Education, Science, and Professional Development Department—*ASCO-SEP*®
American Society of Clinical Oncology
2318 Mill Road, Suite 800
Alexandria, VA 22314
Phone: 888-282-2552
Email: ascou@asco.org

Printed in the United States of America.

Cover photograph, credit to STEVE GSCHMEISSNER/SCIENCE PHOTO LIBRARY, used with permission, is of cancer cells and monocyte. Colored scanning electron micrograph (SEM) of the interaction between a monocyte and prostate cancer cells. Monocytes activated by cytokines (cell signaling proteins) or other agents are cytotoxic for cancer cells. Magnification: x 2500 when printed at 10 centimeters wide.

LETTER FROM THE EDITOR

Dear Colleague:

On behalf of ASCO, I am pleased to present the 6th edition of *ASCO-SEP®: Medical Oncology Self-Evaluation Program*. This self-evaluation resource was designed to assist you in staying current in medical oncology, to provide test questions for assessing your knowledge, and to assist you in your care of patients with cancer. In addition, through your use of *ASCO-SEP®* you may earn credit for the maintenance of certification (MOC) process. The response to the opportunity to receive MOC points for reading *ASCO-SEP®* and completing the chapter-related multiple-choice questions has been tremendous. We will continue to provide the opportunity to receive MOC points for your work with *ASCO-SEP® 6th Edition.*

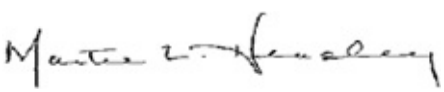
ASCO-SEP® is a comprehensive learning tool that includes 22 chapters focused on specific disease sites and oncology topics, as well as more than 180 multiple-choice questions that can be used for self-study. The "Key Points" in each chapter section facilitate review of important facts and concepts. *ASCO-SEP® 6th Edition* continues to feature vital updates at the beginning of each chapter, highlighting new data that have significantly informed practice and/or our understanding of cancer.

For this 6th edition, all of the self-assessment questions are new, providing learners with unique opportunities for review. Also available is the *ASCO-SEP® 6th Edition* Mock Examination, which can be accessed at ASCO University (university.asco.org/SEP). This convenient online study tool provides yet another resource for self-evaluation. All questions in the Mock Examination are new and do not include any test items from the book.

This *ASCO-SEP® 6th Edition* would not have been possible without the efforts of three outstanding Associate Editors who dedicated substantial time and commitment to ensure the high quality of the content: Matthew I. Milowsky, MD, Scott M. Schuetze, MD, PhD, and S. Vincent Rajkumar, MD. The success of this publication has relied on the time and talents of many contributors, including chapter authors and peer reviewers who graciously shared their time and expertise. I am also grateful for the tireless and expert support of the ASCO staff.

Thank you for participating in this worthwhile continuing medical education program. If you have comments or suggestions regarding *ASCO-SEP®*, please email ascou@asco.org.

Sincerely,



Martee L. Hensley, MD, MSc
Editor, *ASCO-SEP® 6th Edition*

EDITOR BIOGRAPHIES

Left to right: S. Vincent Rajkumar, MD, Matthew I. Milowsky, MD, Martee L. Hensley, MD, MSc, and Scott M. Schuetze, MD, PhD

Martee L. Hensley, MD, MSc, is Professor of Medicine, Weill Cornell Medical College and Attending Physician, Gynecologic Medical Oncology service, Memorial Sloan Kettering Cancer Center. She serves as Co-Chair of the Uterine Task Force of the National Cancer Institute's Gynecologic Cancer Steering Committee, Co-Chair of the NCI-EORTC-Cancer Research UK International Rare Cancer Initiative for Gynecologic Sarcomas, and as member of the NRG Developmental Therapeutics and Uterine Corpus Committees. She is Chair, Hospital Quality Assurance Committee, at Memorial Sloan Kettering.

Matthew I. Milowsky, MD, is an Associate Professor of Medicine and Urology, Section Chief of the Genitourinary Oncology Service, and Co-Director of the Urologic Oncology Program at the University of North Carolina at Chapel Hill Lineberger Comprehensive Cancer Center.

S. Vincent Rajkumar, MD, is an Edward W. and Betty Knight Scripps Professor of Medicine and Consultant in the Division of Hematology at the Mayo Clinic, Rochester, Minnesota. He serves as Co-Chair of the International Myeloma Working Group, and Chair of the NCI ECOG-ACRIN myeloma steering committee.

Scott M. Schuetze, MD, PhD, is Clinical Professor of Medicine in the Division of Hematology/Oncology, University of Michigan Comprehensive Cancer Center. He is the Director of the Connective Tissue Oncology Program in the University of Michigan Comprehensive Cancer Center and Medical Co-Director of the Oncology Clinical Trials Support Unit in Michigan Medicine.

DISCLOSURE INDEX

In compliance with standards established by the Accreditation Council for Continuing Medical Education (ACCME), it is ASCO's policy to ensure balance, independence, objectivity, and scientific rigor in all of its educational activities through the disclosure of financial relationships, among other measures. All *ASCO-SEP® 6th Edition* editors, authors, and peer reviewers are required to disclose all relationships with commercial interests. The financial interests or relationships requiring disclosure are outlined in ASCO's Policy for Relationships with Companies (asco.org/rwc).

The intent of this policy is to identify relationships openly, so readers can form their own judgments about the publication in light of these relationships. It remains for readers to determine whether the contributor's outside interests reflect a possible bias in the publication or the conclusions presented. The categories of relationships that contributors are required to disclose are detailed here as a guide to the disclosure statements that appear in the following Disclosure Index:

ITEMS REQUIRING DISCLOSURE

- Employment
- Leadership
- Stock and Other Ownership Interests
- Honoraria
- Consulting or Advisory Role
- Speakers' Bureau
- Research Funding
- Patents, Royalties, Other Intellectual Property
- Expert Testimony
- Travel, Accommodations, Expenses
- Other Relationship

EDITORIAL BOARD DISCLOSURES

Financial relationships reported by members of the *ASCO-SEP®* Editorial Board are provided below. During all phases of planning, areas of conflict were managed through a peer-review process and/or through individual recusal when appropriate. All relationships are considered self-held and compensated unless otherwise noted. *(I = immediate family member; Inst = My Institution)*

MARTEE L. HENSLEY, MD, MSc

- *Employment: Sanofi (I)*
- *Stock and Other Ownership Interests: Sanofi (I)*

- *Consulting or Advisory Role: Onclive, Janssen, Lilly, Tesaro, EMD Serono*
- *Research Funding: Bristol-Myers Squibb (Inst), Johnson & Johnson (Inst)*
- *Patents, Royalties, Other Intellectual Property: Author, UpToDate*

MATTHEW I. MILOWSKY, MD
- *Research Funding: Inovio Pharmaceuticals (Inst), Innocrin Pharma (Inst), Incyte (Inst), MedImmune (Inst), X4 Pharma (Inst), Bristol-Myers Squibb (Inst), Roche/Genentech (Inst), BioClin Therapeutics (Inst), Merck (Inst), Cerulean Pharma (Inst), Pfizer (Inst), Mirati Therapeutics (Inst), Acerta Pharma (Inst), Seattle Genetics (Inst)*
- *Travel, Accommodations, Expenses: Roche/Genentech*

S. VINCENT RAJKUMAR, MD
- *No Relationships to Disclose*

SCOTT M. SCHUETZE, MD, PhD
- *Consulting or Advisory Role: Daiichi Sankyo, Janssen, EMD Serono*
- *Research Funding: Adaptimmune (Inst), Karyopharm Therapeutics (Inst), Lilly (Inst), Plexxikon (Inst), CytRx Corporation (Inst), BioMed Valley Discoveries (Inst), Amgen (Inst), Janssen (Inst), AB Science (Inst)*

AUTHOR DISCLOSURES

The *ASCO-SEP*® Editorial Board has reviewed all author disclosure reports, identified potential conflicts of interest, and implemented strategies to manage those areas of conflict, where they exist. All relationships are considered self-held and compensated unless otherwise noted. *(I = immediate family member; Inst = My Institution)*

ALEX A. ADJEI, MD, PhD
- *No Relationships to Disclose*

FREDERICK R. APPELBAUM, MD
- *Stock and Other Ownership Interests: Adaptive Biotechnologies, Igenica*
- *Honoraria: Amgen, Celator, National Marrow Donor Program, Neumedicines*
- *Consulting or Advisory Role: National Marrow Donor Program, Igenica*

SHRUJAL BAXI, MD, MPH
- *Consulting or Advisory Role: Bristol-Myers Squibb, AstraZeneca*
- *Travel, Accommodations, Expenses: AstraZeneca*

BRUCE E. CLURMAN, MD, PhD
- *No Relationships to Disclose*

HARVEY JAY COHEN, MD
- *No Relationships to Disclose*

HOWARD A. FINE, MD

- *No Relationships to Disclose*

DAVID R. GANDARA, MD
- *Consulting or Advisory Role: Synta, Novartis, Celgene, Boehringer Ingelheim, AstraZeneca, Genentech, Merck, Pfizer, Sanofi, Response Genetics, Lilly, ARIAD, Clovis Oncology, Guardant Health, Mirati Therapeutics*
- *Research Funding: Bristol-Myers Squibb (Inst), Genentech (Inst), Lilly (Inst), Merck (Inst), Novartis (Inst), AstraZeneca/MedImmune (Inst), Clovis Oncology (Inst), Johnson & Johnson (Inst)*

TARA C. GANGADHAR, MD
- *Honoraria: Medscape*
- *Research Funding: Merck (Inst), Incyte (Inst), Bristol-Myers Squibb (Inst)*

JONATHAN E. GRIM, MD, PhD
- *Stock and Other Ownership: Medtronic (I), Pfizer (I), Vanguard Health Care Mutual Fund*

TUFIA C. HADDAD, MD
- *No Relationships to Disclose*

MARTEE L. HENSLEY, MD, MSc
- *Employment: Sanofi (I)*
- *Consulting or Advisory Role: EMD Serono, Insys Therapeutics, Janssen*
- *Research Funding: Johnson & Johnson (Inst)*
- *Patents, Royalties, Other Intellectual Property: Author, UpToDate*

ARIF H. KAMAL, MD, MBA, MHS
- *Consulting or Advisory Role: Insys Therapeutics*

RAVINDRAN KANESVARAN, BSc, MD, MRCP, FAMS
- *Honoraria: Astellas Pharma, Novartis, Janssen*
- *Consulting or Advisory Role: Pfizer, Astellas Pharma, Novartis, Mundipharma*
- *Research Funding: Sanofi (Inst), Janssen (Inst)*
- *Travel, Accommodations, Expenses: Astellas Pharma*

BRENT R. LOGAN, PhD
- *Consulting or Advisory Role: Telesta Therapeutics, Celgene, Rockwell Medical*

CHARLES L. LOPRINZI, MD
- *Consulting or Advisory Role: Cubist, Mitsubishi Tanabe Pharma, PledPharma, Lpath, Coronado Biosciences, Insys Therapeutics (Inst), QUE Oncology (Inst), Metys (Inst), Janssen (Inst)*
- *Research Funding: Pfizer (Inst), Janssen (Inst)*
- *Travel, Accommodations, Expenses: Cubist*

RAJIV S. MAGGE, MD

- *No Relationships to Disclose*

MATTHEW I. MILOWSKY, MD
- *Research Funding: BIND Therapeutics (Inst), Dendreon (Inst), Exelixis (Inst), Johnson & Johnson (Inst), Mirati Therapeutics (Inst), Pfizer (Inst), Cerulean Pharma (Inst), Merck (Inst), Seattle Genetics (Inst), Acerta Pharma (Inst), BioClin Therapeutics (Inst), Roche/Genentech (Inst)*

TIMOTHY J. MOYNIHAN, MD
- *No Relationships to Disclose*

RODRIGO RAMELLA MUNHOZ, MD
- *Consulting or Advisory Role: Roche, MSD*
- *Speakers' Bureau: Bristol-Myers Squibb, Roche, MSD, AstraZeneca*
- *Research Funding: Lilly, Roche*
- *Travel, Accommodations, Expenses: Bristol-Myers Squibb, MSD, Roche, AstraZeneca*

ALFRED I. NEUGUT, MD, PhD
- *Stock and Other Ownership Interests: Stemline Therapeutics*
- *Consulting or Advisory Role: Pfizer, Teva, Otsuka, United Biosource Corporation, EHE International*

DAVID G. PFISTER, MD
- *Consulting or Advisory Role: Boehringer Ingelheim*
- *Research Funding: Boehringer Ingelheim, AstraZeneca, Exelixis, Novartis, MedImmune, Merck*

MICHAEL A. POSTOW, MD
- *Honoraria: Bristol-Myers Squibb, Merck*
- *Consulting or Advisory Role: Amgen, Bristol-Myers Squibb*
- *Research Funding: Bristol-Myers Squibb (Inst)*
- *Travel, Accommodations, Expenses: Bristol-Myers Squibb*

S. VINCENT RAJKUMAR, MD
- *No Relationships to Disclose*

JONATHAN W. RIESS, MD, MS
- *Honoraria: Roche/Genentech*
- *Consulting or Advisory Role: Celgene, ARIAD, Clovis Oncology, Medtronic*
- *Research Funding: Onconova Therapeutics, Millennium (Inst), Novartis (Inst), Merck (Inst)*
- *Travel, Accommodations, Expenses: Roche/Genentech, Celgene*

ERIN SALO-MULLEN, MS, MPH, GCG
- *No Relationships to Disclose*

LYNN M. SCHUCHTER, MD

- *Research Funding: GlaxoSmithKline (Inst), Merck (Inst), Bristol-Myers Squibb (Inst)*

SCOTT M. SCHUETZE, MD, PhD
- *Honoraria: EMD Serono, Janssen*
- *Consulting or Advisory Role: EMD Serono, Janssen*
- *Research Funding: AB Science (Inst), Janssen (Inst), Threshold Pharmaceuticals (Inst), Amgen (Inst), ZIOPHARM Oncology (Inst), BioMed Valley Discoveries (Inst), CytRx Corporation (Inst), Plexxikon (Inst), Lilly (Inst)*

MANISH A. SHAH, MD
- *Consulting or Advisory Role: Lilly*
- *Research Funding: Lilly/ImClone (Inst), Gilead Sciences (Inst), Merck (Inst)*

SONALI M. SMITH, MD
- *Honoraria: Celgene, Janssen*
- *Consulting or Advisory Role: Genentech/Roche, Seattle Genetics, TG Therapeutics, Gilead Sciences, Seattle Genetics, Immunogenix, Pharmacyclics, NanoString Technologies, Genmab*

ZSOFIA K. STADLER, MD
- *Consulting or Advisory Role: Allergan (I), Genentech/Roche (I), Regeneron (I), Optos (I), Adverum (I)*

ROLAND B. WALTER, MD, PhD, MS
- *Consulting or Advisory Role: Amphivena Therapeutics, Covagen AG, AstraZeneca, Seattle Genetics, Pfizer, Celgene, Janssen, Agios, BiolineRx, Emergent BioSolutions*
- *Research Funding: Seattle Genetics, Amgen, Celator, CSL Behring, Amphivena Therapeutics, Abbvie, Arog, Pharmacyclics, Stemline Therapeutics, ADC Therapeutics, Covagen AG*
- *Patents, Royalties, Other Intellectual Property: First Named Inventor: Combination of epigenetic factors and bispecific compounds targeting CD33 and CD3 in the treatment of myeloid leukemia*

CONTINUING EDUCATION AND MAINTENANCE OF CERTIFICATION

PROGRAM OVERVIEW

The *ASCO Self-Evaluation Program*® (*ASCO-SEP*®) is a comprehensive resource designed to help physicians assess their level of knowledge in the various areas of oncology and provide a current understanding of cancer, its treatment, and the supportive care needed to optimize the quality of life for people with cancer. This program includes 22 chapters and a companion self-assessment tool with rationales covering the full range of topics in oncology, including major cancer types, epidemiology and cancer prevention, management strategies for elderly patients, clinical trial design and statistics, molecular biology, and an overview of biologic therapy.

