it to every listener. It does so by converting the Vector into an Enumeration and running through every element in the list by calling nextElement() until hasMoreElements()

returns false. To send the event to a listener, it calls the listener's `dialAdjusted()` method. Note that `nextElement()` returns an `Object`; we must cast this object to `DialListener` before we can deliver the event.

To show how the applet is used, I included a simple applet called `DialApplet`. This applet places a `Dial` and a `Scrollbar` in a border layout. Any change to either the dial or the scrollbar is reflected by the other. The applet implements both `DialListener` and `AdjustmentListener`, and therefore has both `dialAdjusted()` and `adjustmentValueChanged()` methods. Although this isn't necessarily a good argument for creating a new event type, it's worth noticing that the logic of the listener methods is much simpler than it would have been if the dial generated adjustment events.

12.2 GridLayout

`GridLayout` arranges components into regularly spaced rows and columns. The components are arbitrarily resized to fit in the resulting areas; their minimum and preferred sizes are consequently ignored. `GridLayout` is most useful for arranging very regular, identically sized objects and for allocating space for Panels to hold other layouts in each region of the container.

`GridLayout` takes the number of rows and columns in its constructor. If you subsequently give it too many objects to manage, it adds extra columns to make the objects fit. You can also set the number of rows or columns to zero, which means that you don't care how many elements the layout manager packs in that dimension. For example, `GridLayout(2,0)` requests a layout with two rows and an unlimited number of columns; if you put ten components into this layout, you'll get two rows of five columns each.

The following applet sets a `GridLayout` with three rows and two columns as its layout manager; the results are shown in Figure 12.3.

Figure 12.3: A grid layout

[Graphic: Figure 12-3]

```
import java.awt.*;

public class Grid extends java.applet.Applet {
    public void init() {
        setLayout( new GridLayout( 3, 2 ));
        add( new Button("One") );
        add( new Button("Two") );
        add( new Button("Three") );
        add( new Button("Four") );
        add( new Button("Five") );
    }
}
```

The five buttons are laid out, in order, from left to right, top to bottom, with one empty spot.

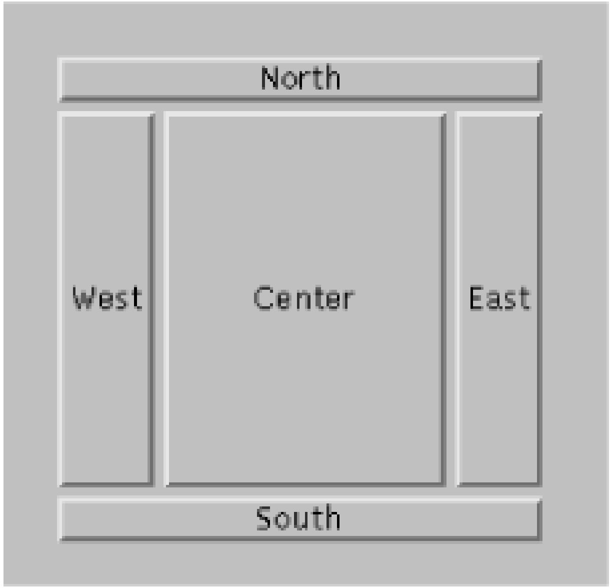
12.3 BorderLayout

`BorderLayout` is a little more interesting. It tries to arrange objects in one of five geographical locations: "North," "South," "East," "West," and "Center," possibly with some padding between. `BorderLayout` is the default layout for `Window` and `Frame` objects. Because each component is associated with a direction, `BorderLayout` can manage at most five components; it squashes or stretches those components to fit its constraints. As we'll see in the second example, this means that you often want to have `BorderLayout` manage sets of components in their own panels.

When we add a component to a border layout, we need to specify both the component and the position at which to add it. To do so, we use an overloaded version of the `add()` method that takes an additional argument as a constraint. This additional argument is passed to the layout manager when the new component is added. In this case it specifies the name of the position for the BorderLayout. Otherwise the `LayoutManager` is not consulted until it's asked to lay out the components.

The following applet sets a `BorderLayout` layout and adds our five buttons again, named for their locations; the result is shown in Figure 12.4.

Figure 12.4: A border layout



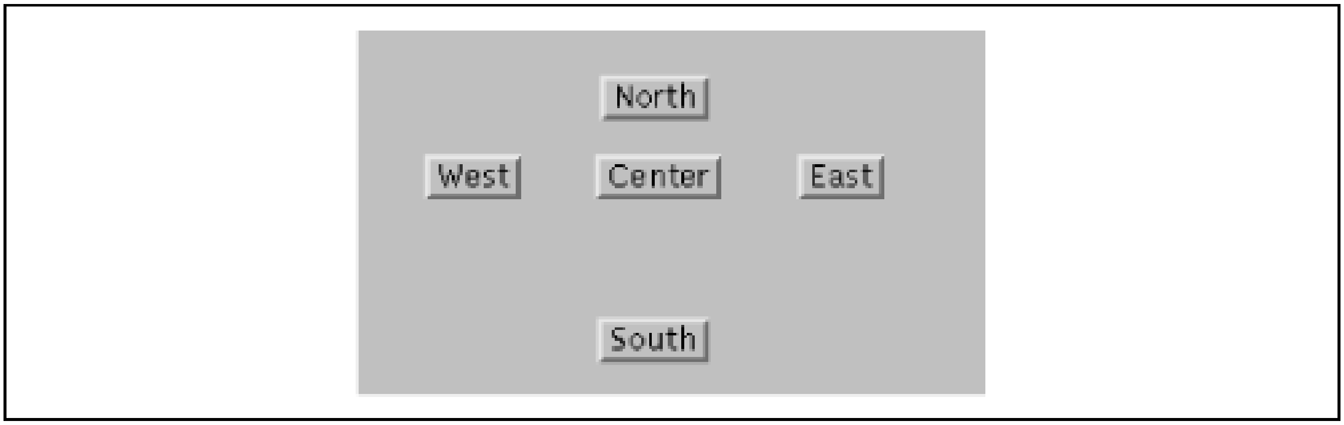
```
import java.awt.*;

public class Border extends java.applet.Applet {
    public void init() {
        setLayout( new java.awt.BorderLayout() );
        add( new Button("North"), "North" );
        add( new Button("East"), "East" );
        add( new Button("South"), "South" );
        add( new Button("West"), "West" );
        add( new Button("Center"), "Center" );
    }
}
```

So, how exactly is the area divided up? Well, the objects at "North" and "South" get their preferred height and are expanded to fill the full area horizontally. "East" and "West" components on the other hand, get their preferred width, and are expanded to fill the remaining area between "North" and "South" vertically. Finally, the "Center" object takes all of the rest of the space. As you can see in Figure 12.5, our buttons get distorted into interesting shapes.

What if we don't want `BorderLayout` messing with the sizes of our components? One option would be to put each button in its own `Panel`. The default layout for a `Panel` is `FlowLayout`, which respects the preferred size of components. The preferred sizes of the panels are effectively the preferred sizes of the buttons, but if the panels are stretched, they won't pull their buttons with them. `Border2` illustrates this approach as shown in Figure 12.5.

Figure 12.5: Another border layout



```
import java.awt.*;

public class Border2 extends java.applet.Applet {
    public void init() {
        setLayout( new BorderLayout() );
        Panel p = new Panel();
        p.add(new Button("East") );
        add( p, "East" );
        p = new Panel();
        p.add(new Button("West") );
        add( p, "West" ;
        p = new Panel();
        p.add(new Button("North") );
        add( p, "North" );
        p = new Panel();
        p.add(new Button("South") );
        add(p, "South" );
        p = new Panel();
        p.add(new Button("Center") );
        add( p, "Center" );
    }
}
```

In this example, we create a number of panels, put our buttons inside the panels, and put the panels into the applet, which has the `BorderLayout` manager. Now, the `Panel` for the "Center" button soaks up the extra space that comes from the `BorderLayout`. Each `Panel`'s `FlowLayout` centers the button in the panel and uses the button's preferred size. In this case, it's all a bit awkward. (This is one of the problems that `getMaximumSize()` will eventually solve.) We'll see how we could accomplish this more directly using `GridBagLayout` shortly.

Finally, this version of the applet has a lot of unused space. If we wanted, we could get rid of the extra space by resizing the applet:

```
setSize( getPreferredSize() );
```

CardLayout

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

12.4 CardLayout

`CardLayout` is a special layout manager for creating the effect of a stack of cards. Instead of arranging all of the container's components, it displays only one at a time. You would use this kind of layout to implement a hypercard stack or a Windows-style set of configuration screens. When you add a component to the layout, you use the two-argument version of `add()`; the extra argument is an arbitrary string that serves as the card's name:

```
add("netconfigscreen", myComponent);
```

To bring a particular card to the top of the stack, call the `CardLayout`'s `show()` method with two arguments: the parent `Container` and the name of the card you want to show. There are also methods like `first()`, `last()`, `next()`, and `previous()` for working with the stack of cards. These methods take a single argument: the parent `Container`. Here's a simple example:

```
import java.awt.*;

public class main extends java.applet.Applet {
    CardLayout cards = new CardLayout();

    public void init() {
        setLayout( cards );
        add( new Button("one"), "one" );
        add( new Button("two"), "two" );
        add( new Button("three"), "three" );
    }

    public boolean action( Event e, Object arg) {
        cards.next( this );
        return true;
    }
}
```

We add three buttons to the layout and cycle through them as they are pressed. In a more realistic example, we would build a group of panels, each of which might implement some part of a complex user interface, and add those panels to the layout. Each panel would have its own layout manager. The panels would be resized to fill the entire area available (i.e., the area of the `Container` they are in), and their individual layout managers would arrange their internal components.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

12.7 Absolute Positioning?

It's possible to set the layout manager to `null`: no layout control. You might do this to position an object on the display at some absolute coordinates. This is almost never the right approach. Components might have different minimum sizes on different platforms, and your interface would not be very portable.

The following applet doesn't use a layout manager and works with absolute coordinates instead:

```
import java.awt.*;

public class MoveButton extends java.applet.Applet {
    Button button = new Button("I Move");

    public void init() {
        setLayout( null );
        add( button );
        button.setSize( button.getPreferredSize() );
        button.move( 20, 20);
    }

    public boolean mouseDown( Event e, int x, int y ) {
        button.move( x, y );
        return ( true );
    }

}
```

Click in the applet area, outside of the button, to move the button to a new location. If you are running the example in an external viewer, try resizing the window and note that the button stays at a fixed position relative to the display origin.

Drawing With the AWT

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

13.2 Colors

The `TestPattern` applet fills its shapes with a number of colors, using the `setColor()` method of the `Graphics` object. `setColor()` sets the current color in the graphics context, so we set it to a different color before each drawing operation. But where do these color values come from?

The `java.awt.Color` class handles color in Java. A `Color` object describes a single color. You can create an arbitrary `Color` by specifying the red, green, and blue values, either as integers between 0 and 255 or as floating-point values between 0.0 and 1.0. You can also use `getColor()` to look up a named color in the system properties table, as described in Chapter 7, *Basic Utility Classes*. `getColor()` takes a `String` color property name, retrieves the integer value from the `Properties` list, and returns the `Color` object that corresponds to that color.

The `Color` class also defines a number of `static final` color values; these are what we used in the `TestPattern` example. These constants, such as `Color.black` and `Color.red`, provide a convenient set of basic colors for your drawings.

Desktop Colors

The `Color` class I just described makes it easy to construct a particular color; however, that's not always what you want to do. Sometimes you want to match a preexisting color scheme. This is particularly important when you are designing a user interface; you might want your components to have the same colors as other components on that platform, and to change automatically if the user redefines his or her color scheme.

That's what the `SystemColor` class is for. A system color represents the color used by the local windowing system in a certain context. The SystemColor class holds lots of pre-defined SystemColors, just like the Color Class holds some pre-defined basic colors. For example, the field `activeCaption` represents the color used for the background to the title of an active window; `activeCaptionText` represents the color used for the title itself. `menu` represents the background color of menu selection; `menuText` represents the color of a menu item's text when it is not selected; `textHighlightText` is the color used when the item is selected; and so on. You could use the `window` value to set the color of a `Window` to match the other Windows on the user's screen--whether or not they're generated by Java programs.

```
myWindow.setBackground( SystemColor.window );
```

Because the `SystemColor` class is a subclass of `Color`, you can use it wherever you would use a `Color`. However, the `SystemColor` constants are tricky. They are constants as far as you, the programmer, are concerned; your code is not allowed to modify them. However, they can be modified at run-time by the Toolkit. If the user changes his color scheme, the system colors are automatically updated to follow suit; as a result, anything displayed with system colors will also change color the next time it is redrawn. For example, the window `myWindow` would automatically change its background color to the new background color.