TARGET AUDIENCE

ASCO-SEP® is targeted to fellows, practicing oncologists, and advanced practitioners. *ASCO-SEP*® is also appropriate for use as a self-assessment tool for individual professional development, or as a teaching tool for training and continuing education purposes.

NEEDS STATEMENT

Although cancer mortality rates decreased 26% in the United States between 1991 and 2015, cancer still remains the second leading cause of death and is expected to become the leading cause in the next few years.[1] Globally, cancer is seen as an increasing burden, with 14.1 million cases diagnosed and 8.2 million cancer deaths around the world in 2012, and an estimated 32.6 million people surviving five or more years post-diagnosis.[2] To meet this challenge, the options available in medical oncology to treat patients with cancer continue to grow in both breadth and complexity. Since the launch of the Fifth Edition of *ASCO-SEP*®, for example, there have been over seventy drug approvals and safety notifications from the U.S. Food and Drug Administration.[3]

ASCO-SEP® reflects within its chapters the state of oncology today. It is not meant to be used as a textbook and does not typically include future directions for research. Rather, this publication serves as a comprehensive overview of the subspecialty of oncology for use in review, self-assessment, and teaching activities; to validate current knowledge; and to improve overall competency in oncology.

LEARNING OBJECTIVES

Upon completion of this educational activity, participants will be able to:

- Apply the basic principles of epidemiology, molecular biology, clinical pharmacology, and clinical trial design to the practice of oncology;
- Incorporate appropriate imaging and diagnostic techniques to accurately identify and stage

neoplastic disease;

- Discuss current treatment options with patients diagnosed with cancer and recommend approaches based on current evidence; and
- Assess and mitigate potential symptoms affecting quality of life and relating to treatment toxicity, comorbidities, or late effects.

CME ACCREDITATION STATEMENT

In support of improving patient care, the American Society of Clinical Oncology is jointly accredited by the Accreditation Council for Continuing Medical Education (ACCME), the Accreditation Council for Pharmacy Education (ACPE), and the American Nurses Credentialing Center (ANCC) to provide continuing education for the healthcare team.

The American Society of Clinical Oncology designates this enduring material for a maximum of 55.5 *AMA PRA Category 1 Credits*™. Physicians should claim only the credit commensurate with the extent of their participation in the activity.

The program content has been reviewed by the Oncology Nursing Certification Corporation (ONCC) and is acceptable for recertification points.

ONCC review is only for designating content to be used for recertification points and is not for CNE accreditation. CNE programs must be formally approved for contact hours by an acceptable accreditor/approver of nursing CE to be used for recertification by ONCC. If the CNE provider fails to obtain formal approval to award contact hours by an acceptable accrediting/approval body, no information related to ONCC recertification may be used in relation to the program.

Total ILNA Points	55.5	

Abbreviation: ILNA, Individual Learning Needs Assessment.

MAINTENANCE OF CERTIFICATION STATEMENT

Successful completion of this CME activity enables the participant to earn up to 55.5 MOC points in the American Board of Internal Medicine's (ABIM) Maintenance of Certification (MOC) program. Participants will earn MOC points equivalent to the amount of CME credits claimed for the activity. It is the CME activity provider's responsibility (ASCO) to submit participant completion information to ACCME for the purpose of granting ABIM MOC credit.

For this course, ASCO will facilitate this submission via the *ASCO-SEP® 6th Edition* CME/MOC Assessment and Evaluation course on ASCO University® at university.asco.org/SEP.

DATE OF ORIGINAL RELEASE

The original release date for this material is May 1, 2018. The Continuing Medical Education credit availability expires May 1, 2020.

MEDIUM USED AND METHOD OF PARTICIPATION

The *ASCO-SEP*® program consists of text, images, written self-assessment items, and an online self-assessment component. After completing the book, the participant is encouraged to respond to questions about the content of the activity and complete an evaluation of the activity. This evaluation can be filled out online by visiting ASCO University® at university.asco.org/SEP. Please note that the passing rate for the activity self-assessment is 70%.

ESTIMATED TIME TO COMPLETE THE ACTIVITY

It is estimated that the time required to complete the entire self-evaluation program is 55.5 hours.

OBTAINING CONTINUING MEDICAL EDUCATION CREDIT AND MAINTENANCE OF CERTIFICATION POINTS

In order to receive a Continuing Medical Education (CME) certificate or Maintenance of Certification points, please complete the evaluation and complete the ABIM MOC submission form and/or click the CME certificate request button available through the *ASCO-SEP*® *6th Edition* Self-Assessment course on ASCO University® at university.asco.org/SEP. All participants will be granted automatic access to this course with their purchase of the book.

OBTAINING A CERTIFICATE OF PARTICIPATION OR CERTIFICATE OF COMPLETION

All nonphysician participants are welcome to submit a request for a Certificate of Participation, through the same evaluation and certificate request process, which may enable nonphysicians to apply their participation toward re-licensure. Please note, however, that all final decisions regarding the awarding of credits will be made by the licensing organization to which the credits were submitted.

Any participant can request a Certificate of Completion for this activity after completing the evaluation if they need a record of their activity usage but do not require documentation for continuing education purposes. Please note that this certificate does not award any *AMA PRA Category 1 Credit*™ or ABIM Maintenance of Certification points.

Both certificate types are also available through the *ASCO-SEP*® *6th Edition* CME/MOC Assessment and Evaluation course on ASCO University® at university.asco.org/SEP.

Questions can be directed to the ASCO Customer Service at 1-888-282-2552 or 703-299-0158, or by email at customerservice@asco.org.

UNLABELED USAGE STATEMENT

The information presented is that of the contributing authors and does not necessarily represent the views of the American Society of Clinical Oncology. Specific therapies discussed may not be approved and/or specified for use as indicated. Therefore, before prescribing any medication, please review the complete prescribing information including indications, contraindications, warnings, precautions, and adverse effects.

COMMERCIAL SUPPORT STATEMENT

No commercial support was received for this activity.

Recent Updates

- A recent study in China suggested that biannual screening with ultrasound and magnetic resonance imaging (MRI) of the liver for patients with cirrhosis resulted in the detection of early-stage hepatocellular carcinomas with a high chance of curative resection and favorable survival. (Kim SY, *JAMA Oncol* 2017)
- Compliance with HPV vaccination for children and adolescents has been poor. (Jeyarajah J, *Clin Pediatr* 2016)
- Studies have shown, and guidelines now indicate, that vaccination for HPV, at least for those ages 9 to 15, can be limited to two doses of the vaccine as opposed to three doses. (Laprise JF, *J Infect Dis* 2016)
- At this time, 9% of cancer in the West is attributable to obesity; a recent International Agency for Research on Cancer Working Group report identified 13 cancers for which there is sufficient evidence and an additional three for which there is limited evidence to link them to obesity. (Arnold M, *Cancer Epidemiol* 2016; Lauby-Secretan B, *N Engl J Med* 2016)

OVERVIEW

Epidemiology is the study of disease in populations, including its distribution, determinants, natural history, and survival. Rather than focusing on the individual patient, its perspective is that of public health. The traditional focus and goal of epidemiology has been the determination of the incidence and mortality rates of cancer in different populations and subgroups, as well as the identification of risk factors for the purpose of disease prevention and control through primary prevention and screening interventions. More recently, the methods of epidemiology have been applied to clinical questions, including the assessment of treatment outcomes, such as survival, and the long-term sequelae of cancer and its treatment.

Because of its emphasis on populations, epidemiology generally uses rates (with denominator populations—rates standardized to a population—and time frames) or relative measures rather than absolute figures to measure relevant statistics. Descriptive epidemiology—the usual starting point for epidemiologists—encompasses incidence and mortality rates, survival rates, and time trends. Incidence and mortality rates are commonly expressed as the number of newly diagnosed patients or deaths per 100,000 in the group at risk.

These rates are usually age- and sex-adjusted, meaning they are mathematically adjusted to a standard population to remove the effects of a population's age and sex distribution, which may change over time. Cancer is primarily a disease of older people. Even with the increase in the number of people in the United States who are age 70 or older during the past 30 years, the number of cancer cases occurring annually has increased or diminished only slightly because many cancers are age dependent. Furthermore, because women have a life

expectancy 7 years longer than that for men, there are substantially more older women than men, so a difference in sex distribution would magnify or diminish with age as well. Thus, adjusting cancer rates for age and sex removes their effects. As a result, a true change in cancer rates because of prevention, better treatment, or new etiologic factors must be assessed by increases or decreases in age- and sex-adjusted incidence and mortality rates.[1,2]

Survival is defined as the time from diagnosis to death. A commonly used measure is the proportion of people alive at 5 years after diagnosis (Table 1-1). For some cancers, such as breast or prostate cancer, this time frame may be too short, as recurrences and deaths may continue to occur long after 5 years; thus, for these cancers, 10-year survival may be a useful measure.

The American Cancer Society (ACS) publishes an annual estimate of the absolute numbers of new cancer cases and deaths.[2] These numbers are widely quoted, especially by the lay press. As noted above, it should be emphasized that these figures are not rates and are subject to fluctuations according to the age and sex distribution of the population. ACS also publishes time trends of incidence and mortality rates for major cancers during the past 75 years; these figures can give interesting insights into the inroads made by primary prevention, screening, and treatment and changes brought about by increases or decreases in risk factors (Figs. 1-1 and 1-2).[2]

Figure 1-2 shows the changes in mortality for selected cancers since 1930. It illustrates the dramatic rise in mortality for lung cancer that accompanied the rise in tobacco use in the 20th century, peaking in men around 1985 and then falling 20 years after the Surgeon General's reports of 1964 and 1968, which publicized the hazards of cigarette smoking and its link to lung cancer. As tobacco use has fallen to around 15% in males, the lung cancer incidence and mortality rates have decreased and will continue to fall for the foreseeable future. Another dramatic change has been the fall in gastric cancer, which was the leading cause of cancer mortality in the United States prior to World War II. Most experts attribute this decline to the increased availability of the electric refrigerator and the concomitant increased consumption of fresh meat, fruits, and vegetables, as opposed to smoked and cured foods, which contain nitrites and other potentially carcinogenic agents.[3] Among women, a dramatic fall in uterine cancer, primarily in the uterine cervix, occurred; this is attributable to the widespread use of the Pap smear for screening after World War II. A decline in breast cancer mortality after the mid-1980s has been attributed to a combination of mammographic screening and advances in treatment, such as the use of adjuvant therapy.[4,5]

Table 1-1 **Definition of Terms Related to Survival**	
Survival time	Time from the initial diagnosis of cancer to death
Disease-free survival	Time from complete remission to relapse of disease
5-year survival rate	Proportion of patients who are alive 5 years after the time of diagnosis
Disease-specific survival rate	Proportion of patients who have not died of the specific disease (does not take into account deaths unrelated to the disease)
Overall survival rate	Proportion of patients who are alive at a specific time after the diagnosis (takes into account all causes of death)

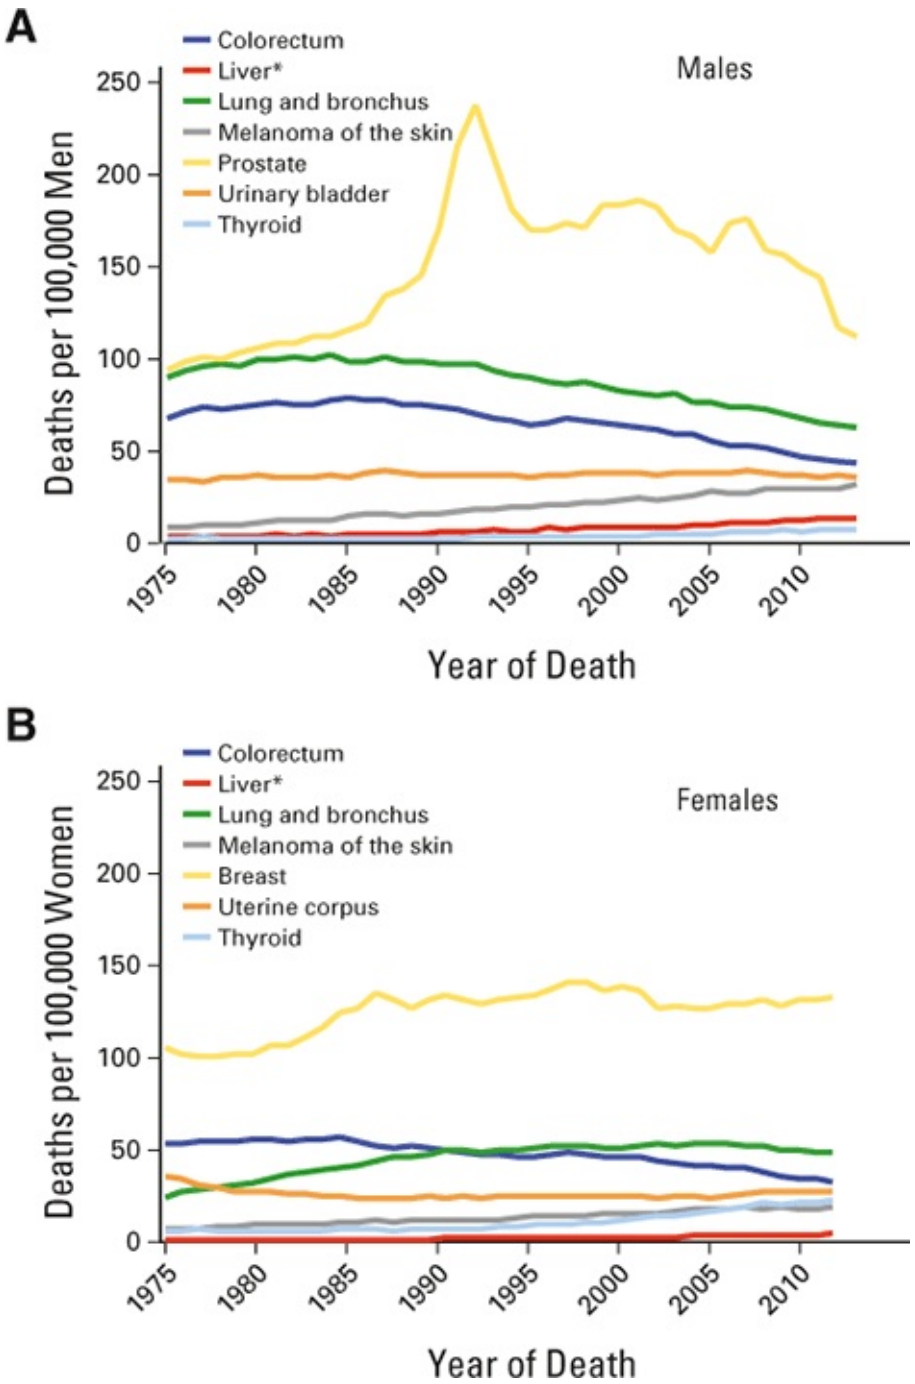

Fig. 1-1 Trends in U.S. incidence rates for selected cancers by sex (1975 to 2013).