The `SystemColor` class has one noticeable shortcoming. You can't compare a system color to a `Color` directly; the `Color.equals()` method doesn't return reliable results. For example, if you want to find out whether the window background color is red, you can't call:

```
Color.red.equals(SystemColor.window);
```

Instead, you should use `getRGB()` to find the color components of both objects, and compare them, rather than comparing the objects themselves.

13.3 Fonts

Text fonts in Java are represented by instances of the `java.awt.Font` class. A `Font` object is constructed from a font name, style identifier, and a point size. We can create a `Font` at any time, but it's meaningful only when applied to a particular component on a given display device. Here are a couple of fonts:

```
Font smallFont = new Font("Monospaced", Font.PLAIN, 10);
Font bigFont = new Font("Serif", Font.BOLD, 18);
```

The font name is a symbolic name for the font family. The following font names should be available on all platforms; Figure 13.4 shows what these fonts look like on a typical platform:[2]

> [2] The names `Helvetica`, `TimesRoman`, `Courier`, `Symbol`, and `ZapfDingbats` are supported in Java 1.1 for backwards compatibility, but shouldn't be used; they may be removed in a future version. `Symbols` and `ZapfDingbats`, which used to be available as `Font` names have now taken their proper place as ranges in the Unicode character table: 2200-22ff and 2700-27ff respectively.

Figure 13.4: Font examples

[Graphic: Figure 13-4]

- Serif (generic name for TimesRoman)
- SansSerif (generic name for Helvetica)
- Monospaced (generic name for Courier)
- Dialog

- DialogInput

The font you specify is mapped to an actual font on the local platform. Java's *fonts.properties* files map the font names to the available fonts, covering as much of the Unicode character set as possible. If you request a font that doesn't exist, you get the default font.

You can also use the `static` method `Font.getFont()` to look up a font name in the system properties list. `getFont()` takes a `String` font property name, retrieves the font name from the `Properties` table, and returns the `Font` object that corresponds to that font. You can use this mechanism, as with Colors, to define fonts with properties from outside your application.

The `Font` class defines three `static` style identifiers: `PLAIN`, `BOLD`, and `ITALIC`. You can use these values on all fonts. The point size determines the size of the font on a display. If a given point size isn't available, `Font` substitutes a default size.[3]

> [3] There is no straightforward way to determine if a given `Font` is available at a given point size in the current release of Java. Fonts are one of Java's weak points. Sun has promised better `Font` handling (and perhaps true, portable `Fonts`) in a future release.

You can retrieve information about an existing `Font` with a number of routines. The `getName()`, `getSize()` and `getStyle()` methods retrieve the symbolic name, point size and style, respectively. You can use the getFamily() method to find out the platform specific font family to which the font actually maps.

Finally, to actually use a `Font` object you can simply specify it as an argument to the `setFont()` method of a `Component` or `Graphics` object. Subsequent text-drawing commands like `drawString()` for that component or in that graphics context use the specified font.

Font Metrics

To get detailed size and spacing information for text rendered in a font, we can ask for a `java.awt.FontMetrics` object. Different systems will have different real fonts available; the available fonts may not match the font you request. Thus, a `FontMetrics` object presents information about a particular font on a particular system, not general information about a font. For example, if you ask for the metrics of a nine-point Monospaced font, what you get isn't some abstract truth about Monospaced fonts; you get the metrics of the font that the particular system uses for nine-point Monospaced--which may not be exactly nine point or even Monospaced.

Use the `getFontMetrics()` method for a `Component` to retrieve the `FontMetrics` for a `Font` as it would appear for that component:

```
public void init() {
    ...
    // Get the metrics for a particular font on this component
    FontMetrics smallFont = myLabel.getFontMetrics( smallFont );
    ...
}
```

The `Graphics` object also has a `getFontMetrics()` method that gets the `FontMetrics` information for the current font in the graphics context.

```
public void paint( Graphics g ) {
    // Get the metrics for the current font
    FontMetrics fm = g.getFontMetrics();
   ...
}
```

The following applet, `FontShow`, displays a word and draws reference lines showing certain characteristics of its font, as shown in Figure 13.5. Clicking in the applet toggles the point size between a small and a large value.

Figure 13.5: The FontShow applet

[Graphic: Figure 13-5]

```
import java.awt.*;
import java.awt.event.*;
public class FontShow extends java.applet.Applet {
    static final int LPAD=25;   // Frilly line padding
    boolean bigFont = true;
    public void init() {
        addMouseListener( new MouseAdapter() {
            public void mouseClicked(MouseEvent e) {
                bigFont = !bigFont;
                repaint();
            }
        } );
    }
    public void paint( Graphics g ) {
        String message = getParameter( "word" );
        g.drawRect(0, 0, getSize().width-1, getSize().height-1);
        if ( bigFont )
            g.setFont( new Font("Dialog",Font.PLAIN,24) );
        else
            g.setFont( new Font("Dialog",Font.PLAIN,12) );
        FontMetrics metrics = g.getFontMetrics();
        int fontAscent = metrics.getMaxAscent ();
        int fontDescent = metrics.getMaxDescent();
        int messWidth = metrics.stringWidth ( message );
        // Center text
        int startX = getSize().width/2 - messWidth/2;
        int startY = getSize().height/2 - fontDescent/2 + fontAscent/2;
        g.drawString(message, startX, startY);
        g.setColor( Color.white );  // Base lines
        g.drawLine( startX-LPAD, startY, startX+messWidth+LPAD, startY );
        g.drawLine( startX, startY+ LPAD, startX, startY-fontAscent-LPAD );
        g.setColor( Color.green );  // Ascent line
        g.drawLine( startX-LPAD, startY-fontAscent, startX+messWidth+LPAD, startY-
fontAscent );
        g.setColor( Color.red );    // Descent line
        g.drawLine( startX-LPAD, startY+fontDescent, startX+messWidth+LPAD,
startY+fontDescent );
    }
}
```

Compile `FontShow` and run it with an applet tag like the following:

```
<applet height=200 width=250 code=FontShow>
    <param name="word" value="Lemming">
</applet>
```

The `word` parameter specifies the text to be displayed.

`FontShow` may look a bit complicated, but there's really not much to it. The bulk of the code is in `paint()`, which simply sets the font, draws our word, and adds a few lines to illustrate some of the font's characteristics (metrics). For fun we also catch mouse clicks (in the `mouseClicked()` method) and alternate the font size by setting the `bigFont` variable and repainting.

By default, text is rendered above and to the right of the coordinates specified in the `drawString()` method. If you think of that starting point as the origin of a coordinate system, we'll call the axes the "baselines" of the font. `FontShow` draws these lines in white. The greatest height the characters stretch above the baseline is called the *ascent* and is shown by a green line. Some fonts also have parts of letters that fall below the baseline. The farthest distance any character reaches below the baseline is called the *descent*. `FontShow` illustrates this with a red line.

We ask for the ascent and descent of our font with the `FontMetrics` `getMaxAscent()` and `getMaxDescent()` methods. We also ask for the width of our string (when rendered in this font) with the `stringWidth()` method. We use this information to center the word in the display area. To center the word vertically, we average the influence of the ascent and descent.

Table 13.2 provides a short list of methods that return useful font metrics.

Table 13.2: Font Metric Methods

Method	**Description**
`getFont()`	`Font` object these metrics describe
`getAscent()`	Height above baseline

`getDescent()`	Depth below baseline
`getLeading()`	Standard vertical spacing between lines
`getHeight()`	Total line height (ascent + descent + leading)
`charWidth(char ch)`	Width of a character
`stringWidth(String str)`	Width of a string
`getWidths()`	The widths of the first 256 characters in this font; returns `int[]`
`getMaxAdvance()`	Maximum character width of any character

Leading space is the padding between lines of text. The `getHeight()` method reports the total height of a line of text, including the leading space.

13.5 Drawing Techniques

Having learned to walk, let's try a jog. In this section, we'll look at some techniques for doing fast and flicker-free drawing and painting. If you're interested in animation or smooth updating, you should read on.[4]

> [4] At this point, you still have to build your own animation software. JavaSoft will be releasing an animation package as part of the Java Media APIs.

Drawing operations take time, and time spent drawing leads to delays and imperfect results. Our goal is to minimize the amount of drawing work we do and, as much as possible, to do that work away from the eyes of the user. You'll remember that our `TestPattern` applet had a blinking problem. It blinked because `TestPattern` performs several, large, area-filling operations each time its `paint()` method is called. On a very slow system, you might even be able to see each shape being drawn in succession. `TestPattern` could be easily fixed by drawing into an off-screen buffer and then copying the completed buffer to the display. To see how to eliminate flicker and blinking problems, we'll look at an applet that needs even more help.

`TerribleFlicker` illustrates some of the problems of updating a display. Like many animations, it has two parts: a constant background and a changing object in the foreground. In this case, the background is a checkerboard pattern and the object is a small, scaled image we can drag around on top of it, as shown in Figure 13.6. Our first version of `TerribleFlicker` lives up to its name and does a very poor job of updating.

Figure 13.6: The TerribleFlicker applet

[Graphic: Figure 13-6]

```
import java.awt.*;
import java.awt.event.*;
public class TerribleFlicker extends java.applet.Applet
```

```
                                        implements MouseMotionListener {
    int grid = 10;
    int currentX, currentY;
    Image img;
    int imgWidth = 60, imgHeight = 60;
    public void init() {
        img = getImage( getClass().getResource(getParameter("img")) );
        addMouseMotionListener( this );
    }
    public void mouseDragged( MouseEvent e ) {
        currentX = e.getX(); currentY = e.getY();
        repaint();
    }
    public void mouseMoved( MouseEvent e ) { }; // complete MouseMotionListener
    public void paint( Graphics g ) {
        int w = getSize().width/grid;
        int h = getSize().height/grid;
        boolean black = false;
        for ( int y = 0; y <= grid; y++ )
            for ( int x = 0; x <= grid; x++ ) {
                g.setColor(  (black = !black) ? Color.black : Color.white );
                g.fillRect( x * w, y * h, w, h );
            }
        g.drawImage( img, currentX, currentY, imgWidth, imgHeight, this );
    }
}
```

Try dragging the image; you'll notice both the background and foreground flicker as they are repeatedly redrawn. What is `TerribleFlicker` doing, and what is it doing wrong?

As the mouse is dragged, `TerribleFlicker` keeps track of its position in two instance variables, `currentX` and `currentY`. On each call to `mouseDragged()`, the coordinates are updated, and `repaint()` is called to ask that the display be updated. When `paint()` is called, it looks at some parameters, draws the checkerboard pattern to fill the applet's area, and finally paints a small version of the image at the latest coordinates.

Our first, and biggest, problem is that we are updating, but we have neglected to implement the applet's `update()` method with a good strategy. Because we haven't overridden `update()`, we are getting the default implementation of the `Component` `update()` method, which looks something like this:

```
// Default implementation of applet update
public void update( Graphics g ) {
    setColor ( backgroundColor );
    fillRect( 0, 0, getSize().width, getSize().height );
    paint ( g );
}
```

This method simply clears the display to the background color and calls our `paint()` method. This is almost never the best strategy, but is the only appropriate default for `update()`, which doesn't know how much of the screen we're really going to paint.

Our applet paints its own background, in its entirety, so we can provide a simpler version of `update()` that doesn't bother to clear the display:

```
// add to TerribleFlicker
public void update( Graphics g ) {
    paint( g );
}
```

This applet works better because we have eliminated one large, unnecessary, and (in fact) annoying graphics operation. However, although we have eliminated a `fillRect()` call, we're still doing a lot of wasted drawing. Most of the background stays the same each time it's drawn. You might think of trying to make `paint()` smarter, so that it wouldn't redraw these areas, but remember that `paint()` has to be able to draw the entire scene because it might be called in situations when the display isn't intact. The solution is to have `update()` help out by restricting the area `paint()` can draw.