Rates are age-adjusted to the 2000 U.S. standard population and adjusted for delays in reporting.

*Liver includes intrahepatic bile duct.

Reproduced from John Wiley & Sons, Inc. copyright 2017: Siegel RL, Miller KD, Jemal A. Cancer statistics, 2017. CA Cancer J Clin. 2017;67:7-30.

In the incidence rates shown in Fig. 1-1, the rise in prostate cancer incidence after 1985 is the most salient curve and reflects the introduction of prostate-specific antigen (PSA) testing to the clinical laboratory and its widespread use for screening. A rise in the incidence of cutaneous melanoma in both men and women has been attributed to both a change in sun exposure patterns in the population and increased skin screening.[6,7]

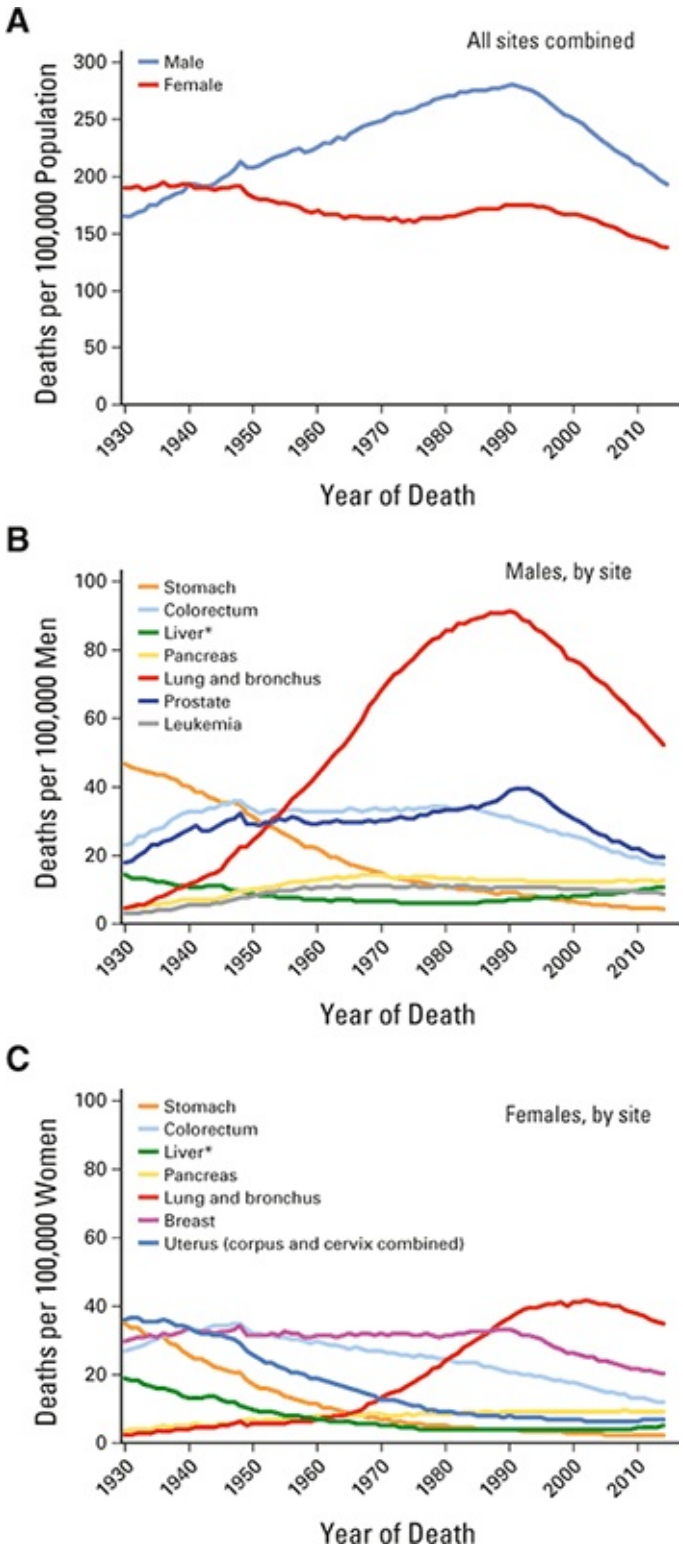

Fig. 1-2 Trends in death rates for selected cancers (1930 to 2014).

Rates are age-adjusted to the 2000 U.S. standard population. Because of changes in the *International Classification of Diseases* (ICD) coding, numerator information has changed over time. Rates for cancers of the lung and bronchus, colorectum, liver, and uterus are affected by these changes.

Mortality rates for liver, pancreas, and uterine corpus cancers are increasing.
*Liver includes intrahepatic bile duct.

KEY POINTS

- Epidemiology is the study of the distribution, etiology, and natural history of disease in populations.
- Epidemiology can include assessment of treatment outcomes, disease prevention, and disease screening.
- Epidemiology addresses these issues with a public health and public policy perspective as opposed to the perspective of the individual patient.

ASSESSING CANCER RISK

Much of epidemiology involves the assessment of cancer risk. A person can be at increased risk of cancer because of extrinsic or intrinsic factors, or a mix thereof.

- Extrinsic influences are factors outside the individual's own body, such as environmental pollutants, cultural/lifestyle habits, medication use, infectious factors, and diet.
- Intrinsic influences are factors unique to each person, such as genetics.
- To assess etiology, risk is usually reported relative to another population. For example, in 2005, the breast cancer mortality rate for black women was 35.6 per 100,000, and the rate for non-Hispanic white women was 25.8 per 100,000. During that period, the relative risk of death for black women was 1.38 times that of white women (35.6 divided by 25.8).[8]

From an epidemiologic perspective, an etiologic agent or risk factor is anything that increases the probability that an individual will develop the disease. These risk factors can include demographic characteristics (e.g., increasing age or race/ethnicity) or lifestyle and behavioral factors, such as smoking. They also include endogenous factors, such as genetic mutations that have been identified as predisposing a person for a disease, such as a deleterious *BRCA1* or *BRCA2* mutation. Most cancers undoubtedly arise from a combination of genetic and exogenous factors that interact to define certain demographic patterns. These patterns are generally recognized as the subpopulations in which a specific cancer is most likely to occur, such as breast cancer being more common in white, older, upper socioeconomic class women.

Certain genetic mutations occur with relatively high frequency, but they convey only a slight increase in the probability of the cancer occurring. These are referred to as "genetic polymorphisms" and are usually thought to provide increased susceptibility to an environmental

carcinogen or to modify risk in some other way. For example, genetic polymorphisms for the cytochrome P450 enzyme system that metabolizes carcinogens in cigarette smoke can cause variability in susceptibility to the effects of cigarette smoke. Better known are the uncommon genetic mutations that convey high risk for the development of malignancy, such as the mutations of the *BRCA* or familial adenomatous polyposis genes. *BRCA1* and *BRCA2* are genes with well-defined DNA sequences. Some *BRCA1* and *BRCA2* mutations increase the risk of breast and ovarian cancers and of certain other malignant diseases as compared with the risk for individuals without the mutations.[9] Advances in our knowledge regarding DNA methylation, histone modification, and other epigenetic phenomena may provide new insights into the effect of environmental factors on carcinogenesis and may suggest new targets for intervention.[10,11]

Knowledge regarding genetic risk factors for a particular cancer and the ability to predict the development of a particular cancer can help oncologists develop and select intervention options and to target such interventions to high-risk populations. Table 1-2 lists selected low-prevalence, high-penetrance genetic syndromes with their associated cancers. Discussion of specific genetic syndromes related to cancers of different organ sites can be found in the disease-specific chapters.

Knowledge of the risk factor also may present ethical dilemmas. Examples include whether to convey knowledge of risk to third parties in a patient's family, how to handle selection of embryos for implantation during in vitro fertilization on the basis of genetic testing, or whether such information can or should be made available to life insurance companies.[12] However, knowledge of the risk factor may allow for early interventions that could prevent disease or limit its severity.

To address risk from genetic factors, it is critical to take a good family history from patients with cancer. This is particularly important for younger patients, who are more likely to harbor a mutation. Such a history should include, at a minimum, a census of all first-degree relatives (i.e., parents, siblings, and children), with their sex, current age or age at death, any cancers diagnosed, and age at diagnosis. Family histories with cancers among the relatives that fit the pattern of a known genetic mutation or early age at diagnosis for certain cancers should lead to further evaluation and testing, possibly by a genetic specialist. The results of these evaluations have implications for the patient regarding risk of further cancers, as well as implications for other blood relatives in the patient's family. For further details on genetic cancer risk assessment and management, see Chapter 6 on Genetic Testing for Hereditary Cancer Syndromes.

Just as with genetic information, the clinician should make an effort to collect other relevant risk-factor information for patients with cancer or for healthy patients who are undergoing wellness exams. Risk information should include, at a minimum, tobacco and alcohol use, height and weight, family history, and occupational history. Other factors should be included as relevant to a specific symptom or diagnosis (e.g., exposure to organic solvents, such as benzene, in those diagnosed with leukemia; exposure to exogenous estrogens in women with postmenopausal bleeding; vaccination history in those with a human papillomavirus [HPV]–related disease). This information can be used to provide advice and guidance to the patient (e.g., regarding tobacco-use cessation), to identify patients at high risk for certain cancers, to guide early detection and prevention strategies, and to assist with the diagnosis of certain cancers.

Table 1-2 **Selected Hereditary Neoplastic Syndromes (Clinical Tests Available)**		
Syndromes	**Site(s) of Most Common Cancer(s)**	**Associated Gene(s)**
Hereditary breast and ovarian cancer	Breast, ovary	*BRCA1, BRCA2*
Cowden	Breast, thyroid	*PTEN*
Li-Fraumeni	Brain, breast, adrenal cortex, leukemia, sarcoma	*TP53*
Familial adenomatous polyposis	Large bowel, small bowel, brain (Turcot), skin, bone (Gardner)	*APC*
Hereditary nonpolyposis colorectal cancer	Colorectal and endometrium, also ovary, pancreas, stomach, small bowel	*MSH2, MLH1, PMS1, PMS2, MSH6*
Multiple endocrine neoplasia (MEN1)	Pancreatic islet cell, pituitary adenoma, parathyroid adenoma	*MEN1*
MEN2	Medullary thyroid, pheochromocytoma	*RET*
Neurofibromatosis type 1	Neurofibrosarcoma, pheochromocytoma	*NF1*
Von Hippel-Lindau	Hemangioblastoma, nervous system, renal cell	*VHL*
Retinoblastoma	Eye, bone	*RB1*
Melanoma, hereditary	Skin	*CDKN2/p16, CDK4*
Basal cell	Skin	*PTCH*
Hereditary diffuse gastric cancer	Stomach, lobular breast	*CDH1*

Chemoprevention and screening are options for certain high-risk populations, as is the modification of high-risk behavior. People at high risk for cancer often undergo intensive screening for the cancer in question. A screening test proven effective for average-risk patients is likely to be of even greater value in those at higher risk. In many circumstances, screening tests that have been shown not to be effective in screening for patients at average risk, such as CA125 for ovarian cancer, may be used by clinicians in screening patients at high risk, such as those with a *BRCA* mutation. But there would be no reason to assume it would be more beneficial for reducing mortality in high-risk patients than in those at average risk. If certain screening tests do reduce mortality, then they may be of more value in those at higher risk but would not necessarily be useful for individuals at average or low risk because of cost or other problems, such as high rates of false-positive results (discussed in more detail in the Cancer

Screening section).

Population categorization is important in epidemiology. Populations can be delineated by sex, nationality, culture, race and ethnicity, socioeconomic status, age, and other characteristics. This is the basis of descriptive epidemiology—along with time trends—and is used to provide clues to etiology. For example, a cancer that has a strong predominance in men may have a specific occupational component to it. Differences in incidence rates for various cancers found in both Japan and the United States have suggested hypotheses regarding diet and the consumption of green tea.[13]

Race and ethnicity are common ways of dividing populations in the United States. Note that race is a sociopolitical categorization.[14] The definitions used by U.S. investigators when generating population statistics are not formulated scientifically on the basis of characteristics such as genes, but rather reflect self-report by the individual and a mix of anatomical traits that often encompasses varying degrees of racial admixture. Much concern has arisen in the past 10 to 15 years with regard to outcome disparities, in particular for a wide range of cancers and for black patients compared with white patients. In some instances, these disparities also reflect differences in incidence, but in others, they may reflect differences in stage at diagnosis, access to treatment, or tumor biology. Race and ethnicity can correlate with other methods of categorization, such as poverty or prosperity, both of which may change the incidence of cancer and its related mortality.

Socioeconomic status and education also can be related to the risk of disease and death. Higher rates of breast cancer among white women in the San Francisco Bay area of California and on Long Island in New York were linked to a higher prevalence of professional women in those areas, who, as a cohort, are less likely to have a full-term pregnancy by age 30—a known risk factor for breast cancer.[15] Socioeconomic status also has been related to the type of treatment received and subsequent outcomes for various cancers, although this variable is heavily confounded with race/ethnicity and education.[16] In a classic study, Ayanian et al.[17] found that women with breast cancer who were uninsured or on Medicaid had a 49% (95% CI; 20, 84) and 40% (95% CI; 4, 89) higher risk of death, respectively, than women with private insurance. A similar effect for socioeconomic status was found for survival of patients with colorectal cancer[18] and for quality of life for prostate cancer survivors.[19]

In analytic epidemiology, observational studies are carried out to ascertain whether associations exist between an exposure and an outcome. Although a statistical association may exist between the two, there is always concern that this may reflect bias in the way the study was conducted or the presence of confounding factors. Confounding factors are factors associated with both the exposure and the outcome that can lead to an observed association, which is not truly a relationship between the two. For example, a study may show that asbestos workers have an elevated risk of lung cancer compared with the general population. However, one must keep in mind that asbestos workers may be heavier smokers than other individuals in the general population, and cigarette smoking is associated with lung cancer risk; thus, smoking may confound the observed association. Therefore, it is mandatory in a study that looks at this exposure and outcome to collect smoking information so that it can be statistically controlled and the individual effect of asbestos exposure can be appropriately measured.

Epidemiologic observational studies fall into two broad categories: cohort studies and case–control studies. Participants in cohort studies are categorized based on their exposure and then followed to determine whether the outcome develops differently in the exposed and unexposed groups. Case–control studies enroll both participants who have the outcome or disease under study and a control group of healthy participants. Both groups are then assessed for exposure.

Both cohort and case–control studies have advantages and disadvantages. In both types, one must try to avoid bias or directional error. For example, in a case–control study, a patient with cancer may be inclined to give a positive answer more frequently than a control participant to a question regarding smoking history—this is referred to as "recall bias."

As a general rule, cohort studies are preferred when the exposure is uncommon and the outcome is common, while case–control studies are preferable with uncommon outcomes. Since the incidence of most cancers, even the most common ones, is relatively low, case–control studies usually are used in cancer research. Their disadvantage is that they are often ambiguous on the temporal relationship between the exposure and the cancer. If you compare 100 patients with colon cancer to 100 patients without colon cancer for their intake of saturated fat, it can be unclear whether a decreased intake in the case patients is related to the disease or preceded the disease. In a cohort study, in which the exposure is ascertained before the cancer has developed, one can be more confident that any observed association preceded the development of disease. On the other hand, because of the low incidence of most cancers, a cohort study requires tens of thousands of subjects to be followed for years. One of the best-known cohort studies, the Nurses' Health Study, followed almost 90,000 nurses for 4 years to generate enough endpoints to determine the risk associated with dietary fat and breast cancer, the most common cancer.[20]

Molecular epidemiology—the use of sophisticated molecular and genetic markers in conjunction with the traditional tools of analytic epidemiology to investigate etiologic or other questions in cancer epidemiology—is a major field within cancer epidemiology. Biomarkers can be used to measure exposures or endpoints in place of the more traditional answers to questionnaires, and, in some instances, biomarkers can give a more objective, unbiased assessment.