Clipping

The `setClip()` method of the `Graphics` class restricts the drawing area of a graphics context to a smaller region. A graphics context normally has an effective clipping region that limits drawing to the entire display area of the component. We can specify a smaller clipping region with `setClip()`.

How is the drawing area restricted? Well, foremost, drawing operations that fall outside of the clipping region are not displayed. If a drawing operation overlaps the clipping region, we see only the part that's inside. A second effect is that, in a good implementation, the graphics context can recognize drawing operations that fall completely outside the clipping region and ignore them altogether. Eliminating unnecessary operations can save time if we're doing something complex, like filling a bunch of polygons. This doesn't save the time our application spends calling the drawing methods, but the overhead of calling these kinds of drawing methods is usually negligible compared to the time it takes to execute them. (If we were generating an image pixel by pixel, this would not be the case, as the calculations would be the major time sink, not the drawing.)

So we can save time in our applet by having our update method set a clipping region that results in only the affected portion of the display being redrawn. We can pick the smallest rectangular area that includes both the old image position and the new image position, as shown in Figure 13.7. This is the only portion of the display that really needs to change; everything else stays the same.

Figure 13.7: Determining the clipping region

[Graphic: Figure 13-7]

An arbitrarily smart `update()` could save even more time by redrawing only those regions that have changed. However, the simple clipping strategy we've implemented here can be applied to many kinds of drawing, and gives quite good performance, particularly if the area being changed is small.

One important thing to note is that, in addition to looking at the new position, our updating operation now has to remember the last position at which the image was drawn. Let's fix our applet so it will use a clipping region. To keep this short and emphasize the changes, we'll take some liberties with design and make our next example a subclass of `TerribleFlicker`. Let's call it `ClippedFlicker`:

```
public class ClippedFlicker extends TerribleFlicker {
    int nextX, nextY;

    public void mouseDragged( MouseEvent e ) {
        nextX = e.getX(); nextY = e.getY();
        repaint();
    }
    void clipToAffectedArea( Graphics g, int oldx, int oldy, int newx,
                                    int newy, int width, int height) {
        int x = Math.min( oldx, newx );
        int y = Math.min( oldy, newy );
        int w = ( Math.max( oldx, newx ) + width ) - x;
        int h = ( Math.max( oldy, newy ) + height ) - y;
        g.setClip( x, y, w, h );
    }
    public void update( Graphics g ) {
        int lastX = currentX, lastY = currentY;
        currentX = nextX; currentY = nextY;
        clipToAffectedArea( g, lastX, lastY, currentX, currentY, imgWidth, imgHeight
);
        paint( g );
    }
}
```

You should find that `ClippedFlicker` is significantly faster, though it still flickers. We'll make one more change in the next section to eliminate that.

So, what have we changed? First, we've overridden `mouseDragged()` so that instead of setting the current coordinates of the image, it sets another pair of coordinates called `nextX` and `nextY`. These are the coordinates at which we'll display the image the next time we draw it.

`update()` now has the added responsibility of taking the next position and making it the current position, by setting the `currentX` and `currentY` variables. This effectively decouples `mouseDragged()` from our painting routines. We'll discuss why this is advantageous in a bit. `update()` then uses the current and next coordinates to set a clipping region on the `Graphics` object before handing it off to `paint()`.

We have created a new, `private` method to help it do this. `clipToAffectedArea()` takes as arguments the new and old coordinates and the width and height of the image. It determines the bounding rectangle as shown in Figure 13.6, then calls `setClip()` to set the clipping region. As a result, when `paint()` is called, it draws only the affected area of the screen.

So, what's the deal with `nextX` and `nextY`? By making `update()` keep track of the next, current, and last coordinates separately, we accomplish two things. First, we always have an accurate view of where the last image was drawn and second, we have decoupled where the next image will be drawn from `mouseDragged()`.

It's important to decouple painting from `mouseDragged()` because there isn't necessarily a one-to-one correspondence between calls to `repaint()` and subsequent calls by AWT to our `update()` method. This isn't a defect; it's a feature that allows AWT to schedule and consolidate painting requests. Our concern is that our `paint()` method may be called at arbitrary times while the mouse coordinates are changing. This is not necessarily bad. If we are trying to position our object, we probably don't want the display to be redrawn for every intermediate position of the mouse. It would slow down the dragging unnecessarily.

If we were concerned about getting every single change in the mouse's position, we would have two options. We could either do some work in the `mouseDragged()` method itself, or put our events into some kind of queue. We'll see an example of the first solution in our `DoodlePad` example a bit later. The latter solution would mean circumventing AWT's own event-scheduling capabilities and replacing them with our own, and we don't want to take on that responsibility.

Double Buffering

Now let's get to the most powerful technique in our toolbox: *double buffering*. Double buffering is a technique that fixes our flickering problems completely. It's easy to do and gives us almost flawless updates. We'll combine it with our clipping technique for better performance, but in general you can use double buffering with or without clipping.

Double buffering our display means drawing into an off-screen buffer and then copying our completed work to the display in a single painting operation, as shown in Figure 13.8. It takes the same amount of time to draw a frame, but double buffering instantaneously updates our display when it's ready.

Figure 13.8: Double buffering

[Graphic: Figure 13-8]

We can get this effect by changing just a few lines of our `ClippedFlicker` applet. Modify `update()` to look like the following and add the new `offScreenImage` instance variable as shown:

```
...
public class DoubleBufferedClipped extends ClippedFlicker {
    Image offScreenImage;
    Graphics offScreenGC;
    public void update( Graphics g ) {
        if ( offScreenImage == null ) {
            offScreenImage = createImage( getSize().width, getSize().height );
            offScreenGC = img.getGraphics();
        }
        int lastX = currentX, lastY = currentY;
        currentX = nextX; currentY = nextY;
        clipToAffectedArea( offScreenGC, lastX, lastY, currentX, currentY, imgWidth, 
imgHeight );
        clipToAffectedArea( g, lastX, lastY, currentX, currentY, imgWidth, imgHeight 
);
        paint( offScreenGC );
        g.drawImage(offScreenImage, 0, 0, this);
    }
}
...
```

Now, when you drag the image, you shouldn't see any flickering. The update rate should be about the same as in the previous example (or marginally slower), but the image should move from position to position without noticeable repainting.

So, what have we done this time? Well, the new instance variable, `offScreenImage`, is our off-screen buffer. It is a drawable `Image` object. We can get an off-screen `Image` for a component with the `createImage()` method. `createImage()` is similar to `getImage()`, except that it produces an empty image area of the specified size. We can then use the off-screen image like our standard display area by asking it for a graphics context with the `Image getGraphics()` method. After we've drawn into the off-screen image, we can copy that image back onto the screen with `drawImage()`.

The biggest change to the code is that we now pass `paint()` the graphics context of our off-screen buffer, rather than that of the on-screen display. `paint()` is now drawing on `offScreenImage`; it's our job to copy the image to the display when it's done. This might seem a little suspicious to you, as we are now using `paint()` in two capacities. AWT calls `paint()` whenever it's necessary to repaint our entire applet and passes it an on-screen graphics context. When we update ourselves, however, we call `paint()` to do its work on our off-screen area and then copy that image onto the screen from within `update()`.

Note that we're still clipping. In fact, we're clipping both the on-screen and off-screen buffers. Off-screen clipping has the same benefits we described earlier: AWT should be able to ignore wasted drawing operations. On-screen clipping minimizes the area of the image that gets drawn back to the display. If your display is fast, you might not even notice the savings, but it's an easy optimization, so we'll take advantage of it.

We create the off-screen buffer in `update()` because it's a convenient and safe place to do so. Also, note that our image observer probably won't be called, since `drawImage()` isn't doing anything nasty like scaling, and the image itself is always available.

The `dispose()` method of the `Graphics` class allows us to deallocate a graphics context explicitly when we are through with it. This is simply an optimization. If we were creating new graphics contexts frequently (say, in each paint()), we could give the system help in getting rid of them. This might provide some performance improvement when doing heavy drawing. We could allow garbage collection to reclaim the unused objects; however, the garbage collection process might be hampered if we are doing intense calculations or lots of repainting.

Off-Screen Drawing

In addition to serving as buffers for double buffering, off-screen images are useful for saving complex, hard-to-produce, background information. We'll look at a simple example: the "doodle pad." `DoodlePad` is a simple drawing tool that lets us scribble by dragging the mouse, as shown in Figure 13.9. It draws into an off-screen image; its `paint()` method simply copies the image to the display area.

Figure 13.9: The DoodlePad applet

[Graphic: Figure 13-9]

```
import java.awt.*;
import java.awt.event.*;
public class DoodlePad extends java.applet.Applet implements ActionListener {
    DrawPad dp;
    public void init() {
        setLayout( new BorderLayout() );
        add( "Center", dp = new DrawPad() );
        Panel p = new Panel();
        Button clearButton = new Button("Clear");
        clearButton.addActionListener( this );
        p.add( clearButton );
        add( "South", p );
    }
    public void actionPerformed( ActionEvent e ) {
        dp.clear();
    }
}
class DrawPad extends Canvas {
    Image drawImg;
    Graphics drawGr;
    int xpos, ypos, oxpos, oypos;
    DrawPad() {
        setBackground( Color.white );
        enableEvents( AWTEvent.MOUSE_EVENT_MASK
            | AWTEvent.MOUSE_MOTION_EVENT_MASK );
    }
    public void processEvent( AWTEvent e ) {
        int x = ((MouseEvent)e).getX(), y = ((MouseEvent)e).getY();
        if ( e.getID() == MouseEvent.MOUSE_DRAGGED ) {
            xpos = x; ypos = y;
            if ( drawGr != null )
                drawGr.drawLine( oxpos, oypos, oxpos=xpos, oypos=ypos );
            repaint();
        } else
        if ( e.getID() == MouseEvent.MOUSE_PRESSED ) {
            oxpos = x; oypos = y;
        }
        super.processEvent(e);
    }
    public void update( Graphics g ) {
        paint(g);
    }
    public void paint( Graphics g ) {
        if ( drawImg == null ) {
            drawImg = createImage( getSize().width, getSize().height );
            drawGr = drawImg.getGraphics();
        }
        g.drawImage(drawImg, 0, 0, null);
    }
    public void clear() {
        drawGr.clearRect(0, 0, getSize().width, getSize().height);
        repaint();
    }
}
```

Give it a try. Draw a nice moose, or a sunset. I just drew a lovely cartoon of Bill Gates. If you make a mistake, hit the **Clear** button and start over.

The parts should be familiar by now. We have made a type of `Canvas` called `DrawPad`. The new `DrawPad` component handles mouse events by enabling both simple mouse events (mouse clicks) and mouse motion events (mouse drags), and then overriding the `processEvent()` method to handle these events. By doing so, we are simulating the old (Java 1.0) event handling model; in this situation, it's a little more convenient than implementing all the methods of the `MouseListener` and `MouseMotionListener` interfaces. The `processEvent()` method handles `MOUSE_DRAGGED` movement events by drawing lines into an off-screen image and calling `repaint()` to update the display. `DrawPad`'s `paint()` method simply does a `drawImage()` to copy the off-screen drawing area to the display. In this way, `DrawPad` saves our sketch information.

What is unusual about `DrawPad` is that it does some drawing outside of `paint()` or `update()`. In our clipping example, we talked about decoupling `update()` and `mouseDragged()`; we were willing to discard some mouse movements in order to save some updates. In this case, we want to let the user scribble with the mouse, so we should respond to every mouse movement. Therefore, we do our work in `processEvent()` itself. As a rule, we should be careful about doing heavy work in event handling methods because we don't want to interfere with other tasks the AWT thread is performing. In this case, our line drawing operation should not be a burden, and our primary concern is getting as close a coupling as possible between the mouse movement events and the sketch on the screen.

In addition to drawing a line as the user drags the mouse, the part of `processEvent()` that handles `MOUSE_DRAGGED()` events maintains a set of old coordinates, to be used as a starting point for the next line segment. The part of `processEvent()` that handles `MOUSE_PRESSED` events resets the old coordinates to the current mouse position whenever the user picks up and moves to a new location. Finally, `DrawPad` provides a `clear()` method that clears the off-screen buffer and calls `repaint()` to update the display. The `DoodlePad` applet ties the `clear()` method to an appropriately labeled button through its `actionPerformed()` method.

What if we wanted to do something with the image after the user has finished scribbling on it? Well, as we'll see in the next section, we could get the pixel data for the image from its `ImageProducer` object and work with that. It wouldn't be hard to create a save facility that stores the pixel data and reproduces it later. Think about how you might go about creating a networked "bathroom wall" where people could scribble on your Web pages.

14.2 Working with Audio

So you've read all the material on drawing and image processing, and you're wondering what in the world audio has to do with images. Well, not much actually, except that true multimedia presentations often combine image techniques such as animation with sound. So we're going to spend a few minutes here talking about audio, for lack of a better place to discuss it.

As we write this, the good people at Sun are hard at work developing the API that Java applets will use for playing audio. A future release of Java will undoubtedly have support for real-time and continuous audio streams, sound management, mixing, synchronization, and filtering. Unfortunately, at the moment, we can tell you only about the basics.

`java.applet.AudioClip` defines an interface for objects that can play sound. An object that implements `AudioClip` can be told to `play()` its sound data, `stop()` playing the sound, or `loop()` continually.

An applet can call its `getAudioClip()` method to retrieve sounds over the network. This method takes an absolute or relative URL to specify where the audio file is located. The viewer may take the sound from a cache or retrieve it over the network. The following applet, `NoisyButton`, gives a simple example:

```
import java.awt.*;
import java.awt.event.*;
public class NoisyButton extends java.applet.Applet implements ActionListener {
    java.applet.AudioClip sound;
    public void init() {
        sound = getAudioClip( getClass().getResource(getParameter("sound")) );
        Button button = new Button("Play Sound");
        button.addActionListener( this );
        add ( button );
    }
    public void actionPerformed( ActionEvent e ) {
        if ( sound != null )
            sound.play();
    }
}
```

```
    *** Update description...
```

NoisyButton retrieves an AudioClip from the server; we use getCodeBase() to find out where the applet lives and getParameter() to find the name of the audio file. (The applet tag that displays NoisyButton must include a parameter tag for sound.) Unfortunately, this is about the extent of what we can do with sound right now. If you want to experiment, there are a few additional methods in the sun.audio classes. Stay tuned for a bigger and better audio API as part of the upcoming Java Media package.

1.3 The java.io Package

The `java.io` package contains the classes that handle fundamental input and output operations in Java. Almost all fundamental I/O in Java is based on streams. A stream represents a flow of data, or a channel of communication, with a reading process at one end of the stream and a writing process at the other end, at least conceptually. As of Java 1.1, the `java.io` package is the largest of the fundamental packages. See Chapter 6, *I/O*, for a more in-depth description of the basic I/O capabilities provided by this package.

Java 1.0 supports only byte streams. The `InputStream` class is the superclass of all of the Java 1.0 byte input streams, while `OutputStream` is the superclass of all the byte output streams. A number of other byte stream classes extend the functionality of these basic streams. For example, the `FileInputStream` and `FileOutputStream` classes read from and write to files, respectively, while `DataInputStream` and `DataOutputStream` read and write binary representations of the primitive Java data types. The main problem with these byte streams is that they do not handle the conversion between the Unicode character set used internally by Java and other character sets used when reading or writing data.

As of Java 1.1, `java.io` contains classes that represent character streams. These character stream classes convert other character encodings that appear in I/O streams to and from Unicode characters. The `Reader` class is the superclass of all the Java 1.1 character input streams, while `Writer` is the superclass of all character output streams. Many of the reader and writer classes have analogous behavior to corresponding byte stream classes. For instance, `FileReader` and `FileWriter` are character streams that read from and write to files, respectively.

The `InputStreamReader` and `OutputStreamWriter` classes provide a bridge between byte streams and character streams. If you wrap an `InputStreamReader` around an `InputStream` object, the bytes in the byte stream are read and converted to characters using the character encoding scheme specified by the `InputStreamReader`. Likewise, you can wrap an `OutputStreamWriter` around any `OutputStream` object, which allows you to write characters and have them converted to bytes.

As of Java 1.1, `java.io` also contains classes to support *object serialization*. Object serialization is the ability to write the complete state of an object to an output stream, and then later recreate that object by reading in the serialized state from an input stream. The `ObjectOutputStream` and `ObjectInputStream` classes handle serializing and deserializing objects, respectively. These classes provide basic serialization capabilities for all objects that implement the `Serializable` interface. Chapter 7, *Object Serialization*, provides a more detailed explanation of the new object serialization functionality in Java 1.1.

The `RandomAccessFile` class is the only class in `java.io` that does not use a stream for reading or writing data. As its name implies, `RandomAccessFile` provides nonsequential access to a file, so you can use it to read from or write to specific locations in a file.

The `File` class represents a file on the local filesystem. The class provides methods to identify a file, both in terms of its path and its filename. There are also methods that retrieve information about a file, such as its status as a directory or a file, its length, and its last modification time.

See Chapter 11, *The java.io Package*, for complete reference material on all of the classes in the `java.io` package.

1.6 The java.text Package

The java.text package is new in Java 1.1. It contains classes that support the parsing and formatting of data. These classes also support the internationalization of Java programs. Internationalization refers to the process of making a program flexible enough to run correctly in any locale. An internationalized program must, however, be localized to enable it to run in a particular locale. The internationalization capabilities in Java are quite significant, especially in this age of the global Internet.

Many of the classes in java.text are meant to handle formatting string representations of dates, times, numbers, and messages based on the conventions of a locale. The Format class is the superclass of all of the classes that generate and parse string representations of various types of data.

The DateFormat class formats and parses dates and times according to the customs and language of a particular locale. By the same token, the NumberFormat class formats and parses numbers, including currency values, in a locale-dependent manner. The MessageFormat class creates a textual message from a pattern string, while ChoiceFormat maps numerical ranges to strings. By themselves, these classes do not provide different results for different locales. However, they can be used in conjunction with ResourceBundle objects from java.util that generate locale-specific pattern strings.

The Collator class handles collating strings according to the rules of a particular locale. Different languages have different characters and different rules for sorting those characters; Collator and its subclass, RuleBasedCollator, are designed to take those differences into account when collating strings. In addition, the CollationKey class optimizes the sorting of a large collection of strings.

The BreakIterator class finds various boundaries, such as word boundaries and line boundaries, in textual data. As you might expect, BreakIterator locates these boundaries according to the rules of a particular locale.

See Chapter 16, *The java.text Package*, for complete reference material on all of the classes in the java.text package.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

2.3 String Concatenation

Java's string concatenation operator (`+`) provides special support for the `String` and `StringBuffer` classes. If either operand of the binary `+` operator is a reference to a `String` or `StringBuffer` object, the operator is the string concatenation operator instead of the arithmetic addition operator. The string concatenation operator produces a new `String` object that contains the concatenation of its operands; the characters of the left operand precede the characters of the right operand in the newly created string.

If one of the operands of the `+` operator is a reference to a string object and the other is not, the operator converts the nonstring operand to a string object using the following rules:

- A `null` operand is converted to the string literal `"null"`.
- If the operand is a non-`null` reference to an object that is not a string, the object's `toString()` method is called. The result of the conversion is the value returned by the object's `toString()` method, unless the return value is `null`, in which case the result of the conversion is the string literal `"null"`.
- A `char` operand is converted to a reference to a string object that has a length of one and contains that character.
- An integer operand (other than `char`) is converted to a string object that contains the base 10 string representation of its value. If the value is negative, the string starts with a minus sign; if it is positive there is no sign character. If the value is zero, the result of the conversion is `"0"`. Otherwise, the string representation of the integer does not have any leading zeros.
- If the operand is a floating-point value, the exact string representation depends on the value being converted. If its absolute value is greater than or equal to 10^-3 or less than or equal to 10^7, it is converted to a string with an optional minus sign (if the value is negative) followed by up to eight digits before the decimal point, a decimal point, and the necessary number of digits after the

decimal point (but no trailing zero if there is more than one significant digit). There is always a minimum of one digit after the decimal point.

- Otherwise, the value is converted to a string with an optional minus sign (if the value is negative), followed by a single digit, a decimal point, the necessary number of digits after the decimal point (but no trailing zero if there is more than one significant digit), and the letter `E` followed by a plus or a minus sign and a base 10 exponent of at least one digit. Again, there is always a minimum of one digit after the decimal point.
- The values `NaN`, `NEGATIVE_INFINITY`, `POSITIVE_INFINITY`, `-0.0`, and `+0.0` are represented by the strings `"NaN"`, `"--Infinity"`, `"Infinity"`, `"--0.0"`, and `"0.0"`, respectively.
- A `boolean` operand is converted to either the string literal `"true"` or the string literal `"false"`.

The following is a code example that uses the string concatenation operator:

```
// format seconds into hours, minutes, and seconds
String formatTime(int t) {
    int minutes, seconds;
    seconds = t%60;
    t /= 60;
    minutes = t%60;
    return t/60 + ":" + minutes + ":" + seconds;
}
```

Java uses `StringBuffer` objects to implement string concatenation. Consider the following code:

```
String s, s1, s2;
s = s1 + s2
```

To compute the string concatenation, Java's compiler generates this code:

```
s = new StringBuffer().append(s1).append(s2).toString()
```

3.2 Synchronizing Multiple Threads

The correct behavior of a multithreaded program generally depends on multiple threads cooperating with each other. This often involves threads not doing certain things at the same time or waiting for each other to perform certain tasks. This type of cooperation is called *synchronization*. This section discusses some common strategies for synchronization and how they can be implemented in Java.

The simplest strategy for ensuring that threads are correctly synchronized is to write code that works correctly when executed concurrently by any number of threads. However, this is more easily said than done. Most useful computations involve doing some activity, such as updating an instance variable or updating a display, that must be synchronized in order to happen correctly.

If a method only updates its local variables and calls other methods that only modify their local variables, the method can be invoked by multiple threads without any need for synchronization. `Math.sqrt()` and the `length()` method of the `String` class are examples of such methods.

A method that creates objects and meets the above criterion may not require synchronization. If the constructors invoked by the method do not modify anything but their own local variables and instance variables of the object they are constructing, and they only call methods that do not need to be synchronized, the method itself does not need to be synchronized. An example of such a method is the `substring()` in the `String` class.

Beyond these two simple cases, it is impossible to give an exhaustive list of rules that can tell you whether or not a method needs to be synchronized. You need to consider what the method is doing and think about any ill effects of concurrent execution in order to decide if synchronization is necessary.

Single-Threaded Execution

When more than one thread is trying to update the same data at the same time, the result may be wrong or inconsistent. Consider the following example:

```
class CountIt {
    int i = 0;
    void count() {
        i = i + 1;
    }
}
```

The method `count()` is supposed to increment the variable `i` by one. However, suppose that there are two threads, `A` and `B`, that call `count()` at the same time. In this case, it is possible that `i` could be incremented only once, instead of twice. Say the value of `i` is 7. Thread `A` calls the `count()` method and computes `i+1` as 8. Then thread `B` calls the `count()` method and computes `i+1` as 8 because thread `A` has not yet assigned the new value to `i`. Next, thread `A` assigns the value 8 to the variable `i`. Finally, thread `B` assigns the value 8 to the variable `i`. Thus, even though the `count()` method is called twice, the variable has only been incremented once when the sequence is finished.

Clearly, this code can fail to produce its intended result when it is executed concurrently by more than one thread. A piece of code that can fail to produce its intended result when executed concurrently is called a *critical section*. However, a critical section does behave correctly when it is executed by only one thread at a time. The strategy of single-threaded execution is to allow only one thread to execute a critical section of code at a time. If a thread wants to execute a critical section that another thread is already executing, the thread has to wait until the first thread is done and no other thread is executing that code before it can proceed.

Java provides the `synchronized` statement and the `synchronized` method modifier for implementing single-threaded execution. Before executing the block in a `synchronized` statement, the current thread must obtain a lock for the object referenced by the expression. If a method is declared with the `synchronized` modifer, the current thread must obtain a lock before it can invoke the method. If the method is not declared `static`, the thread must obtain a lock associated with the object used to access the method. If the method is declared `static`, the thread must obtain a lock associated with the class in which the method is declared. Because a thread must obtain a lock before executing a `synchronized` method, Java guarantees that `synchronized` methods are executed one thread at a time.