Many contemporary studies use epidemiologic methodology to address clinical questions in oncology. When randomized trials may be difficult to conduct, observational studies, such as cohort or case–control studies, may be used to answer typical questions regarding the efficacy of a drug or the incidence of an adverse event from a drug and also to ascertain the cost-effectiveness of a particular intervention. Therefore, an understanding of these analytic tools is imperative for the modern oncologist.

KEY POINTS

- Cancer risk can be increased by both intrinsic and extrinsic influences.
- To assess etiology, a population risk is usually reported relative to another population.
- A key element in population statistics and rates is the presence of a denominator population.
- Germline genetic mutations, which confer an increased risk for a number of cancers, have been identified. Patients who may carry a germline heritable predisposition to cancer can be identified in the clinical setting if one is alert to the clinical manifestations of these syndromes and the patient's family history.
- A good clinical history can also identify key exogenous risk factors, such as tobacco, alcohol, hormonal, and infectious exposures and certain occupational risk factors.
- Cohort studies and case–control studies are key tools in the conduct of observational

research and the identification of risk factors for cancer.

- Differences in cancer risk exist across populations and individuals on the basis of various characteristics, such as race/ethnicity, gender, age, socioeconomic status, and education. Molecular and genetic biomarkers of cancer risk are an area of active epidemiologic research.

PATTERNS OF CARE, DISPARITIES, AND OUTCOMES RESEARCH

Although descriptive epidemiology and the determination of etiologic risk factors have been the traditional domains of epidemiology, the assessment of treatment outcomes in populations has become an important aspect of this discipline. Clinical trials demonstrate "efficacy" of a treatment. How well the intervention works in the population as a whole in routine practice is referred to as "effectiveness." A phase II clinical trial can demonstrate the efficacy of a treatment intervention (e.g., tumor shrinkage), and a phase III study compares two interventions to determine which is superior. Prevention trials usually require phase III studies to show efficacy.

The study of patterns of care or treatments that are already in clinical use is an aspect of outcomes research. Studies often demonstrate geographic and regional differences in the treatment of cancers. For example, for women with localized breast cancer, the decision to treat with lumpectomy and radiation therapy or with mastectomy may vary depending on the patient's geographic location.[21] Similar regional differences have been noted for prostate cancer screening and for the types of treatment used for localized prostate cancer.[22]

Health disparities generally can be defined as differences in outcomes related to a disease among one segment of the population compared with the general population. In current usage, the term is usually applied to subpopulations that are thought to be disadvantaged in some way, such as by race/ethnicity, increasing age, socioeconomic status, sexual orientation, rural residence, etc., and the public policy interest in disparities stems from an interest in finding avoidable and correctable causes for the disparities. For cancer-related disparities, such causes may reflect differences in risk-factor exposure, screening utilization, access to care, quality of care, or tumor biology.

The most notable example of disparities are the differences seen between blacks and whites in America with regard to cancer statistics. Estimates from the American Cancer Society in 2016 indicate that blacks had a lower projected lifetime risk for all cancers (40.8% for males, 34.3% for females) than whites (42.4% for males, 39.0% for females); despite this, blacks were at greater risk of cancer-related mortality for males (23.4% for black males vs. 22.8% for white males) and equal mortality for females (19.4% for blacks vs. 19.5% for whites).[23] Black patients are at increased risk of mortality from a wide variety of cancers.[24,25] As an example, differences in tobacco usage have been responsible for disparities in mortality from squamous cell carcinoma of the esophagus between black and white patients.[26] A study from the Southwest Oncology Group found persistent racial disparities for women with breast and ovarian cancers entered into phase III trials despite similar stage, treatment, and follow-up, suggesting that biologic differences may also play a role.[27]

Many of the disparities in outcomes among groups defined by race and socioeconomic status have been linked to differences in patterns of care. For example, treatment is less than optimal for a substantial proportion of patients with cancer who are poor or of certain ethnic backgrounds.[28] The reasons for these variations in care are complex. Some are the result of

sociocultural differences in attitudes toward therapy.[29] Patient–physician communication also can play a major role.[30] In other cases, poverty, lack of insurance, or underinsurance can make access to care difficult.[17,28,31] Logistical difficulties, such as a lack of adequate transportation to a treatment center, may play a role. Patients with severe comorbid disease or poor performance status may justifiably not be offered aggressive cancer treatments because these patients are at higher risk of a treatment-related morbidity.

To date, outcomes research on disparities has focused primarily on the identification of the circumstances under which significant disparities occur and their possible etiologies (e.g., whether they stem from biologic differences or from differences in access to care). Significant advances have occurred in this area over the past 15 years, and it is only now that interventions are beginning to be tested and to bear fruit. One good example is the New York City Department of Health and Human Services' efforts to provide colonoscopy screening to adults older than age 50. This effort has achieved a colonoscopy screening rate of 70% with no significant racial/ethnic disparities.[32] Similar mammography rates have also been achieved among racial/ethnic groups in many populations. Interestingly, although there remains a large gap between breast cancer mortality rates in whites and blacks, a recent report demonstrated that black women and white women in the United States now have nearly identical breast cancer incidence rates, possibly reflecting changes in socioeconomic status, age at first giving birth, and parity among black women.[33]

KEY POINTS

- Most clinical trials are designed to determine "efficacy," meaning how well the treatment works in a selected environment. Some larger trials and outcomes studies are designed to show "effectiveness," meaning how well the treatment works in the population as a whole.
- Epidemiologic methodology, used in the field of health outcomes research, has been active in determining areas where disparities in incidence and mortality exist and possible causes for these disparities. Having this information may lead to interventions.

CANCER PREVENTION

Prevention is intended to reduce cancer incidence and mortality. Primary cancer prevention is best defined as the use of interventions to reduce cancer incidence. Important to prevention is the fact that carcinogenesis is not a distinct event but rather a process that occurs over time. It is a cumulative continuum of discrete cellular changes resulting in uncontrolled proliferation and growth. Primary prevention involves interventions or manipulations of the genetic, biologic, and environmental factors in the causal pathway of carcinogenesis. Smoking cessation, sun avoidance, diet modification, weight loss and increased physical activity, cancer virus vaccination, and chemoprevention (e.g., tamoxifen for breast cancer prevention) are primary prevention activities.[34] Screening for asymptomatic cancers, which is intended to detect cancers earlier so that treatment can be introduced more promptly and effectively to reduce mortality, is referred to as "secondary prevention." This may be confusing, since the term *secondary prevention* is also frequently used to refer to prevention for disease survivors (e.g., tobacco cessation in lung cancer survivors). For some cancers, such as cervix cancer and

colorectal cancer, intraepithelial neoplasia is an intermediate step in carcinogenesis, and treatment of this condition is a form of cancer prevention.[35]

SMOKING CESSATION

Tobacco use is the most avoidable risk factor for cardiovascular disease, pulmonary disorders, and cancer. Smoking cessation and avoidance have the potential to save and extend more lives than any other public health activity. A smoker has a one in three lifetime risk of dying prematurely of a smoking-related disease. More human lives are lost because of cardiovascular disease caused by smoking than from smoking-related cancer. In addition to lung cancer, cigarette smoking has been linked to cancers of the upper aerodigestive tract (lip, oral cavity, pharynx, and larynx), esophagus, kidney, bladder, pancreas, small bowel, and colon.[36]

The risk from tobacco smoke is not necessarily limited to the smoker. Epidemiologic studies suggest that environmental tobacco smoke, often called “secondhand smoke” or “passive smoke,” may cause lung cancer and other pulmonary diseases in nonsmokers. The amount of smoke exposure and the degree of inhalation of cigarette smoke are correlated with the risk of mortality associated with lung cancer. Light and low-tar cigarettes are not safer because smokers tend to inhale them more frequently and more deeply. Compared with their nonfiltered counterparts, filtered cigarettes allow smaller particles to get into the peripheral parts of the lung and cause different histologic subtypes of cancer,[37-39] specifically adenocarcinomas. Those who stop smoking almost immediately stop increasing their risk of cancer, although it takes some time before their risk of cancer declines. Some carcinogen-induced gene mutations may persist for years. The use of e-cigarettes has been advocated by some as a substitute for regular cigarettes because of the much lower exposure to carcinogens; this remains a controversial approach to tobacco cessation, and it is unclear at present whether there is a total lack of risk from this form of smoking (discussed as follows).

The vast majority of adult American smokers begin smoking before age 18; two-thirds are nicotine-dependent in their high school years.[40] Therefore, communicating health messages to the pediatric and adolescent population is a major public health challenge. Studies show that a physician’s simple advice to avoid or quit smoking can improve the quit rate by two-thirds.[41] Despite this, a survey found that although more than 80% of oncologists assess their patients’ smoking behavior, fewer than 20% feel confident enough to intervene in this important area.[42]

Among the most effective smoking cessation interventions are governmental actions. Tax increases on cigarettes and restrictions on venues where smoking is permitted have been very effective in reducing smoking prevalence rates.[43] Current smoker rates are down to less than 20% in the United States, approaching 15%, and most tobacco-related cancers in this country now occur in former smokers. However, smoking remains a major factor globally, especially in Asia, and lung cancer is the leading cause of cancer mortality worldwide. Much concern has been raised in particular about smoking rates in India and China, and global efforts to reduce smoking rates are being increased.[44-47]

Smoking is an addiction. It is easier for light smokers—the less addicted—to quit. Experts believe that heavy smokers generally need an intensive, broad-based cessation program that includes counseling, behavioral strategies, and drug therapy. If drug therapy is needed, the recommended first-line therapies are nicotine-replacement therapy, bupropion, and varenicline, with clonidine and nortriptyline as possible second-line therapies.[41] Most Americans who successfully quit smoking do so on their own, without participation in an organized cessation program, but this process can be strongly enhanced by even a small amount of encouragement

from a health care provider. Smokers who stop completely are more likely to be successful than smokers who gradually reduce the number of cigarettes smoked or change to cigarettes containing lower amounts of tar or nicotine. The smoker who is quitting goes through a process with identifiable stages that include contemplation of quitting, an action phase during which the smoker quits, and a maintenance phase. As noted above, there now exist numerous effective strategies beyond counseling for advising and assisting the cooperative patient with his or her goals.[48,49]

Electronic cigarette (e-cigarette) use has recently been growing as another tool to enhance tobacco cessation. This device, which provides nicotine for the user who is addicted, but without the harmful carcinogenic exposures, is controversial in that some see it as an improvement over regular smoking, while others oppose its use because they feel that it provides a more acceptable alternative to total tobacco cessation.[50,51] In the short term, e-cigarettes do appear to be less harmful than regular cigarettes,[52] but long-term data on their carcinogenic or other harms are lacking[53]; the American Society of Clinical Oncology (ASCO) and the American Association for Cancer Research have released a policy statement recommending caution in their use until more evidence is available.[54]

Cigar smokers do not inhale, but the health risks associated with cigars are similar to those of cigarettes, especially the risks of oral cavity, laryngeal, esophageal, and lung cancers (the risk of lung cancer rises with increased depth of inhalation).[55] Smokeless tobacco, or chewing tobacco, is the fastest-growing segment of the tobacco industry and represents a serious health risk. Chewing tobacco has been linked to dental caries, gingivitis, oral leukoplakia, and oral cancer. In addition, the nitrosamines found in this product have been shown to cause lung cancer in animal studies. Esophageal cancer is linked to the carcinogens in tobacco that dissolve in saliva, are swallowed, and then come into contact with the esophagus. In certain parts of the world, smoking opium has also been associated with esophageal cancer etiology, presumably from the polycyclic aromatic hydrocarbons in the smoke.[56]

The use of marijuana is now legal in at least two states and millions of Americans are regular users. Most of the studies on marijuana use and cancer risk have focused on the upper aerodigestive tract and lung, but at present there is no clear-cut evidence of an association with marijuana use and these cancers.[57] The only cancer with which marijuana use has been consistently associated is testicular cancer, for which three case–control studies have shown an association, though a biologic explanation for this association has not been established.[58-60]

ALCOHOL

Alcohol ingestion is responsible for an estimated 5 to 10% of cancer cases in Europe and the United States, specifically for cancers of the oral cavity, pharynx, larynx, esophagus, liver, colorectum, and female breast.[61] The mechanisms by which it causes cancer vary from site to site.

The classical association of alcohol with carcinogenesis has been in the upper aerodigestive tract, where it has acted as a tumor promoter in association with tobacco use in the etiology of squamous cell malignancies. As tobacco use has declined, the incidence of these malignancies has declined as well, and it is not clear that alcohol ingestion alone has a significant carcinogenic effect for squamous cell malignancies of the oral cavity or esophagus. It does not appear to be carcinogenic alone for adenocarcinomas of the esophagus.[62]

Another tumor linked to alcohol consumption is hepatocellular carcinoma (HCC). HCC occurs in this context in heavy drinkers, as the causal chain involves the development of cirrhosis.[63] In

addition, alcohol use in moderation can act to enhance liver carcinogenesis caused by hepatitis viruses.[64]

While the relative risk is not high, but because breast cancer is so common, one of the most important effects of alcohol may be through breast cancer, in which even modest consumption is associated with elevated risk. The Nurses' Health Study found a 30% increased risk of breast cancer for women who drank 1.5 to 2 drinks per day (relative risk [RR], 1.28; 95% CI, 0.97, 1.69).[65] The Million Women Study, conducted in the United Kingdom, showed that women who consumed an average of one drink per day had a 12% increased risk of breast cancer (95% CI; 9, 14).[66] This effect appears to be due to increased estrogen and androgen levels in women consuming moderate levels of alcohol, though other plausible mechanisms have been proposed.[67]

Although there are some suggestive data, no clear associations have been established between alcohol intake and either colorectal or pancreatic cancer in the United States. It is worth mentioning that at moderate doses, many believe that alcohol ingestion has salutary effects on cardiovascular health.[68]

SUN AVOIDANCE

Results of epidemiologic studies show a correlation between the risk of nonmelanoma skin cancers (basal cell and squamous cell carcinomas) and cumulative exposure to ultraviolet radiation. Possible risk factors for melanoma include a propensity to sunburn, a large number of benign melanocytic nevi, and atypical nevi. A history of severe sunburns, especially in childhood and adolescence, is associated with increased risk of melanoma in adulthood. Recently, concern has been raised about the increasing use of indoor tanning and tanning beds, as it is increasingly clear that tanning beds increase the risk of melanoma.[69,70] Measures calling for their regulation have been proposed.[71]

Reduction of sun exposure through the use of protective clothing and a change in one's pattern of outdoor activities to avoid the most intense and direct sunlight have been advocated as ways to reduce the risk of skin cancer. Although past studies have been inconclusive, one randomized trial did confirm that sunscreen use can reduce the risk of melanoma.[72,73]

DIET MODIFICATION

Rates of cancers of the breast, colon, endometrium, and prostate are higher in North America and western Europe than in Asia. Immigrants from Asia and their offspring acquire a higher risk for these cancers after they have been in the United States for some time. These observations, as well as data from animal studies, are the basis for the hypothesis that dietary modification can significantly lower cancer risk for individuals in the United States.[74] Diet is a highly complex exposure to many nutrients and chemicals. Low-fat diets, which are usually low in red meat and high in fruits and vegetables, may render some protection through anticarcinogens found in vegetables, fruits, legumes, nuts, and grains. Potentially protective substances found in foods include phenols, sulfur-containing compounds, and flavones.[75] Although the cancer-prevention benefits are theoretical and not fully demonstrated, such a diet does lower the risk of cardiac disease. However, vitamins, minerals, or nutritional supplements in amounts greater than those provided by a good diet have not been demonstrated to be of value. Most randomized trials of vitamin supplements have not shown benefit in terms of prevention and, in some instances, have even shown harm (discussed in the section on Chemoprevention).