Modifying the `count()` method to make it a `synchronized` method ensures that it works as intended.

```
class CountIt {
    int i = 0;
    synchronized void count() {
        i = i + 1;
    }
}
```

The strategy of single-threaded execution can also be used when multiple methods update the same data. Consider the following example:

```
class CountIt2 {
    int i = 0;
    void count() {
        i = i + 1;
    }
    void count2() {
        i = i + 2;
    }
}
```

By the same logic used above, if the `count()` and `count2()` methods are executed concurrently, the result could be to increment `i` by 1, 2, or 3. Both the `count()` and `count2()` methods can be declared as `synchronized` to ensure that they are not executed concurrently with themselves or each other:

```
class CountIt2 {
    int i = 0;
    synchronized void count() {
        i = i + 1;
    }
    synchronized void count2() {
        i = i + 2;
    }
}
```

Sometimes it's necessary for a thread to make multiple method calls to manipulate an object without another thread calling that object's methods at the same time.

Consider the following example:

```
System.out.print(new Date());
System.out.print(" : ");
System.out.println(foo());
```

If the code in the example is executed concurrently by multiple threads, the output from the two threads will be interleaved. The `synchronized` keyword provides a way to ensure that only one thread at a time can execute a block of code. Before executing the block in a `synchronized` statement, the current thread must obtain a lock for the object referenced by the expression. The above code can be modified to give a thread exclusive access to the `OutputStream` object referenced by `System.out`:

```
synchronized (System.out) {
    System.out.print(new Date());
    System.out.print(" : ");
    System.out.println(foo());
}
```

Note that this approach only works if other code that wants to call methods in the same object also uses similar `synchronized` statements, or if the methods in question are all `synchronized` methods. In this case, the `print()` and `println()` methods are `synchronized`, so other pieces of code that need to use these methods do not need to use a `synchronized` statement.

Another situation in which simply making a method `synchronized` does not provide the needed single-threaded execution occurs when an inner class is updating fields in its enclosing instance. Consider the following code:

```
public class Z extends Frame {
    int pressCount = 0;
    ...
    private class CountButton extends Button
                              implements ActionListener {
        public void actionPerformed(ActionEvent evt) {
            pressCount ++;
        }
    }
    ...
}
```

If a `Z` object instantiates more than one instance of `CountButton`, you need to use single-threaded execution to ensure that updates to `pressCount` are done correctly. Unfortunately, declaring the `actionPerformed()` method of `CountButton` to be `synchronized` does not accomplish that goal because it only forces the method to acquire a lock on the instance of `CountButton` it is associated with before it executes. The object you need to acquire a lock for is the enclosing instance of `Z`.

One way to have a `CountButton` object capture a lock on its enclosing instance of `Z` is to update `pressCount` inside of a `synchronized` statement:

```
synchronized (Z.this) {
    pressCount ++;
}
```

The drawback to this approach is that every piece of code that accesses `pressCount` in any inner class of Z must be in a similar synchronized statement. Otherwise, it is possible for pressCount to be updated incorrectly. The more pieces of code that need to be inside of synchronized statements, the more places there are to introduce bugs in your program.

A more robust approach is to have the inner class update a field in its enclosing instance by calling a synchronized method in the enclosing instance:

```
public class Z extends Frame {
    int pressCount = 0;
    synchronized incrementPressCount() {
        pressCount++;
    }
    ...
    private class CountButton extends Button
                              implements ActionListener {
        public void actionPerformed(ActionEvent evt) {
            incrementPressCount();
        }
    }
    ...
}
```

Optimistic Single-Threaded Execution

When multiple threads are updating a data structure, single-threaded execution is the obvious strategy to use to ensure correctness of the operations on the data structure. However, single-threaded execution can cause some problems of its own. Consider the following example:

```
public class Queue extends java.util.Vector {
    synchronized public void put(Object obj) {
        addElement(obj);
    }
    synchronized public Object get() throws EmptyQueueException {
        if (size() == 0)
            throw new EmptyQueueException();
        Object obj = elementAt(0);
        removeElementAt(0);
        return obj;
    }
}
```

This example implements a first-in, first-out (FIFO) queue. If the get() method of a Queue object is called when the queue is empty, the method throws an exception. Now suppose that you want to write the `get()` method so that when the queue is empty, the method waits for an item to be put in the queue, rather than throwing an exception. In order for an item to be put in the queue, the `put()` method of the queue must be invoked. But using the single-threaded execution strategy, the `put()` method will never be able to run while the `get()` method is waiting for the queue to receive an item. A good way to solve this dilemma is to use a strategy called *optimistic single-threaded execution*.

The optimistic single-threaded execution strategy is similar to the single-threaded execution strategy. They both begin by getting a lock on an object to ensure that the currently executing thread is the only thread that can execute a piece of code, and they both end by releasing that lock. The difference is what happens in between. Using the optimistic single-threaded execution strategy, if a piece of code discovers that conditions are not right to proceed, the code releases the lock it has on the object that enforces single-threaded execution and waits. When another piece of code changes things in such a way that might allow the first piece of code to proceed, it notifies the first piece of code that it should try to regain the lock and proceed.

To implement this strategy, the `Object` class provides methods called `wait()`, `notify()`, and `notifyAll()`. These methods are inherited by every other class in Java. The following example shows how to implement a queue that uses the optimistic single-threaded execution strategy, so that when the queue is empty, its `get()` method waits for the queue to have an item put in it:

```
public class Queue extends java.util.Vector {
    synchronized public void put(Object obj) {
        addElement(obj);
        notify();
    }
    synchronized public Object get() throws EmptyQueueException {
        while (size() == 0)
            wait();
        Object obj = elementAt(0);
        removeElementAt(0);
        return obj;
    }
}
```

In the above implementation of the `Queue` class, the `get()` method calls `wait()` when the queue is empty. The `wait()` method releases the lock that excludes other threads from executing methods in the `Queue` object, and then waits until another thread calls the `put()` method. When `put()` is called, it adds an item to the queue and calls `notify()`. The `notify()` method tells a thread that is waiting to return from a `wait()` method that it should attempt to regain its lock and proceed. If there is more than one thread waiting to regain the lock on the object, `notify()` chooses one of the threads arbitrarily. The `notifyAll()` method is similar to `notify()`, but instead of choosing one thread to notify, it notifies all of the threads that are waiting to regain the lock on the object.

Notice that the `get()` method calls `wait()` inside a `while` loop. Between the time that `wait()` is notified that it should try to regain its lock and the time it actually does regain the lock, another thread may have called the `get()` method and emptied the queue. The `while` loop guards against this situation.

Rendezvous

Sometimes it is necessary to have a thread wait to continue until another thread has completed its work and died. This type of synchronization uses the rendezvous strategy. The `Thread` class provides the `join()` method for implementing this strategy. When the `join()` method is called on a `Thread` object, the method returns immediately if the thread is dead. Otherwise, the method waits until the thread dies and then returns.

Balking

Some methods should not be executed concurrently and have a time-sensitive nature that makes postponing calls to them a bad idea. This is a common situation when software is controlling real-world devices. Suppose you have a Java program that is embedded in an electronic control for a toilet. There is a method called `flush()` that is responsible for flushing a toilet, and `flush()` can be called from more than one thread. If a thread calls `flush()` while another thread is already executing `flush()`, the second call should do nothing. A toilet is capable of only one flush at a time, and having a concurrent call to the `flush()` method result in a second flush would only waste water.

This scenario suggests the use of the balking strategy. The balking strategy allows no more than one thread to execute a method at a time. If another thread attempts to execute the method, the method simply returns without doing anything. Here is an example that shows what such a `flush()` method might look like:

```
boolean busy;
void flush() {
    synchronized (this) {
        if (busy)
            return;
        busy = true;
    }
    // code to make flush happen goes here
    busy = false;
}
```

Explicit Synchronization

When the synchronization needs of a thread are not known in advance, you can use a strategy called explicit synchronization. The explicit synchronization strategy allows you to explicitly tell a thread when it can and cannot run. For example, you may want an animation to start and stop in response to external events that happen at unpredictable times, so you need to be able to tell the animation when it can run.

To implement this strategy, the `Thread` class provides methods called `suspend()` and `resume()`. You can suspend the execution of a thread by calling the `suspend()` method of the `Thread` object that controls the thread. You can later resume execution of the thread by calling the `resume()` method on the `Thread` object.

5.4 Hashtables

The `Dictionary` class is an `abstract` class that defines methods for associating key objects with value objects. Given a key, an instance of `Dictionary` is able to return its associated value. The `Hashtable` class is a concrete subclass of `Dictionary` that uses a data structure called a *hashtable* and a technique called *chained hashing* to allow values associated with keys to be fetched with minimal searching. You might use a `Hashtable` object to associate weather reports with the names of cities and towns, for example.

Before explaining hashtables or chained hashing, consider the problem of finding a key/value pair in an array that contains references to key/value pairs in no particular order. The array might look something like what is shown in Figure 5.1.

Figure 5.1: An array of key/value pairs

[Graphic: Figure 5-1]

Since we cannot make any assumptions about where in the array a key is to be found, the most reasonable search strategy is a linear search that starts at one end of the array and looks at each array element until it finds what it is looking for or reaches the other end of the array. For an array with just a few elements, a linear search is a reasonable strategy, but for an array with hundreds of elements it is not. If we know where in the array to look for a key, however, we can eliminate most of the searching effort. Knowing where to look for a key is the idea behind a hashtable.

With a hashtable, each key object has a relatively unique integer value that is called a *hashcode*. The `Object` class defines a `hashCode()` method, so every object in Java has such a method. The hashcode returned by this method computes an array index for a key object as follows:

```
array.length % hashCode()
```

This array index, or hash index, stores the key/value pair in a hashtable array. If there is nothing stored at that index, the key/value pair is placed at that position in the array. However, if there is already a key/value pair at that hash index, the `Hashtable` stores the key/value pair in a linked list at that position in the array. This strategy for managing multiple keys with the same hash index is called *chained hashing*. The array for hashtable that uses this strategy might look like Figure 5.2.

Figure 5.2: An array of key/value pairs that uses chained hashing

[Graphic: Figure 5-2]

Now, when we want to fetch a key/value pair, all we have to do is recalculate the hash index for the key object and look at that position in the hashtable array. If the key stored at that hash index is the right key, then we have found what we are looking for by examining only one array element instead of searching. However, if the key is not the right key, all we have to do is search the items in the linked list at that position to find our key/value pair.

You can create a Hashtable object using the constructor that takes no arguments:

```
Hashtable h = new Hashtable()
```

This constructor creates an empty Hashtable. There are other constructors that take parameters to allow you to tune the performance of a Hashtable object. The first parameter you can specify is the capacity of the hash table, which is the length of the array used to implement it. The longer the array, the less likely it is that multiple keys will share the same hash index. The default array length is 101. To create a Hashtable object with an array length of 1009, use the following constructor:

```
Hashtable h = new Hashtable(1009);
```

The number that you choose for the array length should be a prime number. If it is not, the key/value pairs stored in the array will tend to be less evenly distributed.

The load factor of a hashtable is the ratio of the number of key/value pairs in the hashtable to the array length. A load factor of 0 means that the Hashtable is empty. As the load factor increases, so does the likelihood that multiple key/value pairs will share the same hash index. When the load factor becomes greater than 1, it means that the number of key/value pairs in a hashtable is greater than the array length, so that at least one hash index is being shared by multiple key/value pairs. Clearly, a low load factor is better than a high load factor in terms of performance. You can specify the maximum permissible load factor for a Hashtable object when you create it. For example:

```
Hashtable h = new Hashtable(1009, .62);
```

If not specified, the maximum load factor for a Hashtable object is .75. When a key/value pair is added to a Hashtable that would otherwise cause the load factor to exceed the maximum value, the Hashtable performs a rehash. This means that the Hashtable creates a new array with a length one greater than double the length of the old array. It then recomputes the hash index for each key/value pair in the old array and stores each key/value pair in the new array at the new hash index. Obviously, this is an undesirable performance hit, so if you know approximately how many items you will add to a Hashtable, you should create one with an appropriate initial capacity.