Despite correlative data, the dietary fat–cancer hypothesis has not been definitively

demonstrated. Case–control and cohort epidemiologic studies yield conflicting results. No prospective clinical trial has demonstrated that cancer can be prevented through lowering dietary fat or increasing fiber intake. Studies, including randomized trials, have consistently shown no effect of dietary fiber intake on colon cancer risk.[76,77] The Women's Health Initiative, which included a randomized trial with a low-fat diet intervention, also did not indicate an effect on risk of cancers of the breast or colon.[78,79] Nonetheless, a randomized trial of more than 2400 women with early-stage breast cancer showed that patients randomly assigned to a low-fat diet, in addition to standard adjuvant therapy, had a significantly improved survival compared with women on a regular diet (hazard ratio [HR], 0.76; 95% CI; 0.60, 0.98).[80]

WEIGHT REDUCTION AND PHYSICAL ACTIVITY

Many consider obesity to be the second most important risk factor for cancer in the United States, after tobacco.[81] In the West, 9% of cancers have been attributed to obesity.[82] Obesity represents the effects of an individual's net caloric intake, which is the amount consumed versus the amount expended through physical activity. Changes in either of these variables will impinge on the measure of obesity, thereby affecting cancer risk. Operationally, obesity is generally measured with the body mass index (BMI): (weight in kg)/(height in meters)^2. For U.S. adults, a BMI greater than 25 is considered overweight and obesity is defined as a BMI greater than 30.

Obesity affects cancer risk through a number of mechanisms, including hormone metabolism, thereby affecting breast, endometrial, colon, and prostate cancer risk, or by increasing esophageal reflux, which affects the occurrence of Barrett metaplasia and esophageal adenocarcinoma.[83-85] The International Agency for Research on Cancer (IARC) of the World Health Organization, a widely accepted source for the classification of cancer-causing agents, has linked 13 cancers to obesity with sufficient evidence that an elevated risk exists for those with an excess BMI (esophageal adenocarcinoma, gastric cardia adenocarcinoma, colorectal cancer, liver cancer, gallbladder cancer, pancreas cancer, postmenopausal breast cancer, uterine cancer, ovarian cancer, renal cell carcinoma, meningioma, thyroid cancer, multiple myeloma) and an additional 3 (fatal prostate cancer, male breast cancer, diffuse large B-cell lymphoma) for which there is limited evidence of a link.[85] Obesity also may increase cancer risk by inducing insulin resistance, hyperinsulinemia, oxidative stress, or inflammation—all of which are associated with increased cancer risk. These phenomena are generally observed in conjunction with obesity with an abdominal distribution of adiposity, and in those who are physically inactive—a syndrome known as metabolic syndrome.[86] There are also adipokines that arise in those who are obese, such as leptin, omentin, and others, that are associated with the promotion of cancer progression.[87]

ASCO recently issued a position statement recognizing the importance of weight and obesity and encouraging efforts to reduce weight in obese and overweight patients.[88] Although obesity does appear to be related to the incidence and prognosis of a number of cancers, there are relatively few data on whether weight loss can ameliorate the risk.[89] At least one recent study of approximately 37,000 postmenopausal women in the Women's Health Initiative showed that intentional weight loss among postmenopausal women was associated with a reduced risk of endometrial cancer; specifically, women who had a greater than 5% intentional weight loss over a 3-year period compared with women with a stable weight had a hazard ratio for endometrial cancer of 0.71 (95% CI; 0.54, 0.95) during an 11-year follow-up period. Those who gained weight had a higher risk of endometrial cancer.[90] Recent studies in this area have focused more

on weight loss among cancer survivors than on the use of weight loss to prevent cancer. Another ASCO statement has recommended that steps be taken to plan large-scale trials to assess the impact of weight loss and increased physical activity on cancer survivors in terms of reducing cancer recurrence and the incidence of new primary cancers.[91]

Physical activity has been studied for two decades and has been shown to be protective primarily for breast cancer and colorectal cancer, as well as for endometrial cancer and prostate cancer. Approximately 25% of the population is considered sedentary, and this lifestyle is considered to be responsible for up to 5% of cancers.[92] For those in whom these cancers develop, increases in physical activity appear to be helpful for survivors, although large, elegant phase III trials are lacking. Its strongest associations appear to be for cancers of the alimentary tract.[93,94]

OCCUPATIONAL CARCINOGENS

Since Percival Pott recognized an increased risk of scrotal cancer among chimney sweeps in 18th-century London, it has been understood that occupational exposures can increase the risk of certain cancers. The most important of the occupational exposures to carcinogens has been to asbestos, which is prominent among construction workers, pipefitters, and shipyard workers. Asbestos has been closely linked to the incidence of mesothelioma, lung cancer, and probably gastrointestinal tract malignancies. Another classic exposure has been radon inhalation, which occurs in uranium miners and potentially from exposure to radon in the home; radon increases the risk of lung cancer. Various other organic and aromatic chemicals are linked to the risks of leukemia and cancers of the urinary collecting system.

IONIZING RADIATION

As noted above, radon exposure through inhalation can be carcinogenic to the lungs. The effects of other sources of radiation exposure and radiation carcinogenesis, particularly on hematologic malignancies, have been well recognized since their discovery at the turn of the 19th into the 20th century. The most prominent source of such exposure stemmed from the atomic bomb explosions in August 1945 in Japan, and much of what we know about radiation dosimetry, latency, and carcinogenic effects comes from the careful and meticulous studies undertaken in the wake of those events. The other major source of radiation exposure is therapeutic radiation, mainly in the treatment of malignancies, hence the observation of second malignancies as a consequence. Exposure to ionizing radiation is associated with an increased risk of breast, lung, esophageal, and bladder cancers, leukemia, sarcoma, and brain tumors. It has also been linked to thyroid cancer when there is exposure to radioactive iodine, as in the aftermath of the Chernobyl nuclear accident, which released radioactive iodine into the atmosphere.[95] Efforts to reduce the use of radiation therapy, to minimize the size of treatment fields, and to avoid the use of an alkylating agent in combination with radiation therapy are well known in order to reduce the risk of second malignancies.[96,97]

Recently, concern has arisen about the increased use of diagnostic radiation exposure in medical care and its potential carcinogenic risks from cumulative exposure. On a population scale, sophisticated modeling has suggested that a significant increase in cancers can be anticipated from this widespread phenomenon.[98] An initial modeling study by Brenner and colleagues estimated that a single computed tomography (CT) scan in the pediatric population could raise the lifetime risk of abdominal cancer by 0.18% and of brain cancer by 0.07%—small but definitive.[99] A subsequent study in the United Kingdom confirmed that one extra leukemia

and one extra brain tumor would occur as a consequence of 10,000 head CT scans conducted in a pediatric population.[100] The risks were estimated to be similar for adults, though the evidence is not as strong. Furthermore, it is estimated that as high as 1.5 to 2.0% of cancers in the United States can now be attributable to diagnostic radiation.[101]

INFECTIOUS AGENTS

Virally induced cancer has been recognized since the early part of the 20th century, with the discovery of Rous sarcoma virus in chickens. In humans, several viruses, including hepatitis B (causing HCC), hepatitis C (HCC), Epstein–Barr virus (Burkitt lymphoma), and HPV (cervix cancer, other anogenital squamous cell malignancies, and head and neck carcinoma) have been clearly established as carcinogenic. An understanding of retroviruses has broadened our appreciation of other viral agents, such as human herpesvirus 8, which is associated with the development of Kaposi sarcoma.[102,103] In addition, the bacterium *Helicobacter pylori* (*H. pylori*) was found to be associated with certain gastric cancers, specifically non–cardia gastric carcinomas and mucosa-associated lymphoid tissue (MALT) lymphomas. These agents provide targets for vaccination as a means of primary prevention. This has been achieved for hepatitis B[104] and for HPV.[105,106] Since the hepatitis B vaccine was introduced in Taiwan in 1984, the risk of hepatoma (the leading cancer in Taiwan) has been reduced by more than 70% among those vaccinated.[107]

Another success has been the introduction of a vaccine for several subtypes of HPV. HPV vaccination is now recommended for young girls prior to becoming sexually active, which should reduce the incidence of cervix cancer by 70% or more. The Centers for Disease Control and Prevention (CDC) recommends the vaccine for boys as well. More recent studies have suggested that one or two vaccinations may suffice to give an adequate immune response versus the previously recommended three vaccinations; fewer vaccinations may increase compliance.[108,109] In fact, for the 9-to-14-year age group, the current recommendation is for two vaccinations given 6 to 12 months apart. As of 2016, HPV vaccination rates for children and adolescents, especially those in the target range of 13 to 17 years, were lagging, with vaccination rates for girls in the 55-to-60% range and for boys in the 35% range.[110] Because these same viruses are involved in other cancers, the incidence of anal, vaginal, penile, and oropharyngeal cancers may also decline, particularly if vaccination of boys becomes common.[111,112]

Another infectious cause of cancer is *Schistosoma haematobium,* which is strongly linked causally with urinary bladder cancer in Egypt.[113] The mechanism by which it causes cancer is poorly understood. Certain liver flukes are also associated with cholangiocarcinoma.

KEY POINTS

- Avoidance of carcinogens is the most efficient way to prevent cancer. Smoking is the cause of nearly one-third of all cancers in the United States. Other environmental influences, such as sun overexposure, certain chemicals, and certain infectious agents, are associated with cancer causation.
- Obesity is a risk factor for cancers, including endometrial, breast, colon, and esophageal adenocarcinoma.

- Vaccination against cancer-causing viruses can decrease the risk for developing cancer. Important examples include hepatitis B vaccination to decrease the risk of HCC and HPV vaccination to decrease the risk of cervix cancer.

CHEMOPREVENTION AND OTHER PREVENTIVE INTERVENTIONS

Cancer chemoprevention is the use of natural or synthetic chemical agents to reverse, suppress, or prevent carcinogenesis before the development of an invasive malignant process.[114] Cancers are prevented through chemoprevention or, in certain cases, through surgical removal of the organ at risk. Although the concept that pharmacologic agents can prevent a cancer is relatively new, the idea that a compound can prevent chronic disease is not. Antihypertensive agents are used to prevent heart disease, kidney disease, and stroke. Lipid-lowering drugs are prescribed to prevent coronary artery disease.

The initial genetic changes of carcinogenesis are termed “initiation.” This alteration can be inherited or acquired. Acquired genetic damage is the result of physical, infectious, or chemical carcinogens (Table 1-3). The influences that cause the initiated cell to change phenotypically are called “promoters.” Known promoters include androgens linked to prostate cancer and estrogen linked to breast and endometrial cancers. The distinction between the initiator and the promoter can sometimes blur; some components of cigarette smoke are referred to as “complete carcinogens” and serve as both initiators and promoters. Cancer can be prevented or controlled through interference with the factors that cause disease initiation, promotion, or progression.

Compounds of interest in chemoprevention include anti-inflammatory agents, antioxidants, differentiating agents, and hormone antagonists. A long-term, randomized, placebo-controlled clinical trial is generally necessary to establish the efficacy of a chemopreventive agent, and several large clinical trials have been completed.[115-117] As discussed in the following sections, tamoxifen,[115] raloxifene,[117] and aromatase inhibitors[118] have been shown to reduce the incidence of breast cancer. In addition, nonsteroidal anti-inflammatory drugs (NSAIDs), particularly aspirin, can reduce the occurrence of colorectal adenomas in various circumstances and have also been shown in long-term follow-up of randomized trials to reduce the incidence of colon cancer, breast cancer, and a variety of other cancers.[119,120] Finasteride and dutasteride reduce the incidence of prostate cancer.[116,121] Retinoids may inhibit head and neck cancers.[122] Selenium and vitamin E were shown not to reduce prostate cancer risk.[123] Other agents of interest for the chemoprevention of breast, colon, and other cancers have included calcium and vitamin D.[124,125] Most observational studies have not shown a benefit from the use of multivitamins. However, in a prospective, randomized trial of a daily multivitamin compared with placebo for U.S. male physicians, there was a small but statistically significant reduction in the incidence of cancer among the men assigned to multivitamin treatment.[126] Statin drugs have also been of interest for chemoprevention and may have some minor preventive activity for prostate cancer.[127] Table 1-4 contains a list of selected large, randomized chemoprevention trials that have been conducted.[115-118,121-123,126,128-153]

Table 1-3 **Examples of Initiators and Promoters of Cancer***

Carcinogen	Associated Cancer or Neoplasm
Alkylating agents	Acute myelocytic leukemia, bladder
Androgens	Prostate
Aromatic amines (dyes)	Bladder
Arsenic	Lung, skin
Asbestos	Lung, pleura, peritoneum
Benzene	Acute myelocytic leukemia
Chromium	Lung
Diethylstilbestrol (prenatal)	Vaginal (clear cell)
Epstein-Barr virus	Burkitt lymphoma, nasopharynx
Estrogens	Endometrium
Estrogen plus progesterone	Breast
Ethyl alcohol	Liver, esophagus, head and neck
Helicobacter pylori	Gastric
Hepatitis B virus	Liver
Hepatitis C virus	Liver
Human T-cell leukemia (HTLV)-1 virus	Adult T-cell leukemia, lymphoma
Human herpesvirus 8 (HHV-8)	Kaposi sarcoma
Human immunodeficiency virus (HIV)	Non-Hodgkin lymphoma, Kaposi sarcoma, squamous cell carcinoma of cervix
Human papillomavirus (HPV)	Squamous cell carcinoma of cervix, anogenital area, oropharynx
Immunosuppressive agents (azathioprine, cyclosporine, corticosteroids)	Non-Hodgkin lymphoma
Nitrogen mustard gas	Lung, head and neck, nasal sinuses
Nickel dust	Lung, nasal sinuses
Phenacetin	Renal pelvis, bladder
Polycyclic aromatic hydrocarbons	Lung, skin (especially squamous cell)
Schistosomiasis	Bladder (squamous cell)
Sunlight (ultraviolet)	Skin (squamous cell and melanoma)
Tobacco (including smokeless)	Upper aerodigestive tract, bladder, pancreas
Vinyl chloride	Liver (angiosarcoma)

*These agents are thought to act as cancer initiators or promoters for the cancers with which they have been associated.

CANCERS OF THE LUNG, HEAD, NECK, AND ESOPHAGUS

Tobacco smoking is the major cause of squamous cell cancers of the lung, head, neck, and esophagus. The risk of a second cancer of the lung, head, or neck is high—as great as 5% per year—for patients cured of these diseases. This is because of "field cancerization," meaning the carcinogens in tobacco smoke affect all tissues exposed to them. Even after smoking cessation, the tissues that have come in contact with smoke have residual molecular damage. For the esophagus, head, and neck, alcohol ingestion has an interactive effect with smoking. Other cancers of the lung (e.g., small cell and adenocarcinoma) also are associated with tobacco use. Very high rates of oral cancer are found in India because of the practice of chewing betel nuts. HPV infection, particularly the HPV-16 subtype, has been linked to oropharyngeal cancer[154]; a significant increase in incidence is anticipated in the coming years

as a consequence, though the introduction of HPV vaccination may reduce this effect.

Table 1-4 Randomized Chemoprevention Trials

Author (Year, Trial Name)	Study Setting/ Endpoint	Number of Patients	Intervention	Primary Outcome
Head and Neck				
Hong et al. (1990)[122]	Prior SCC	103	Isotretinoin (100 mg/m^2/day)	Positive (SPT)
Bolla et al. (1994)[128]	Prior SCC	316	Etretinate (50, 25 mg/day)	Negative
Khuri et al. (2006)[129]	Prior SCC	1190	Isotretinoin (30 mg/day)	Negative
Lung				
Virtamo et al. (2003; ATBC Cancer Prevention Study)[130]	Lung cancer	29,133	Carotene (20 mg/day); vitamin E (50 mg/day)	Negative
Omenn et al. (1996; CARET)[131]	Lung cancer	18,314	Carotene (30 mg/day); vitamin A (25,000 IU/day)	Negative
Pastorino et al. (1993)[132]	Prior NSCLC	307	Vitamin A (300,000 IU/day)	Positive (SPT)
van Zandwijk et al. (2000)[133]	Prior HNC, NSCLC	2,592	Vitamin A (300,000/150,000 IU/day); NAC (600 mg/day)	Negative
Lippman et al. (2001)[134]	Prior NSCLC	1,166	Isotretinoin (30 mg/day)	Negative

Abbreviations: AK, actinic keratosis; BC, breast cancer; BCC, basal cell carcinoma; bid, twice daily; CBC, contralateral breast cancer; DCIS, ductal carcinoma in situ; HNC, head and neck cancer; NAC, *N*-acetylcysteine; NSCLC, non-small cell lung cancer; qod, every other day; SCC, squamous cell carcinoma; SPT, second primary tumor.

In the United States, incidence rates for esophageal adenocarcinoma are among the most rapidly increasing since the late 1970s. This cancer occurs as a sequela of Barrett esophagus and is thought to be the result of gastroesophageal reflux disease.[155] Esophagogastroduodenoscopy often is used as regular surveillance to detect Barrett esophagus among patients with gastroesophageal reflux disease; however, there is no convincing evidence that demonstrates a reduction in the subsequent incidence or mortality of esophageal adenocarcinoma.

Rates of squamous cell carcinoma of the esophagus have been declining concomitantly with the rise of adenocarcinoma, reflecting the decline of smoking prevalence. Very high rates of

squamous cell carcinoma have been identified in a belt spanning central Asia from northern Iran to China,[156] with evidence implicating local risk factors, such as the ingestion of very hot tea and the smoking of opium.[56,155,157]

Several large-scale studies have been launched to assess potential chemopreventive agents for patients at high risk for lung cancer. The Alpha-Tocopherol, Beta-Carotene (ATBC) Cancer Prevention Trial[130] and the Beta-Carotene and Retinol Efficacy Trial (CARET)[131] were prevention trials that showed the importance of testing even seemingly harmless chemoprevention agents, such as vitamins, before widespread use. The results of both trials are in contrast to numerous observational studies. The ATBC trial enrolled Finnish male smokers between ages 50 and 69. Participants received alpha-tocopherol, beta-carotene, both, or placebo in a randomized, 2×2 factorial design. After a median follow-up of 6 years, there was a significant increase in lung cancer incidence and mortality for the participants who received beta-carotene. Alpha-tocopherol had no effect on lung cancer mortality. CARET enrolled 17,000 smokers and workers exposed to asbestos. Participants were randomly assigned to four arms and received beta-carotene, retinol, both, or placebo in a 2×2 factorial design. The results of the trial demonstrated a 28% increase in lung cancer and a 17% increase in deaths for the participants receiving beta-carotene. The reason for this outcome is uncertain; it occurred despite beta-carotene's role as both an antioxidant and a precursor to retinol.

Retinoids have shown some efficacy as chemopreventive agents for squamous cell malignancies of the head and neck, possibly by promoting terminal differentiation.[128] One study randomly assigned 103 patients with a first primary squamous cell carcinoma of the head and neck to the retinoid analogue 13-*cis*-retinoic acid or to placebo.[122] At 3 years, there were two second primary head and neck cancers in the intervention group compared with 12 in the placebo group ($p = 0.005$). However, because of toxicities, two follow-up phase III trials (in curatively treated NSCLC or head and neck cancer patients) were conducted using lower doses of 13-*cis*-retinoic acid and both had negative results.[129,134]

GASTRIC CANCERS

Heavy intake of smoked and cured meats and foods, limited consumption of fresh fruits and vegetables, and infection with *H. pylori* are associated with an increased risk of gastric cancer.[3] Gastric cancer was the most common cancer in the United States prior to World War II, but it is now much less common. This decline is thought to be the result of increased consumption of fresh meats, fruits, and vegetables and decreased consumption of cured/smoked foods. Experimental evidence of causality is scarce. Gastric cancer remains a very common malignancy in Japan, Latin America, China, and in parts of the developing world. A randomized trial in China of eradication of *H. pylori* infection with a combination of omeprazole, amoxicillin, clavulanate, and metronidazole did not show a reduction in subsequent gastric cancer incidence. Nonetheless, patients who had no gastric pathology at study entry did show a significant reduction in gastric cancer incidence in subgroup analysis.[158] The rates of cancer of the gastric cardia and esophageal adenocarcinoma are rising, and there is evidence to suggest that this may be a consequence of recent declines in the prevalence of *H. pylori.*[159] It is unclear why cancers of the proximal stomach and distal stomach may have inverse associations with the presence of *H. pylori.* Nonetheless, it may be one reason the incidence of distal gastric cancer in the United States has been declining while the incidence of proximal and gastroesophageal junction cancer incidence has been rising.[160]

COLON CANCER

Findings from epidemiologic studies suggest that NSAIDs, such as piroxicam, sulindac, and aspirin, have protective effects against adenomatous polyps and invasive cancer.[119,120,161] The results of prospective intervention trials have demonstrated positive effects on the prevention of polyps. Meta-analyses of randomized trials of aspirin designed to assess other endpoints have demonstrated that these agents prevent colon cancer.[119,120] In a placebo-controlled trial, high-dose celecoxib, a cyclooxygenase-2 (COX-2) inhibitor, was found to reduce the occurrence of colorectal polyps for patients with familial adenomatous polyposis.[162] A prospective, randomized trial of patients with a history of colorectal adenomas demonstrated a 20% reduction in recurrence of polyps for patients who received celecoxib.[163] Trials to assess COX-2 inhibitors and other NSAIDs for the prevention of colorectal adenomas have shown preventive benefits; however, these agents are associated with increased cardiovascular risk. Another study suggested that the risk of colon cancer can be reduced by doses of aspirin as low as 80 mg daily.[164] One observational study suggested that COX-2 inhibitors could improve mortality when used for patients with node-positive colon cancer.[165] This may be partly because of a beneficial effect on cancer metastasis.[166] Several subsequent studies have confirmed that aspirin used as an adjuvant therapy for stage III colon cancer could reduce mortality, and several randomized trials have been initiated.[167,168]

The Women's Health Initiative was a prospective, randomized study involving postmenopausal women randomly assigned to either combination estrogen plus progestin or to placebo. The rate of colorectal cancer was lower for women taking the study drug compared with those taking placebo.[169] However, the effect is offset by the cardiovascular and breast cancer risks associated with treatment with estrogen plus progestin.[170]

The results of epidemiologic studies indicate that diets high in calcium are associated with a lower risk of colon cancer. However, in the Women's Health Initiative study, calcium and vitamin D supplementation did not lower the incidence of colorectal cancer.[149] Evidence from prospective, randomized studies shows that calcium supplementation decreases the risk of recurrence of adenomatous polyps by approximately 20%.[171] However, a more recent trial failed to confirm these findings.[172] Calcium binds bile and fatty acids, reducing intraluminal exposure to compounds that cause hyperproliferation of the colonic epithelium.

Meat and fat intake have been linked to colorectal cancer incidence in numerous observational studies. Nonetheless, another Women's Health Initiative randomized, controlled trial found that there was no difference in the incidence of colorectal cancer among women assigned to a low-fat diet as compared with controls, though this study was relatively short-term and the difference in fat intake may have been too small.[79]

Colectomy is used as a preventive measure for individuals at extremely high risk of colon cancer as a result of a history of ulcerative colitis or of a genetic predisposition to the disease, such as familial adenomatous polyposis.[173]

No chemopreventive agent is currently recommended for the prevention of colorectal cancer for individuals at average risk, although the U.S. Preventive Services Task Force (USPSTF) has recently updated its guidelines for the use of low-dose aspirin for the prevention of coronary artery disease for adults at average risk to include the benefit of a reduction in colorectal cancer incidence as well.[174] The use of NSAIDs for patients with familial adenomatous polyposis following colectomy may be reasonable in conjunction with endoscopic screening.[162,175,176] For patients with hereditary nonpolyposis colon cancer, a randomized trial demonstrated that the use of 600 mg of aspirin for 2 years substantially reduced the incidence of colorectal cancer.[177]

LIVER CANCER

Hepatitis B–induced HCC is one of the most commonly diagnosed cancers in Asia. The use of hepatitis B vaccine has been advocated for its ability to prevent the disease. Reductions in the incidence of HCC in Taiwan and elsewhere suggest some success.[104] Although HCC is much less common in the United States, there has been a rise in incidence rates because of an epidemic of hepatitis C, which also leads to HCC, but for which no vaccine is available. For patients who are diagnosed with hepatitis C, new drug treatment to eradicate the hepatitis C virus may be expected to decrease the risk for HCC in the future. As a result, increased efforts at screening for chronic hepatitis C have been recommended; the CDC currently recommends screening all those born between 1945 and 1965 for hepatitis C, as well as those with a known elevated risk.[178]

BREAST CANCER

Tamoxifen has mixed estrogenic and antiestrogenic activities. It acts as an estrogen agonist in the endometrium and bone and as an estrogen antagonist in breast tissue. It also upregulates transforming growth factor beta, which decreases breast cell proliferation. In randomized, placebo-controlled trials to assess tamoxifen as adjuvant therapy for patients with early-stage breast cancer, this drug was found to prevent new cancers in the contralateral breast. The Breast Cancer Prevention Trial was a randomized, placebo-controlled study of more than 13,000 women at high risk for breast cancer. After a median treatment of 69 months, tamoxifen was found to decrease the risk of breast cancer by 49%. It also was associated with a reduction in bone fractures and with a small increase in the risk of endometrial cancer, stroke, pulmonary emboli, and deep vein thrombosis.[115,146] The Study of Tamoxifen and Raloxifene (STAR) trial compared tamoxifen with the selective estrogen-receptor modulator raloxifene for postmenopausal women; it was found that raloxifene decreased the risk of invasive breast cancer by rates similar to those for tamoxifen, but did not decrease the risk of noninvasive breast cancer. Compared with tamoxifen, raloxifene was associated with a lower risk of endometrial cancer, as well as with a lower risk of thromboembolic events and cataracts.[117] Further follow-up of the STAR trial for more than 6 years found that approximately 75% of the effectiveness of raloxifene versus tamoxifen was maintained with significantly less toxicity.[179] Another randomized trial showed that an aromatase inhibitor, exemestane, could also prevent breast cancer in postmenopausal women.[118] In a trial with 4560 postmenopausal women randomly assigned to exemestane or placebo, exemestane reduced the risk of breast cancer by 65% (95% CI; 0.18, 0.70) as compared with placebo. Similarly, the Second International Breast Cancer Intervention Study (IBIS-II) examined another aromatase inhibitor, anastrozole, in 1920 postmenopausal women and found the risk of breast cancer to be reduced by 53% (95% CI; 0.32, 0.68).[148] Despite these trials, uptake of these drugs for breast cancer prevention has been relatively low.[180]

The Women's Health Initiative was discontinued early in part because of the increased risk of breast cancer (odds ratio, 1.26) among women who were postmenopausal and who were taking active hormone-replacement estrogens with progestins.[181] A parallel trial of estrogen alone compared with placebo for women with a prior hysterectomy did not show an increased risk of breast cancer among women taking estrogen.[182] An analysis of the Women's Health Initiative trials concluded that there was no overall benefit of postmenopausal estrogens for women, except perhaps for short-term reduction of hot flashes.[183]

Prophylactic bilateral mastectomy to prevent breast cancer has not been assessed in a

randomized trial. In a prospective series of 139 women at high risk for breast cancer because of deleterious germline *BRCA1* or *BRCA2* mutations, 76 chose prophylactic bilateral mastectomy and 63 chose close surveillance. At 3 years, no breast cancer was diagnosed in those who chose surgery; eight women in the surveillance group had been diagnosed with breast cancer.[184] This study was small, of short duration, and by design, prone to selection biases. However, the observation that the short-term risk of breast cancer appears to be lower for women with certain *BRCA1* and *BRCA2* mutations who choose prophylactic mastectomy has been confirmed in other studies.[185,186] Because this surgery leaves some breast tissue behind, a patient's risk is not reduced to zero. When coupled with prophylactic bilateral salpingo-oophorectomy, ovarian cancer risk is markedly decreased, and there is an added benefit for breast cancer prevention.[186] Retrospective analysis of mastectomies for 214 women at high risk for breast cancer because of a family history suggests that prophylactic mastectomy can lead to a 90% reduction in risk.[187] One large study of patients from 11 centers investigated 1079 women with deleterious *BRCA* mutations and compared those who self-selected salpingo-oophorectomy with those who did not. With 3 years of follow-up, the prophylactic surgery was associated with an 85% reduction in the risk of gynecologic cancer and a 72% reduction in the risk of breast cancer in the *BRCA1* group, but there was no clear benefit for *BRCA2* carriers.[188]

A Cochrane review concluded that bilateral prophylactic mastectomy for those at very high risk for breast cancer (e.g., those with deleterious *BRCA* mutations) was effective in reducing the incidence and subsequent mortality from breast cancer.[189] One study has suggested that prophylactic bilateral oophorectomy in this setting would prevent at least 80% of ovarian cancers as well.[190]

PROSTATE CANCER

Androgens stimulate prostate cell proliferation and, in laboratory animals, cause prostate carcinogenesis. Finasteride decreases androgenic stimulation of the prostate by inhibiting 5-alpha reductase. This enzyme, which is found in high amounts in the prostate, converts testosterone to the more potent dihydrotestosterone. Finasteride was tested as a preventive agent for prostate cancer in the Prostate Cancer Prevention Trial—a 10-year, randomized, placebo-controlled study involving 18,000 men age 55 or older. Results of the study showed that this drug was associated with a 24.8% reduction in the risk of prostate cancer during the treatment period. There were some initial concerns regarding an observed increased incidence of high-grade tumors that developed while patients were treated with finasteride.[191] Later reanalyses showed that these observations were a result of the statistical methods used and that there were no true increases in high-grade tumors.[192]

A study of another 5-alpha-reductase inhibitor, dutasteride, also found a protective effect against prostate cancer.[121] Long-term follow-up of the finasteride study showed that, despite the reduction in incidence of prostate cancer, there was no improvement in overall survival.[193] Although finasteride reduced the incidence across all Gleason grades, it reduced the prevalence of lower-grade tumors disproportionately. This raises the interesting question of whether the use of a chemopreventive agent is worthwhile solely for incidence reduction if a reduction in mortality does not accompany it.