After you have created a Hashtable object, you can add new key/value pairs to it, or modify the value in an existing key/value pair, by calling the put() method. The put() method takes two arguments: a reference to a key object and a reference to a value object. It first looks for a key/value pair in the hashtable with the key equal to the specified key. If there is such a key/value pair, the put() method replaces the previous value with the specified value and returns a reference to the previous value object. If, however, there is no such key/value pair, the put() method creates a new key/value pair, adds it to the hashtable and returns null. Here is a fragment of a class that uses a Hashtable to store weather forecasts.

```
import java.util.Hashtable;
class WeatherForecastDictionary {
    private Hashtable ht = new Hashtable(13291);
    public void putForecast(String locale, WeatherForecast forecast) {
        ht.put(locale, forecast);
    }
...
```

The `get()` method returns the value associated with a given key in a `Hashtable` object. It takes one argument that is a reference to the key it should search for. If the `get()` method does not find a key/value pair with a key equal to the specified key, it returns `null`. Here is a method that uses the `get()` method to retrieve a weather forecast:

```
public WeatherForecast getForecast(String locale) {
    return (WeatherForecast)ht.get(locale);
}
```

The various equality tests done by a `Hashtable` use a given key object's `equals()` method. Because of the way that an object's `hashCode()` and `equals()` methods are used by the `Hashtable` class, it is important that if you override the definition of either of these methods, you do so in a consistent way. In other words, if two objects are considered equal by the `equals()` method for the class, then the `hashCode()` method for each object must return the same hashcode value. If that is not the case, when those objects are used as keys in a `Hashtable` object, the `Hashtable` will produce inconsistent results.

Once you have added key/value pairs to a `Hashtable`, you can use the `keys()` and `elements()` methods to get `Enumeration` objects that iterate through the key and value objects, respectively. The `containsKey()` method allows you to search the `Hashtable` for a particular key object, while `contains()` searches for a particular value object. The `Hashtable` class also defines a `remove()` method for removing key/value pairs from a `Hashtable`.

6.2 Output Streams and Writers

The `OutputStream` class is an `abstract` class that defines methods to write a stream of bytes sequentially. Java provides subclasses of the `OutputStream` class for writing to files and byte arrays, among other things. Other subclasses of `OutputStream` can be chained together to provide additional logic, such as writing multibyte data types or converting data to a string representation. It is also easy to define a subclass of `OutputStream` that writes to another kind of destination.

In Java 1.1, the `Writer` class is an `abstract` class that defines methods to write to a stream of characters sequentially. Many of the byte-oriented subclasses of `OutputStream` have counterparts in the character-oriented world of `Writer` objects. Thus, there are subclasses of `Writer` for writing to files and character arrays.

OutputStream

The `OutputStream` class is the `abstract` superclass of all other byte output stream classes. It defines three `write()` methods for writing to a raw stream of bytes:

```
write(int b)
write(byte[] b)
write(byte[] b, int off, int len)
```

Some `OutputStream` subclasses may implement buffering to increase efficiency. `OutputStream` provides a method, `flush()`, that tells the `OutputStream` to write any buffered output to the underlying device, which may be a disk drive or a network.

Because the `OutputStream` class is `abstract`, you cannot create a "pure" `OutputStream`. However, the various subclasses of `OutputStream` can be used interchangeably. For example, methods often take `OutputStream` parameters. This means that such a method accepts any subclass of `OutputStream` as an argument.

`OutputStream` is designed so that `write(byte[])` and `write(byte[], int, int)` call `write(int)`. Thus, when you subclass `OutputStream`, you only need to define the `write()` method. However, for efficiency's sake, you should also override `write(byte[], int, int)` with a method that can write a block of data more efficiently than writing each byte separately.

Writer

The `Writer` class is the `abstract` parent class of all other character output stream classes. It defines nearly the same methods as `OutputStream`, except that the `write()` methods deal with characters instead of bytes:

```
write(int c)
write(char[] cbuf)
write(char[] cbuf, int off, int len)
write(String str)
write(String str, int off, int len)
```

`Writer` also includes a `flush()` method that forces any buffered data to be written to the stream.

`Writer` is designed so that `write(int)` and `write(char[])` both call `write(char[], int, int)`. Thus, when you subclass `Writer`, you only need to define the `write(char[], int, int)` method. Note that this design is different from, and more efficient than, that of `OutputStream`.

OutputStreamWriter

The `OutputStreamWriter` class serves as a bridge between `Writer` objects and `OutputStream` objects. Although an `OutputStreamWriter` acts like a character stream, it converts its characters to bytes using a character encoding scheme and writes them to an underlying `OutputStream`. This class is the output counterpart of `InputStreamReader`. When you create an `OutputStreamWriter`, specify the underlying `OutputStream` and, optionally, the name of an encoding scheme. The following example shows how to construct an `OutputStreamWriter` that writes characters to a file, encoded using the ISO 8859-5 encoding:

```
String fileName = "encodedfile.txt";
String encodingName = "8859_5";
OutputStreamWriter out;
try {
    FileOutputStream fileOut = new FileOutputStream (fileName);
    out = new OutputStreamWriter (fileOut, encodingName);
} catch (UnsupportedEncodingException e1) {
    System.out.println(encodingName + " is not a supported encoding scheme.");
} catch (IOException e2) {
    System.out.println("The file " + fileName + " could not be opened.");
}
```

FileWriter and FileOutputStream

The `FileOutputStream` class is a subclass of `OutputStream` that writes a stream of bytes to a file. The `FileOutputStream` class has no explicit open method. Instead, the file is implicitly opened, if appropriate, when you create the `FileOutputStream` object. There are several ways to create a `FileOutputStream`:

- You can create a `FileOutputStream` by passing the name of a file to be written:

  ```
  FileOutputStream f1 = new FileOutputStream("foo.txt");
  ```

- Another constructor is available in Java 1.1 that allows you to specify whether you want to append to the file or overwrite it. The following example constructs a `FileOutputStream` that appends the given file:

  ```
  FileOutputStream f1 = new FileOutputStream("foo.txt", true);
  ```

- You can create a `FileOutputStream` with a `File` object:

  ```
  File f = new File("foo.txt");
  FileOutputStream f2 = new FileOutputStream(f);
  ```

- You can create a `FileOutputStream` with a `FileDescriptor` object. A `FileDescriptor` encapsulates the native operating system's representation of an open file. You can get a `FileDescriptor` from a `RandomAccessFile` by calling its `getFD()` method. You create a `FileOutputStream` that writes to the open file associated with a `RandomAccessFile` as follows:

  ```
  RandomAccessFile raf;
  raf = new RandomAccessFile("z.txt","rw");
  FileInputStream f3 = new FileOutputStream(raf.getFD());
  ```

  The `FileWriter` class is a subclass of `Writer` that writes a stream of characters to a file. The characters to be written are converted to bytes using the default character encoding scheme. If you do not want to use the default encoding scheme, you need to wrap an `OutputStreamWriter` around a `FileOutputStream` as shown above. You can create a `FileWriter` from a filename, a `File` object, or a `FileDescriptor` object, as described above for `FileOutputStream`.

StringWriter

The `StringWriter` class is a subclass of `Writer` that stores its data in a `String` object. Internally, it uses a `StringBuffer`, which can be examined using `getBuffer()`. A `String` containing the data that has been written can be obtained with `toString()`. The following example creates a `StringWriter` and writes data into it:

```
StringWriter out = new StringWriter();
char[] buffer = {'b', 'o', 'o', '!', 'h', 'a'};
out.write('B');
out.write("uga");
out.write(buffer, 0, 4);
System.out.println(out.toString());
```

This example produces the following output:

```
Bugaboo!
```

CharArrayWriter and ByteArrayOutputStream

The `CharArrayWriter` class is a subclass of `Writer` that writes characters to an internal array. There are three ways to retrieve the data that has been written to the `CharArrayWriter`:

- The `toCharArray()` method returns a reference to a copy of the internal array.
- The `toString()` method returns a `String` constructed from the internal array.
- The `writeTo()` method writes the internal array to another `Writer`.

This example demonstrates how to create a `CharArrayWriter`, write data into it, and retrieve the data:

```
CharArrayWriter out = new CharArrayWriter();
try {
    out.write("Daphne");
}catch (IOException e) {}
char[] buffer = out.toCharArray();
System.out.println(buffer);
String result = out.toString();
System.out.println(result);
```

This example produces the following output:

```
Daphne
Daphne
```

The internal buffer of the `CharArrayWriter` is expanded as needed when data is written. If you know how many characters you will be writing, you can make your `CharArrayWriter` a little more efficient by passing an initial size to its constructor.

`ByteArrayOutputStream` is the byte-oriented equivalent of `CharArrayWriter`. It works in much the same way, with the following exceptions:

- The `write()` methods deal with bytes, not characters. Additionally, `ByteArrayOutputStream` does not have the `write(String)` methods that `CharArrayWriter` defines.
- Instead of `toCharArray()`, `ByteArrayOutputStream` has a `toByteArray()` method.
- Three `toString()` methods are provided. The one with no arguments converts the bytes in the internal array to characters using the default encoding scheme.[1] In Java 1.1, the `toString(int)` method is deprecated, since it does not convert bytes to characters appropriately. Instead, pass an encoding name to `toString(String)`; this method correctly converts the internal byte array to a character string.

[1] In Java 1.1, the default encoding scheme is used for the conversion. In earlier versions, characters are simply created using the eight bits of each byte as the low eight bits of the character.

PipedOutputStream and PipedWriter

The `PipedOuputStream` class is a subclass of `OutputStream` that facilitates communication between threads. A `PipedOutputStream` must be connected to a `PipedInputStream` to be useful, as it writes bytes that can be read by a connected `PipedInputStream`. There are a few ways to connect a `PipedOutputStream` to a `PipedInputStream`. You can first create the `PipedInputStream` and pass it to the `PipedOutputStream` constructor like this:

```
PipedInputStream pi = new PipedInputStream();
PipedOutputStream po = new PipedOutputStream(pi);
```

You can also create the `PipedOutputStream` first and pass it to the `PipedInputStream` constructor like this:

```
PipedOutputStream po = new PipedOutputStream();
PipedInputStream pi = new PipedInputStream(po);
```

The `PipedOutputStream` and `PipedInputStream` classes each have a `connect()` method you can use to explicitly connect a `PipedOutputStream` and a `PipedInputStream` as follows:

```
PipedOutputStream po = new PipedOutputStream();
PipedInputStream pi = new PipedInputStream();
po.connect(pi);
```

Or you can use `connect()` as follows:

```
PipedOutputStream po = new PipedOutputStream();
PipedInputStream pi = new PipedInputStream();
pi.connect(po);
```

Only one `PipedInputStream` can be connected to a `PipedOutputStream` at a time. If you use a `connect()` method to connect a `PipedOutputStream` to an already connected `PipedInputStream`, any unread bytes from the previously connected `PipedOutputStream` are lost.

`PipedWriter` is the character-based equivalent of `PipedOutputStream`. It works in the same way, except that a `PipedWriter` is connected to a `PipedReader` to complete the pipe, using either the appropriate constructor or the `connect()` method.

FilterOutputStream and FilterWriter

The `FilterOutputStream` class is a wrapper class for `OutputStream` objects. Conceptually, objects that belong to a subclass of `FilterOutputStream` are wrapped around another `OutputStream` object. The constructor for this class requires an `OutputStream`. The constructor sets the object's `out` instance variable to reference the specified `OutputStream`, so from that point on, the `FilterOutputStream` is associated with the given `OutputStream`. All of the methods of `FilterOutputStream` work by calling the corresponding methods in the underlying `OutputStream`. Because the `close()` method of a `FilterOutputStream` calls the `close()` method of the `OutputStream` that it wraps, you do not need to explicitly close the underlying `OutputStream`.

A FilterOutputStream does not add any functionality to the object that it wraps, so by itself it is not very useful. However, subclasses of the FilterOutputStream class do add functionality to the objects that they wrap in two ways:

- Some subclasses add logic to the methods of OutputStream. For example, the BufferedOutputStream class adds logic that buffers write operations.

- Other subclasses add new methods. An example of this is DataOutputStream, which provides methods for writing primitive Java data types to the stream.

The FilterWriter class is the character-based equivalent of FilterOutputStream. A FilterWriter is wrapped around an underlying Writer object; the methods of FilterWriter call the corresponding methods of the underlying Writer. However, unlike FilterOutputStream, FilterWriter is an abstract class, so you cannot instantiate it directly.

DataOutputStream

The DataOutputStream class is a subclass of the FilterOutputStream class that provides methods for writing a variety of data types to an OutputStream. The DataOutputStream class implements the DataOutput interface, so it defines methods for writing all of the primitive Java data types.