Testosterone-replacement therapy (TRT) has also become more popular over the past decade. As many as 3% of men older than age 50 receive some form of it. As a consequence, the question of its relationship to prostate cancer risk has been raised. No cohort study large

enough to adequately address the question has been conducted to date, but several small studies have shown no evidence of an increase in prostate cancer risk associated with TRT, nor has there been evidence of progression of existing prostate cancer induced by the concomitant use of TRT.[194]

Findings from epidemiologic studies indicate a correlation between a high intake of antioxidants, such as selenium and vitamin E, and a lower risk of prostate cancer. The results of a small, randomized skin cancer prevention trial of selenium compared with placebo showed a significant decrease in the number of prostate cancers among men treated with selenium compared with men receiving placebo.[195] Eight years into the ATBC Cancer Prevention Trial, which enrolled 29,000 men in Finland, 99 cases of prostate cancer were reported among men receiving vitamin E and 151 cases were reported among men taking the placebo (RR, 0.66; 95% CI; 0.52, 0.86).[196] The cancers diagnosed were almost all detected as a result of the workup of symptoms because there is no routine prostate cancer screening in Finland. However, this difference had disappeared by the 18-year follow-up of this study.[197]

The prostate cancer findings in both of these trials were incidental results of a secondary analysis. A prospective, randomized, placebo-controlled trial—the Selenium and Vitamin E Cancer Prevention Trial (SELECT)—assessed these drugs in 32,400 participants and reported no reduction in prostate cancer incidence.[123]

GYNECOLOGIC CANCER

Conization, loop electrosurgical excision procedure (LEEP), cryosurgery, electrocauterization, laser ablation, or even hysterectomy can be used to treat cervix dysplasia or intraepithelial neoplasia, both of which are precursors to invasive cervix cancer. Vaccines for HPV have been approved for young girls and boys and should lower the incidence of cervix cancer because they have already been shown to decrease the incidence of intraepithelial neoplasia.[198]

Studies have shown a strong protective effect against ovarian cancer for oral contraceptive hormone preparations.[199] However, there is no current recommendation for their routine use for prevention. For women at very high risk for ovarian cancer because of a *BRCA* genetic mutation, bilateral salpingo-oophorectomy after completion of childbearing remains the treatment of choice (including fallopian tube removal).[200] Women with Lynch syndrome, associated with large and small bowel polyps and cancers, are at elevated risk for endometrial cancer and ovarian cancer. For these women, prophylactic hysterectomy and bilateral salpingo-oophorectomy may also be recommended.

KEY POINTS

- Drugs and vitamins to be used for prevention need to undergo the same rigorous assessment of efficacy and toxicity as do therapeutic agents prior to recommendation. Indeed, because they are generally administered to a healthy population, their toxicity profile must be far safer than those of drugs used in the therapeutic setting.
- Most randomized trials of vitamins or nutritional supplements as chemopreventive agents have had negative results.
- Hormone inhibitors for hormone-dependent cancers, including tamoxifen and aromatase inhibitors for breast cancer and antiandrogens for prostate cancer, have proven

efficacious as preventive agents and may have a role in clinical practice, though the benefits must be weighed against potential side effects.

- Aspirin and other COX-2 inhibitors have also been shown to have preventive effects against colorectal cancer in particular, and possibly against other malignancies as well.
- The identification of infectious agents, such as hepatitis B and HPV, as causes of cancer has had profound consequences in terms of providing highly effective interventions, specifically vaccinations, that have led not just to reduced mortality but also to reduced incidence of their associated cancers (HCC, cervical and other anogenital cancers).

CANCER SCREENING

Cancer screening is an attempt to detect cancer or its precursors early in asymptomatic individuals, with the goal of intervening and decreasing morbidity and mortality. A screening test is not typically diagnostic for cancer; rather, it determines whether cancer might be present and whether additional testing, including a biopsy and staging, is necessary. To be of true benefit, screening must lead to earlier treatment that offers a better outcome, usually reduced mortality, compared with treatment that would occur at the onset of symptoms. Because of various biases (discussed in the following section), the ideal evaluation of a screening technology is through the assessment of disease-specific and overall mortality in a prospective, randomized clinical trial.

Early detection of an apparently localized cancer does not automatically confer benefit. There are screening tests for some diseases that have been found to be of no benefit, such as chest x-ray screening for lung cancer or urine screening for vanillylmandelic acid to detect neuroblastoma.[201] A number of common screening tests used in the United States offer undetermined benefits.

POTENTIAL BIASES

The evaluation of the benefits of a screening test is subject to several biases, including lead time, length, and selection biases, the influences of which are reduced in a randomized trial.[202] These biases can lead one to believe that there is a benefit to a screening test when, in truth, there is none; there may even be a net harm. Screening, regardless of benefit, will usually increase the number of specific cancers diagnosed. It also can produce a shift in stage toward lower stages; this will appear to improve survival statistics without reducing mortality (i.e., the number of deaths from a given cancer per number of people at risk for the disease). In such a case, the apparent duration of survival, measured from the date of diagnosis, would increase without lives truly being saved or life expectancy being changed.

When pure lead-time bias occurs, survival—the time from diagnosis to death—is increased, but treatment does not prolong life. Patients do not live longer; they are merely diagnosed at an earlier date. The screening test only prolongs the time the individual is aware of the disease and the time the individual is treated as a patient.

Length bias occurs when slow-growing, less-aggressive cancers are detected during screening. Cancers diagnosed as the result of the onset of symptoms between scheduled screenings are, on average, more aggressive, and treatment outcomes are not as favorable. An extreme form of length bias is termed “overdiagnosis bias,” or detection of pseudo-disease. Some undetected, slow-growing tumors fulfill the histologic criteria for cancer but would never

be clinically significant or cause death. This phenomenon is compounded by the fact that the most common cancers are most frequent among older people. Other competing causes of death, such as heart disease, become more relevant. This is particularly common in prostate cancer.

Selection or volunteer bias must be considered when assessing the results of any clinical trial. The group most likely to seek entry in the study may differ from the general population to which the study results might be applied. In an assessment of a group of individuals undergoing screening, individuals may have volunteered because of a particular risk factor not found in the larger population, such as a strong family history. In general, volunteers are more health-conscious and are likely to have better prognoses or lower mortality rates regardless of actually being screened; this trend is referred to as the "healthy volunteer effect."

ASSESSMENT OF SCREENING TESTS

Because of the biases described above, a screening intervention is best evaluated in a population-based, randomized, controlled screening trial with disease-specific mortality as the endpoint.[202] Because gold-standard randomized screening trials for cancer are perforce large (often involving thousands of people) and last for years, less-definitive study designs often are used to estimate the efficacy and effectiveness of screening practices. In order of strength of evidence from nonrandomized studies, efficacy can by assessed using the following:

- Findings of internally controlled trials in which intervention-allocation methods other than randomization are used, such as allocation determined by birth date or by date of clinic visit;
- Results of cohort or case–control analytic observational studies;
- Findings of multiple time series studies, with or without the intervention; and
- Opinions of respected authorities based on clinical experience, descriptive studies, or consensus reports of experts.

The last form of evidence is the weakest, because even experts can easily be misled by the biases previously described.

POTENTIAL HARMFUL EFFECTS

Subjects can be harmed as a result of screening. A harmful effect can be associated with the test itself, the workup of positive results of screening tests (both true-positive and false-positive results), and injuries from the treatment of true-positive results. Screening can detect some cancers that would never have caused medical problems; the unnecessary treatment of these cancers can be harmful. In addition to the aforementioned adverse effects of screening, there are the financial and emotional costs associated with screening and with all of the extra tests and treatments.

ACCURACY

The accuracy of any medical test is usually described using four indices: sensitivity, specificity, positive predictive value, and negative predictive value. The results of screening tests can be classified into four categories. Definitions and calculations for these terms are provided in Tables 1-5 and 1-6. Sensitivity and specificity are relatively independent of the underlying prevalence or risk of the population being screened, but the positive and negative predictive

values are highly dependent on prevalence (Table 1-7). In other words, screening is most beneficial, efficient, and economical when targeting a cancer common to the general population or groups with a high prevalence (or high risk) of the specific disease being screened. Sensitivity need not be extremely high (Table 1-7). However, it is worth reiterating that the key criterion for the public health recommendation of a screening test is that it is able to reduce cancer mortality.[203]

Table 1-5 Types of Results of Screening Tests

	Condition Present	Condition Absent
Positive Results	True positive (A)	False positive (B)
Negative Results	False negative (C)	True negative (D)

A screening test that is not efficacious in reducing mortality in an average-risk population does not become efficacious if used in a high-risk population. Conversely, if a screening test is efficacious in reducing mortality, it is certainly preferred to use this test for higher-risk populations (e.g., those with family history) or as a lung cancer screening test in smokers, but this is because the yield will be higher, and thus the cost-effectiveness and, more importantly, the positive predictive value will be better (i.e., there will be fewer false positives). But if the screening test is not effective (i.e., does not reduce mortality), it will also not reduce mortality in higher-risk populations and should not be used. A good example is chest x-ray screening, which has been shown not to reduce lung cancer mortality. It would not work any better in heavy smokers or asbestos workers, and it should not be used in those populations either. The Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial recently demonstrated that CA125 and transvaginal ultrasound screening are not effective in reducing mortality from ovarian cancer (discussed as follows). Thus, despite their significantly higher risk, the use of such screening would also not be indicated in *BRCA* carriers.

Table 1-6 Indices for Describing the Accuracy of Screening Tests

Term	Definition	Ability of Test	Equation
Sensitivity	Proportion of people with the disease who have a positive result on a screening test	To detect disease when it is present	A / (A + C)
Specificity	Proportion of people who do not have the disease who have a negative result on a screening test	To correctly identify the absence of disease	D / (B + D)
Positive predictive value	Proportion of people with a positive result on a screening test who actually have the disease	To accurately predict the presence of disease	A / (A + B)
Negative predictive value	Proportion of people who have a negative result on a screening test who truly do not have the disease	To accurately predict the absence of disease	D / (C + D)

Abbreviations: A, true-positive result; B, false-positive result; C, false-negative result; D, true-negative result.

Table 1-7 Influence of Prevalence on Predictive Value

Positive Predictive Value (PPV) for a Disease with Prevalence of 5 Affected Individuals per 1000 Population			Positive Predictive Value for a Disease with Prevalence of 1 Affected Individual per 10,000 Population		
	Sensitivity			Sensitivity	
	0.8	0.95		0.8	0.95
Specificity	PPV	PPV	Specificity	PPV	PPV
0.95	7%	9%	0.95	0.2%	0.2%
0.999	80%	83%	0.999	7%	9%

KEY POINTS

- Evaluation of the benefits/efficacy of a cancer screening test is far more complicated than simply performing the test and detecting localized cancers.
- The biases of screening are volunteer selection, lead time, length, and overdiagnosis. These biases can make a screening test appear beneficial when there is actually no benefit, or they may even cause harm.
- To offset these biases, a randomized trial is the best way to assess a screening test with the endpoint of reduction in cancer-related mortality.
- While not the metrics by which to decide whether a screening test should be used on a large scale, sensitivity, specificity, and positive predictive value can be important measures of the efficiency of a screening test and can inform the clinician about the rate of false positives and false negatives.

SCREENING FOR SPECIFIC CANCERS

Results from well-executed studies show convincing evidence that screening for cervix, colorectal, and breast cancers is beneficial at certain ages for people at average risk. Although special surveillance of individuals at high risk for some specific cancers because of family history or genetic risk may be prudent, few studies have been carried out to assess its true worth. Lung cancer screening with low-dose CT imaging has also been approved and recommended for those at elevated risk because of heavy smoking.

A number of organizations have evaluated certain screening tests and considered whether to endorse routine use of such measures. The USPSTF[204] and the Canadian Task Force on Preventive Health Care[205] each published screening recommendations after a rigorous review process. Each recommendation is made with a thorough, structured evaluation of the literature by screening experts. The ACS publishes the most commonly quoted screening guidelines (Table 1-8).[206]

BREAST CANCER

Studies of breast self-examination have not shown that this practice decreases mortality.[207] The results of the largest randomized, controlled study of breast self-examination reported to date showed both an increased rate of biopsy and enhanced detection of benign lesions, but little or no stage shift and no reduction in breast cancer mortality.[208] As a result, the ACS no longer recommends breast self-examination as a routine screening test.[206] Findings from several randomized trials indicate that screening women older than age 50 who are at average risk using mammography alone or mammography and clinical breast examination every 1 to 2 years decreases mortality by 20 to 30%. Each trial has been criticized for a certain aspect of its design, but there is power in the consistency of the observations.[209] A recent population analysis from Great Britain estimates that the introduction of mammographic screening to the United Kingdom starting in 1991 for women ages 49 to 64 years has led to an overall reduction in breast cancer mortality of 21%.[210]

Table 1-8 **Screening Recommendations for Asymptomatic Patients with Normal Risk**[206]

Test or Procedure	U.S. Preventive Services Task Force	Canadian Task Force on Preventive Health Care	American Cancer Society
Fecal occult blood testing (FOBT) for colorectal cancer	Annual FOBT or fecal immunochemical test (FIT), starting at age 50	FOBT or FIT every 2 years, starting at age 50	Annual FOBT or FIT, starting at age 50 (FIT preferred)
Flexible sigmoidoscopy for colorectal cancer	Flexible sigmoidoscopy every 5 years, starting at age 50	Flexible sigmoidoscopy every 10 years, starting at age 50 or older	Flexible sigmoidoscopy every 5 years, starting at age 50; consider combining with annual FOBT or FIT
Double-contrast barium enema for colorectal cancer	No recommendation	No recommendation	Every 5 years, starting at age 50
Colonoscopy for colorectal cancer	Every 10 years, starting at age 50	Insufficient evidence	Every 10 years, starting at age 50
CT colonography for colorectal cancer	Every 5 years, starting at age 50	Insufficient evidence	Every 5 years, starting at age 50
Digital rectal examination (DRE)	No recommendation	Poor evidence to include or exclude for men older than age 50	No recommendation
Prostate-specific antigen (PSA) and DRE for prostate cancer	Insufficient evidence to recommend	Insufficient evidence to include PSA in periodic health exam (PHE); poor evidence to include or exclude DRE from PHE	Shared decision between physician and patient. Annually, starting at age 50 in men with a life expectancy of 10 or more years
Pap test for cervix cancer	Starting at age 21, Pap smear every 3 years from age 21 to age 65; alternatively, Pap smear combined with HPV testing every 5 years, starting at age 30	Starting at age 25, screen every 3 years to age 69	Starting at age 21, screen every 3 years with conventional Pap tests or liquid-based Pap tests; at or after age 30, women with three normal tests in a row may screen every 3 years with cervix cytology alone, or every 5 years with HPV DNA test plus cervix cytology; women age 65 or older who have had three or more normal Pap tests and no abnormal tests in the past 10 years and women who have had a total hysterectomy stop cervix cancer screening
Breast self-examination (BSE) for breast cancer	Recommends against clinicians teaching women how to perform BSE	Insufficient evidence to make recommendation	No longer recommended
Clinical breast examination (CBE) for breast cancer	Insufficient evidence to recommend adding over and above mammography	No longer recommended at any age	No longer recommended at any age
Mammography for breast cancer	Every 2 years for women ages 50 to 74; screening before age 50 should take into account patient context and patient values regarding specific benefits and harms	Mammography every 2–3 years for women ages 50 to 74	Annually starting at age 45. Women ages 40-44 years should have the opportunity to begin mammographic screening. Women 55 or older should transition to biannual screening; clinical breast exam not recommended
Low-dose CT (LDCT) scan for lung cancer	For those ages 55 to 80 who have a 30-pack-year smoking history who currently smoke or who have quit within the past 15 years, annual LDCT	For those ages 55 to 74 with a 30-pack-year smoking history who currently smoke or who have quit within the past 15 years, annual screening up to three consecutive times	For those ages 55 to 74 with a 30-pack-year smoking history who currently smoke or who have quit within the past 15 years, discuss potential benefits and harms of screening and emphasize smoking cessation

*These recommendations are for the general population—asymptomatic people who have no risk factors, other than age or gender, for the targeted condition. Abbreviations: CT, computed tomography; HPV, human papillomavirus.