You create a DataOutputStream by passing a reference to an underlying OutputStream to the constructor. Here is an example that creates a DataOutputStream and uses it to write the length of an array as an int and then to write the values in array as long values:

```
void writeLongArray(OutputStream out, long[] a) throws IOException {
    DataOutputStream dout = new DataOutputStream(out);
    dout.writeInt(a.length);
    for (int i = 0; i < a.length; i++) {
        dout.writeLong(a[i]);
    }
}
```

BufferedWriter and BufferedOutputStream

The BufferedWriter class is a subclass of Writer that stores output destined for an underlying Writer in an internal buffer. When the buffer fills up, the entire buffer is written, or flushed, to the underlying Writer. Using a BufferedWriter is usually faster than using a regular Writer because it reduces the number of calls that must be made to the underlying device, be it a disk or a network. You can use the flush() method to force a BufferedWriter to write the contents of the buffer to the underlying Writer.

The following example shows how to create a BufferedWriter around a network socket's output stream:

```
public Writer getBufferedWriter(Socket s) throws IOException {
    OutputStreamWriter converter = new OutputStreamWriter(s.getOutputStream());
    return new BufferedWriter(converter);
}
```

First, create an OutputStreamWriter that converts characters to bytes using the default encoding scheme. After they are converted, the bytes are written to the socket. Then simply wrap a BufferedWriter around the OutputStreamWriter to buffer the output.

The BufferedOutputStream class is the byte-based equivalent of BufferedWriter. It works in the same way as BufferedWriter, except that it buffers output for an underlying OutputStream. Here's how you would rewrite the previous example to create a BufferedOutputStream around a socket:

```
public OutputStream getBufferedOutputStream(Socket s) throws IOException {
    return new BufferedOutputStream(s.getOutputStream());
}
```

PrintWriter and PrintStream

The PrintWriter class is a subclass of Writer that provides a set of methods for printing string representations of every Java data type. A PrintWriter can be wrapped around an underlying Writer object or an underlying OutputStream object. In the case of wrapping an OutputStream, any characters written to the PrintWriter are converted to bytes using the default encoding scheme.[2] Additional constructors allow you to specify if the underlying stream should be flushed after every line-separator character is written.

> [2] You can achieve the same effect using an OutputStreamWriter, but it is easier to use the PrintWriter(OutputStream) constructor. However, if you want to use an encoding scheme other than the default one, you need to create your own OutputStreamWriter.

The PrintWriter class provides a print() and a println() method for every primitive Java data type. As their names imply, the println() methods do the same thing as their print() counterparts, but also append a line separator character.

The following example demonstrates how to wrap a PrintWriter around an OutputStream:

```
boolean b = true;
char c = '%'
double d = 8.31451
int i = 42;
String s = "R = ";
PrintWriter out = new PrintWriter(System.out, true);
out.print(s);
out.print(d);
out.println();
out.println(b);
out.println(c);
out.println(i);
```

This example produces the following output:

```
R = 8.31451
```

```
true
%
42
```

PrintWriter objects are often used to report errors. For this reason, the methods of this class do not throw exceptions. Instead, the methods catch any exceptions thrown by any downstream OutputStream or Writer objects and set an internal flag, so that the object can remember that a problem occurred. You can query the internal flag by calling the checkError() method.

Although you can create a PrintWriter that flushes the underlying stream every time a line-separator character is written, this may not always be exactly what you want. Suppose that you are writing a program that has a character-based user interface, and that you want the program to output a prompt and then allow the user to input a response on the same line. In order to make this work with a PrintWriter, you need to get the PrintWriter to write the characters in its buffer without writing a line separator. You can do this by calling the flush() method.

PrintWriter is new as of Java 1.1; it is more capable than the PrintStream class. You should use PrintWriter instead of PrintStream because it uses the default encoding scheme to convert characters to bytes for an underlying OutputStream. The constructors for PrintStream are deprecated in Java 1.1. In fact, the whole class probably would have been deprecated, except that it would have generated a lot of compilation warnings for code that uses System.out and System.err.

6.3 File Manipulation

While streams are used to handle most types of I/O in Java, there are some nonstream-oriented classes in `java.io` that are provided for file manipulation. Namely, the `File` class represents a file on the local filesystem, while the `RandomAccessFile` class provides nonsequential access to data in a file. In addition, the `FilenameFilter` interface can be used to filter a list of filenames.

File

The `File` class represents a file on the local filesystem. You can use an instance of the `File` class to identify a file, obtain information about the file, and even change information about the file. The easiest way to create a `File` is to pass a filename to the `File` constructor, like this:

```
new File("readme.txt")
```

Although the methods that the `File` class provides for manipulating file information are relatively platform independent, filenames must follow the rules of the local filesystem. The `File` class does provide some information that can be helpful in interpreting filenames and path specifications. The variable `separatorChar` specifies the system-specific character used to separate the name of a directory from what follows.[3] In a Windows environment, this is a backslash (`\`), while in a UNIX or Macintosh environment it is a forward slash (`/`). You can create a `File` object that refers to a file called `readme.txt` in a directory called `myDir` as follows:

```
new File("myDir" + File.separatorChar + "readme.txt")
```

The `File` class also provides some constructors that make this task easier. For example, there is a `File` constructor that takes two strings as arguments: the first string is the name of a directory and the second

[3] This information is also available as `System.getProperty('file.separator')`, which is how the `File` class gets it.

string is the name of a file. The following example does the exact same thing as the previous example:

```
new File("myDir", "readme.txt")
```

The `File` class has another constructor that allows you to specify the directory of a file using a `File` object instead of a `String`:

```
File dir = new File("myDir");
File f = new File(dir, "readme.txt");
```

Sometimes a program needs to process a list of files that have been passed to it in a string. For example, such a list of files is passed to the Java environment by the `CLASSPATH` environment variable and can be accessed by the expression:

```
System.getProperty("java.class.path")
```

This list contains one or more filenames separated by separator characters. In a Windows or Macintosh environment, the separator character is a semicolon (`;`), while in a UNIX environment, the separator character is a colon (`:`). The system-specific separator character is specified by the `pathSeparatorChar` variable. Thus, to turn the value of `CLASSPATH` into a collection of `File` objects, we can write:

```
StringTokenizer s;
Vector v = new Vector();
s = new StringTokenizer(System.getProperty("java.class.path"),
                        File.pathSeparator);
while (s.hasMoreTokens())
    v.addElement(new File(s.nextToken()));
```

You can retrieve the pathname of the file represented by a `File` object with `getPath()`, the filename without any path information with `getName()`, and the directory name with `getParent()`.

The `File` class also defines methods that return information about the actual file represented by a `File` object. Use `exists()` to check whether or not the file exists. `isDirectory()` and `isFile()` tell whether the file is a file or a directory. If the file is a directory, you can use `list()` to get an array of filenames for the files in that directory. The `canRead()` and `canWrite()` methods indicate whether or not a program is allowed to read from or write to a file. You can also retrieve the length of a file with `length()` and its last modified date with `lastModified()`.

A few `File` methods allow you to change the information about a file. For example, you can rename a file with `rename()` and delete it with `delete()`. The `mkdir()` and `mkdirs()` methods provide a way to create directories within the filesystem.

Many of these methods can throw a SecurityException if a program does not have permission to access the filesystem, or particular files within it. If a SecurityManager has been installed, the checkRead() and checkWrite() methods of the SecurityManager verify whether or not the program has permission to access the filesystem.

FilenameFilter

The purpose of the FilenameFilter interface is to provide a way for an object to decide which filenames should be included in a list of filenames. A class that implements the FilenameFilter interface must define a method called accept(). This method is passed a File object that identifies a directory and a String that names a file. The accept() method is expected to return true if the specified file should be included in the list, or false if the file should not be included. Here is an example of a simple FilenameFilter class that only allows files with a specified suffix to be in a list:

```
import java.io.File;
import java.io.FilenameFilter;
public class SuffixFilter implements FilenameFilter {
    private String suffix;
    public SuffixFilter(String suffix) {
        this.suffix = "." + suffix;
    }
    public boolean accept(File dir, String name) {
        return name.endsWith(suffix);
    }
}
```

A FilenameFilter object can be passed as a parameter to the list() method of File to filter the list that it creates. You can also use a FilenameFilter to limit the choices shown in a FileDialog.

RandomAccessFile

The RandomAccessFile class provides a way to read from and write to a file in a nonsequential manner. The RandomAccessFile class has two constructors that both take two arguments. The first argument specifies the file to open, either as a String or a File object. The second argument is a String that must be either "r" or "rw". If the second argument is "r", the file is opened for reading only. If the argument is "rw", however, the file is opened for both reading and writing. The close() method closes the file. Both constructors and all the methods of the RandomAccessFile class can throw an IOException if they encounter an error.

The `RandomAccessFile` class defines three different `read()` methods for reading bytes from a file. The `RandomAccessFile` class also implements the `DataInput` interface, so it provides additional methods for reading from a file. Most of these additional methods are related to reading Java primitive types in a machine-independent way. Multibyte quantities are read assuming the most significant byte is first and the least significant byte is last. All of these methods handle an attempt to read past the end of file by throwing an `EOFException`.

The `RandomAccessFile` class also defines three different `write()` methods for writing bytes of output. The `RandomAccessFile` class also implements the `DataOutput` interface, so it provides additional methods for writing to a file. Most of these additional methods are related to writing Java primitive types in a machine-independent way. Again, multibyte quantities are written with the most significant byte first and the least significant byte last.

The `RandomAccessFile` class would not live up to its name if it did not provide a way to access a file in a nonsequential manner. The `getFilePointer()` method returns the current position in the file, while the `seek()` method provides a way to set the position. Finally, the `length()` method returns the length of the file in bytes.

7.3 Versioning of Classes

One you have written a class that works with serialization, the next concern is that serialized instances of that class can be deserialized by programs that use a different version of the same class.

After a class is written, it is often necessary to modify its definition as requirements change or new features are needed. Deserialization may fail if the definition of a class in use when an instance was serialized is different than the definition in use when the instance is deserialized. If you do not take any measures to assure the serialization mechanism that the two classes are different versions of the same class, deserialization fails by throwing an `InvalidClassException`. And even if the serialization mechanism is satisfied that the two class definitions represent different versions of the same class, it may find incompatible differences between the definitions.

The following changes to the definition of a class are noticed by the serialization mechanism:

- Adding or deleting instance variables.
- Moving a class up or down the inheritance hierarchy.
- Making a non-`static`, non-`transient` variable either `static` or `transient` has the same effect as deleting the variable. Similarly, changing a variable that is `static` or `transient` to be non-`static` or non-`transient` has the same effect as adding the variable.
- Changing the data type of a `transient` variable from a primitive data type to an object reference type or from an object reference type to a primitive data type.
- Changing the `readObject()` or `writeObject()` method of a class so that it calls `defaultReadObject()` or `defaultWriteObject()` when it did not previously, or so that it does not call one of these methods when it did previously. The removal or addition of a `readObject()` or `writeObject()` method that does not call `defaultReadObject()` or `defaultWriteObject()` has a similar effect.

- Changing a class from `Serializable` to `Externalizable` or from `Externalizable` to `Serializable`.

It's possible to code around some of these problems if you can first convince the serialization mechanism that the two class definitions are different versions of the same class. In order to convince the serialization mechanism of such a thing, the class definition used for deserialization of an object must define a `static final long` variable named `serialVersionUID`. If the class used for serialization also defined that variable with the same value, the two class definitions are assumed to define different versions of the same class.

If the class used for serialization does not define `serialVersionUID`, the serialization mechanism performs the comparison using a value that is computed by calling the `ObjectStreamClass.getSerialVersionUID()` method. That computation is based on the fields defined by the class. To take advantage of this automatic computation when you define `serialVersionUID`, you should use the *serialver* program that comes with the JDK to determine the appropriate value for `serialVersionUID`. The *serialver* program computes a value for `serialVersionUID` by calling the `ObjectStreamClass.getSerialVersionUID()` method.

Assuming you've convinced the serialization mechanism that the two class definitions represent different versions of the same class, here is some advice on how to deal with the differences that can be worked around:

Missing variables

> If the class used to deserialize an object defines variables the class used to serialize the object did not define, the serialized object does not contain any values for those variables. This situation can also arise if the class used to serialize the object defined a variable as `static` or `transient`, while the class used to deserialize the object defines it as non-`static` or non-`transient`.
>
> When an object is deserialized and there are variables missing in its serialized form, the variables in the deserialized object are set to default values. In other words, the value of such a variable is `true` if it has an arithmetic data type, `false` if it has a `boolean` data type, or `null` if it has an object reference type. Deserialization ignores intializers in variable declarations.
>
> When you add variables to a `Serializable` class, consider the possibility that the new version of the class will deserialize an object serialized with an older version of the class. If that happens and it is unacceptable for the new variables to have default values after deserialization, you can define a `validateObject()` method for the class to check for the default values and provide acceptable values or throw an `InvalidObjectException`.

Extra variables

If the serialized form of an object contains values for variables that are not defined by the class used to deserialize that object, the values are read and then ignored. If the value of such a variable is an object, the object is created and immediately becomes a candidate for garbage collection.

Missing classes

If the class used to deserialize an object inherits from an ancestor class that the class used to serialize the object did not inherit from, the serialized object does not contain any values for the variables of the additional ancestor class. Just as with missing variables, those variables are deserialized with their default values.

When you add an ancestor class to a `Serializable` class, consider the possibility that the new version of the class will deserialize an object serialized with an older version of the class. If that happens and it is unacceptable for instance variables in the new ancestor class to have default values after deserialization, you can define a `validateObject()` method for the class to check for the default values and provide acceptable values or throw an `InvalidObjectException`.

Extra classes

If the class used to serialize an object inherits from an ancestor class that the class used to deserialize the object does not inherit from, the values for the variables defined by that extra ancestor class are read but not used.

Adding writeObject() and readObject() methods

You can add `writeObject()` and `readObject()` methods to a class that did not have them. In order to deserialize objects that were serialized using the older class definition, the new methods must begin by calling `defaultWriteObject()` and `defaultReadObject()`. That ensures that information written out using default logic is still processed using default logic.

If the `writeObject()` and `readObject()` methods write and read additional information to and from the byte stream, you should also add an additional variable to the class to serve as a version indicator. For example, you might declare an `int` variable and initialize it to one. If, after `defaultReadObject()` returns, the value of that variable is `0`, you know the object was serialized using the old class definition and that any additional information that would have been written by the `writeObject()` method will not be there.

Removing writeObject() and readObject() methods

If you remove `writeObject()` and `readObject()` methods from a class and deserialize an object using the new class definition, the information written by a call to `writeObject()` is simply read by the default logic and any additional information is ignored.

Changing a class so that it implements Serializable

If a superclass of an object did not implement `Serializable` when the object was serialized, and that superclass does implement `Serializable` when the object is deserialized, the result is similar to the missing class situation. There is no information about the variables of the newly `Serializable` superclass in the byte stream, so its instance variables are initialized to default values.

Changing a class so that it does not implement Serializable

If a superclass of an object implemented `Serializable` when the object was serialized, and that superclass does not implement `Serializable` when the object is deserialized, the result is similar to the extra class situation. The information in the byte stream for that class is read and discarded.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

8.2 URL Objects

The URL class provides higher-level access to data than sockets do. A URL object encapsulates a Uniform Resource Locator (URL) specification. Once you have created a URL object, you can use it to access the data in the location specified by the URL. A URL allows you to access the data without needing to be aware of the details of the protocol being used, such as HTTP or FTP. For some types of data, a URL object provides a way to get the data already encapsulated in an appropriate kind of object. For example, a URL can provide JPEG data encapsulated in an ImageProducer object or text data encapsulated in a String object.

You can create a URL object as follows:

```
try {
    URL js = new URL("../../../../www.javasoft.com/index.html");
}catch (MalformedURLException e) {
    return;
}
```

This type of URL specification is called an absolute URL specification because it completely specifies where to find the data. It is also possible to create a URL object with a relative URL specification that is combined with an absolute specification:

```
try {
   URL jdk = new URL(js,"java.sun.com/products/JDK/index.html");
}catch (MalformedURLException e) {
    return;
}
```

In this example, the URL created in the previous example is combined with a relative URL specification that doesn't specify a network address or a root directory. The constructor can only combine the specifications if the protocol for both specifications is the same. If no protocol is specified, HTTP is assumed. The rules for combining the specifications depend on the protocol. In fact, the syntax rules for the portion of the URL after the protocol and up to an optional # depend on the protocol. If there's a # in the URL specification, the portion of the spec after the # is considered reference information that specifies a location within a file.

Once you have created a `URL` object, you can use the following access methods to get the information that the `URL` object encapsulates:

- `getProtocol()`
- `getHost()`
- `getFile()`
- `getPort()`
- `getRef()`

If you want to determine if two `URL` objects refer to the same file, you can use the `sameFile(URL)` method, which compares all the information in two `URL` objects except the reference information.

The highest level of functionality available from a `URL` object is provided by the `getContent()` method. The `getContent()` method tries to determine the type of data in the file specified by the `URL`, and then it returns the contents of the file encapsulated in an appropriate object for that type of data. For example, if the file contains GIF data, `getContent()` returns an ImageProducer object. If the type of data is not explicitly specified, `getContent()` tries to guess the type from the filename extension and possibly also from the contents of the file. The data type names that Java uses conform to the naming scheme for MIME data types, as do the filename extensions that are recognized. The data types that correspond to various file extensions are shown in Table 8.2.

Table 8.2: File Extensions and Data Types

Suffix	**Data Type**	**Suffix**	**Data Type**
.a [1]	`application/octet-stream`	*.ms*	`application/x-troff-ms`
.ai	`application/postscript`	*.mv*	`video/x-sgi-movie`
.aif	`audio/x-aiff`	*.nc*	`application/x-netcdf`
.aifc	`audio/x-aiff`	*.o* [1]	`application/octet-stream`

.lib [2]	application/octet-stream	*.ustar*	application/x-ustar

.man	application/x-troff-man	*.uu*	application/octet-stream
.me	application/x-troff-me	*.wav*	audio/x-wav
.mime	message/rfc822	*.wsrc*	application/x-wais-source
.mov	video/quicktime	*.xbm*	image/x-xbitmap
.movie	video/x-sgi-movie	*.xpm*	image/x-xpixmap
.mpe	video/mpeg	*.xwd*	image/x-xwindowdump
.mpeg	video/mpeg	*.z* [2]	application/octet-stream
.mpg	video/mpeg	*.zip* [2]	application/zip

Footnotes:

[1] UNIX only.

[2] Windows only.

If the filename does not end with a recognized extension, the first few bytes of the file are examined. If the first few bytes match the signature of a known type, the file is assumed to be of that type. Table 8.3 shows the byte combinations that are recognized.

Table 8.3: File Contents and Corresponding File Type

File Begins with	**Inferred Data Type**
"GIF8"	image/gif
"#def"	image/x-bitmap
"! XPM2"	image/x-pixmap
"<html>"	text/html
"<head>"	text/html
"<body>"	text/html

If you want to access the raw contents of a file instead of getting it encapsulated in an object, you can call the `openStream()` method of a `URL`. The `openStream()` method returns a reference to an `InputStream` object that you can use to read the file.

URLConnection Objects

After a URL object has parsed its specification, it actually creates a URLConnection object that is responsible for the protocol that it uses. The URLConnection is also responsible for determining the type of data in the file. The object is an instance of a subclass of URLConnection that is specific to the protocol specified by the URL object. As of Java 1.1, the java.net package includes the HttpURLConnection class for the HTTP protocol.

The URLConnection object for a URL provides complete control over the downloading of data from that URL. Unfortunately, the functionality of URLConnection is quite complex and goes beyond the scope of this book. For a detailed explanation of URLConnection, see *Java Network Programming* by Eliotte Rusty Harold, published by O'Reilly & Associates.

JAVA IN A NUTSHELL | JAVA LANG REF | JAVA AWT REF | JAVA FUND CLASSES REF | EXPLORING JAVA

9.2 ClassLoader

Java supports dynamically loaded classes, so the class loading mechanism plays an important role in the Java security model. The default class loading mechanism in Java loads classes from local files found relative to directories specified by the `CLASSPATH` environment variable. The `CLASSPATH` environment variable should have a value made up of one or more directory paths separated by a colon. The path implied by the package of a class is relative to the directories specified in the `CLASSPATH` environment variable.

In contrast, an instance of the `java.lang.ClassLoader` class defines how classes are loaded over the network. You can specify a security policy for loading classes by defining a subclass of `ClassLoader` that implements the policy. The `loadClass()` method of a `ClassLoader` loads a top-level class, such as a subclass of `Applet`. That `ClassLoader` object then becomes associated with the loaded class. You can retrieve the `ClassLoader` object that loads the class by calling the `getClassLoader()` of an instance of the loaded class; every class in Java inherits this method from the `Object` class.

An object of a class loaded using a `ClassLoader` can attempt to load additional classes without explicitly using a `ClassLoader` object. The object does this by calling the `forName()` method of the `Class` class. However, if a `ClassLoader` object is associated with any pending method invocation in the current thread, the `forName()` method uses that `ClassLoader` to load the additional classes. In essence, this means that the object can only load classes through its associated `ClassLoader`.

If Java security is implemented correctly, an untrusted applet cannot escape the security policy implemented by the `ClassLoader` object used to load it because it cannot access any other `ClassLoader` objects. An applet should not be able to create its own `ClassLoader` objects. It is the responsibility of the `checkCreateClassLoader()` method of `SecurityManager` to enforce this restriction.

Because a `SecurityManager` can determine the `ClassLoader`, if any, used to load a class, it can use the `ClassLoader` to help determine the trustworthiness ofthe class. Classes loaded by different

ClassLoader objects cannot accidentally be mixed up because a class is identified by the combination of its fully qualified name and its ClassLoader.

BufferedOutputStream

Name

BufferedOutputStream

Synopsis

Class Name:

`java.io.BufferedOutputStream`

Superclass:

`java.io.FilterOutputStream`

Immediate Subclasses:

None

Interfaces Implemented:

None

Availability:

JDK 1.0 or later

Description

A `BufferedOutputStream` object provides a more efficient way to write just a few bytes at a time to an `OutputStream`. `BufferedOutputStream` objects use a buffer to store output for an associated `OutputStream`. In other words, a large number of bytes are stored in an internal buffer and only written when the buffer fills up or is explicitly flushed. A `BufferedOutputStream` is more efficient than a regular `OutputStream` because the data is written to memory, rather than a disk or a network. Minimizing the number of write operations to a disk or the network minimizes the cumulative overhead for these operations.

You should wrap a `BufferedOutputStream` around any `OutputStream` whose `write()` operations may be time consuming or costly, such as a `FileOutputStream`.

Class Summary

```
public class java.io.BufferedOutputStream
             extends java.io.FilterOutputStream {
  // Variables
  protected byte[] buf;
  protected int count;
  // Constructors
  public BufferedOutputStream(OutputStream out);
  public BufferedOutputStream(OutputStream out, int size);
  // Instance Methods
  public synchronized void flush();
  public synchronized void write(int b);
  public synchronized void write(byte[] b, int off, int len);
}
```

Variables

buf

protected byte[] buf

Description

> The buffer that stores the data for the output stream.

count

protected int count

Description

> The current position in the buffer.

Constructors

BufferedOutputStream

public BufferedOutputStream(OutputStream out)

Parameters

`out`

The output stream to buffer.

Description

This constructor creates a `BufferedOutputStream` that acts on the specified `OutputStream`, using a buffer with the default size of 512 bytes.

public BufferedOutputStream(OutputStream out, int size)

Parameters

`out`

The output stream to buffer.

`size`

The size of buffer to use.

Description

This constructor creates a `BufferedOutputStream` that acts on the specified `OutputStream`, using a buffer that is `size` bytes long.

Instance Methods

flush

public synchronized void flush() throws IOException

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.flush()`

Description

This method writes the contents of the buffer to the underlying output stream. It is called automatically when the buffer fills up. You can also call it before the buffer is full. This is known as "flushing" the buffer. This method blocks until the underlying `write()` is complete.

write

public synchronized void write(int b) throws IOException

Parameters

`b`

The value to write.

Throws

`IOException`

If any kind of I/O error occurs.

Overrides

`FilterOutputStream.write(int)`

Description