Experts disagree on whether women of average risk between ages 40 and 49 benefit from screening (Table 1-8). A meta-analysis of seven large randomized trials showed no benefit from mammography screening for women in this age group when assessed 5 to 7 years after trial entry.[211] There was a small benefit for women at 10 to 14 years after entry, which may have been the result of screening these women after they turned 50.[212] There is no consensus on the age at which to cease screening. A reanalysis sponsored by the USPSTF suggested that screening before age 50 was not necessarily beneficial.[213] Although there was a potential 18% reduction in mortality, the number needed to screen to achieve this and the concomitant number of false positives that needed to be evaluated were so high that the USPSTF argued that the risk:benefit ratio for screening before age 50 was not worthwhile. More recently, the ACS also amended its longstanding screening guidelines to recommend that screening for women at average risk begin at age 45, while women age 55 or older undergo mammography biennially.

In addition, the ACS no longer recommends clinical breast examinations.[206,214]

The results from outcomes studies show that there is substantial variation among U.S. radiologists regarding recommendations for additional testing or biopsy. This disparity is especially notable among younger women. In large cohorts, nearly half of all women between ages 40 and 49 screened annually for 10 years will have false-positive mammograms necessitating repeat mammography, ultrasound examination, MRI, or biopsy. In addition, the diagnosis of ductal carcinoma in situ has risen dramatically since the widespread introduction of mammographic screening for women younger than age 50.

Mammography may not be as sensitive for detecting breast cancers among women with *BRCA1* or *BRCA2* mutations, possibly because cancers in these women tend to develop at a younger age, when mammography is less sensitive. Studies have suggested that MRI has greater sensitivity than mammography or ultrasound. Its high cost and unproven survival benefit make it undesirable for general use, but it can increase yield in a cost-effective fashion for young *BRCA* mutation carriers,[215,216] as well as for other women at increased risk for breast cancer.[217] The ACS has developed guidelines[218] for the use of MRI for women who have a lifetime risk of breast cancer that is 20 to 25% or greater as determined by the BRCAPRO statistical model[219] or in some other way. Another category of women who are at elevated risk for breast cancer are those with dense breasts; recommendations for them vary, sometimes including ultrasound, MRI, or other tests in addition to mammography.

CERVIX CANCER

The introduction of screening with the Pap test in the late 1940s was accompanied not just by a decline in cervix cancer mortality, but also by a decline in cervix cancer incidence of at least 70%[220] (Fig. 1-1) as a consequence of its efficacy in the detection of preneoplastic lesions. This test has remained the mainstay of cervix cancer screening, though guidelines for the frequency and age range for its use have recently been revised (Table 1-8). Pap smear testing is now recommended for average-risk women in the United States starting at age 21, regardless of their sexual history, with an interval between screenings of 3 years. At age 30, the screening interval can be increased to 5 years and the cytologic testing can be combined with HPV DNA testing. If still normal by age 65 years, further screening could be stopped. Those with special risk factors, such as those who are HIV-positive, should be screened more intensively.[221]

The recognition that HPV causes cervix cancer added a new potential tool for cervix cancer screening, HPV DNA testing. However, exactly how to incorporate this test into routine screening for average-risk women in the United States remains in flux. One large study conducted in the European Union randomly assigned approximately 100,000 women ages 25 to 60 to cytology alone or to HPV testing plus reflex liquid-based cytology. The study found that HPV-based screening was more sensitive in finding cervical neoplasia than Pap smears alone and was more effective in reducing the incidence of cervical cancer (0 in the group randomly assigned to HPV screening vs. 9 in the group without HPV testing). However, no mortality benefit was demonstrated.[222] Furthermore, in women younger than age 30, transient HPV infections are common; this limits the usefulness of the test in that age range. Data from randomized trials suggest that HPV screening could provide greater protection against invasive cervix cancer than cytology screening, starting at age 30, and with screening intervals of 5 years or more.[223]

At this time, the most reasonable recommendation for HPV screening for average-risk women in the United States are that it be used in conjunction with Pap smear testing for women

over age 30 (Table 1-8). At least for now, HPV testing as a single screening modality, while recommended by some groups under some circumstances, does not appear to have sufficient evidence to support its use to the exclusion of Pap smear testing. On the other hand, HPV DNA testing as the sole means of screening has been recommended for use in resource-poor environments where Pap tests are difficult to conduct properly, such as certain African countries. In addition, HPV testing can be used to identify women at higher risk for the development of cervical intraepithelial neoplasia when the Pap test cytologic diagnosis is atypical squamous cells of undetermined significance.[224]

With regard to women who have received the vaccine for HPV, it should be noted that this does not provide immunity against all high-risk HPV types. Thus, for now, it is recommended that the standard routine screening practices be maintained in recipients of the HPV vaccine.[225]

COLORECTAL CANCER

Potential options for colorectal cancer screening include:

- Fecal occult blood testing,
- Sigmoidoscopy,
- Colonoscopy,
- Radiographic barium contrast studies, and
- CT colonography.

The results of randomized studies indicate that annual fecal occult blood testing can reduce colorectal cancer mortality by one-third.[226] The rate of false-positive results for fecal occult blood testing is 1 to 5%. Less than 10% of patients with occult blood found in stool have cancer, and approximately one-fifth to one-third have adenomas. In recent years, the fecal immunochemical test has generally been replacing the traditional guaiac-based fecal occult blood test in settings where stool testing is employed.[227]

Findings from two case–control studies found that screening sigmoidoscopy is associated with a decrease in mortality among participants age 50 or older.[228] The results from other studies show that approximately one-half of all polyps are found with the 35-cm flexible scope and two-thirds to three-quarters are found with a 60-cm scope. Diagnosis of polyps by sigmoidoscopy should lead to evaluation of the entire colon with colonoscopy.

There are three published randomized trials of sigmoidoscopy. One, from Great Britain,[229] showed a clear-cut mortality benefit for sigmoidoscopy that was quite dramatic and may justify the use of sigmoidoscopy as a routine screening test, perhaps even as an alternative to colonoscopy. A second trial, from Italy, showed an 18% statistically significant reduction in colorectal cancer incidence and a 22% reduction in overall mortality that was not statistically significant.[230] The PLCO trial in the United States has also reported the results of its randomized trial of sigmoidoscopy—the largest of the three studies, with over 150,000 participants.[231] This study showed significant 21% and 26% reductions in overall colorectal cancer incidence and mortality, respectively. All three randomized trials showed dramatic and significant reductions in distal colon cancer incidence and mortality, but no benefit for cancers in the proximal colon (which is not imaged with sigmoidoscopy).

Several recent reports, all well-conducted observational studies, explored the benefits of colonoscopy in reducing mortality. At least four such reports found that, although colonoscopy

did reduce incidence and mortality in the left colon, it did not have the same expected benefits on the right side of the colon. The reasons for these findings were unclear and may represent differences in the biology of right-sided compared with left-sided lesions or differences in the expertise of endoscopists in examining the right side of the colon.[232] A case–control study by Baxter et al.[233] demonstrated an overall reduction in colorectal cancer mortality of about 60% with the use of screening colonoscopy and showed a benefit of screening for the right colon; presumably this was because this study was done in the United States and the vast majority of colonoscopies in the United States are done by gastroenterologists who have greater expertise than surgeons or primary care doctors, who were the main endoscopists in the prior studies. The Harvard cohort studies confirmed the overall benefit of colonoscopy as well as its benefit on the right side of the colon as compared to sigmoidoscopy.[234]

Although no prospective, randomized studies have clearly demonstrated a mortality benefit for screening colonoscopy, it is considered prudent to recommend colonoscopy as a screening tool for individuals at average risk for colorectal cancer This rationale is an extension of the available data for sigmoidoscopy, which show a mortality benefit for left-sided cancers, albeit no benefit for the right side of the colon, where the sigmoidoscope does not reach.[235] Colonoscopy should be used for those at high risk, such as those with a genetic predisposition to colorectal cancer and those with inflammatory bowel disease. Little information is available on the utility of the barium enema as a screening tool. Recent interest has centered on CT (virtual) colonography as well, though no studies to date have shown that it reduces mortality. The evidence suggests that, in certain instances, it may substitute for colonoscopy.

Published guidelines for colorectal cancer screening continue to evolve. Although the ACS currently recommends the full range of screening tests listed above as options for screening, new guidelines were published in 2016 by the USPSTF.[236] These guidelines suggest sharing decision making with patients and that patients be offered a choice of screening tests. The guidelines no longer recommend the barium enema, nor do they recommend the guaiac-based fecal occult blood test. Instead, patients are encouraged to choose among the FIT test, the endoscopic procedures (sigmoidoscopy and colonoscopy), and CT colonography.

LUNG CANCER

Screening for lung cancer with chest x-ray and sputum cytologic testing was evaluated in four randomized lung cancer screening trials in the 1960s and 1970s. No reduction in lung cancer mortality was seen in those studies.[237,238] A randomized trial of chest x-ray screening was recently conducted as part of the PLCO study to reevaluate its value. The results of this study reaffirmed the absence of a mortality benefit for chest x-ray screening.[239]

Studies have shown that low-dose spiral CT scanning can diagnose lung cancers at early stages, but it was unclear whether this would save lives.[240,241] This technology was evaluated in a large, randomized clinical trial of heavy smokers, which compared CT screening with chest x-ray screening. These results were reported from the National Lung Screening Trial (NLST)[242] and showed a 20% reduction in mortality for the arm screened with CT. Spiral CT also can detect many benign processes that cause noncalcified lung radiodensities; these are false-positive findings. Spiral CT does increase the number of lesions diagnosed and, thus, will increase the number of diagnostic and therapeutic procedures performed (see Chapter 8 on Lung Cancer). Overall policy reviews conducted for spiral CT screening concluded that the benefits for certain subgroups of heavy smokers outweigh the negatives of overdetection and false positives.[243,244] The USPSTF now recommends CT screening for current or former heavy

smokers of more than 30 pack-years.[245] Several societies have added CT screening to their guidelines as well.[246]

OVARIAN CANCER

Adnexal palpation, transvaginal ultrasound, and measurement of serum CA125 have been considered for ovarian cancer screening and none has been shown to be effective. No randomized prospective trial of screening for ovarian cancer has shown an improvement in ovarian cancer mortality. The results of such screening tests could lead to futile invasive diagnostic testing that might include laparotomy. The PLCO trial randomly assigned over 78,000 women to screening with CA125 and transvaginal ultrasound for 4 years or usual care; no difference in ovarian cancer mortality was found.[247] A large British trial randomly assigned over 200,000 women to either multimodal screening with CA125 and transvaginal ultrasound, annual transvaginal ultrasound alone, or no screening. The study did not show a clear-cut benefit to screening at a median follow-up of 11 years, though follow-up continues.[248]

PROSTATE CANCER

The digital rectal examination (DRE) and measurement of serum PSA are commonly used in the United States, although most professional organizations advise caution in the use of such screening tools (Table 1-8). Prostate cancer is prone to lead-time bias, length bias, and overdiagnosis. Although screening using PSA levels and DRE clearly detects many asymptomatic cancers, its ability to reliably distinguish tumors that could be lethal but are still curable from those that pose little or no threat to health is limited. It has been estimated that 20 to 40% of localized prostate cancers diagnosed during screening are indolent and clinically nonsignificant.[249,250] Treatment of screen-detected cancers may cause morbidity, such as impotence and urinary incontinence, and carries a small risk of death.

Most expert organizations do not recommend screening for prostate cancer. The USPSTF last reviewed the evidence in support of screening in 2012 and found there was insufficient evidence to recommend it.[251] As might be expected, this decision was met with great controversy. The ACS and the American Urological Association recommend that men older than age 50 at normal risk be offered screening and be allowed to make a choice after being informed of its potential risks and benefits (Table 1-8).

The interim results of two large randomized trials of prostate screening have been reported. The PLCO trial randomly assigned 76,693 men to 6 years of annual screening with PSA or regular management according to community standards. In essence, 85% of the men in the intervention group were screened whereas more than 40% of the men in the control arm were screened. After 7 to 10 years, there was no mortality benefit (HR, 1.13; 95% CI; 0.75, 1.70).[252] The European Randomised Study of Screening for Prostate Cancer (ERSPC) randomly assigned 182,000 men in seven countries; each country had slight differences in study design. The intervention group was offered PSA screening every 4 years (every 2 years in Sweden), and 82% participated; a cutoff of 3 was used for the PSA rather than the usual 4. With a median follow-up of 9 years, the HR for mortality was 0.80 (95% CI; 0.65, 0.98). It is notable that 1410 men needed to be screened (16% of patients being screened had an abnormal PSA and required biopsy and further evaluation) to prevent 1 death, and 48 cases of prostate cancer were detected among those 1410 men to save that one life.[253]

SKIN CANCER

No randomized study has been conducted to assess whether screening for skin cancer decreases mortality, and evidence is lacking to establish the benefits of screening for skin cancer.[254] Screening programs in Scotland and Australia may have caused a stage shift in diagnosed melanomas.[255] These programs also may reinforce sun avoidance and other prevention behaviors.

OTHER CANCERS

The dramatic rise in the incidence of esophageal adenocarcinoma during the past two decades has raised concerns regarding prevention. These tumors are known to arise from Barrett esophagus—a metaplastic change in the esophageal mucosa that later progresses to dysplasia and malignancy. The main risk factor for Barrett esophagus is gastroesophageal reflux disease, a condition that has increased dramatically, perhaps in part because of the epidemic of obesity. Thus, there has been a major effort to conduct esophagogastroduodenoscopy on patients with persistent gastroesophageal reflux disease to detect early-stage Barrett esophagus and to intervene in this pathway with the use of proton-pump inhibitors and close surveillance with endoscopy. This has become a recommendation of the American Gastroenterological Association, despite the absence of a randomized trial or other high-quality evidence demonstrating a significant benefit from the point of view of cancer prevention or a mortality benefit.[256]

Although this chapter has focused on cancer screening in the United States, it is worth noting that screening for some cancers may be worthwhile in countries where these cancers are more common. One example is oral cancer, which is the most common cancer among men in India, largely because of the chewing of betel nuts. A randomized trial has shown that in one region, the use of visual screening of the oral cavity reduced mortality significantly.[257]

HCC is a common cancer in large portions of East Asia and Africa, related to chronic hepatitis B infection. A trial was conducted in Shanghai of more than 18,000 carriers of hepatitis B, who were randomly assigned to a serum alpha-fetoprotein test plus ultrasonography every 6 months or no screening. At 5 years, HCC mortality was reduced by 37% in the screened group (HR, 0.63; 95% CI; 0.41, 0.98).[258] The use of radiographic procedures to screen for HCC in patients with preexisting liver disease and cirrhosis was confirmed in another study, from Korea, which showed that the combined use of ultrasound and MRI could detect most HCC at an early stage when it was likely to be resectable.[259] Another common screening test is the use of photofluorography in Japan to screen for gastric cancer. No randomized trial has been conducted to confirm the efficacy of this test in reducing mortality.[260]

One study compared villages in China that were in an area endemic for high rates of squamous cell carcinoma of the esophagus. Fourteen villages (6827 patients) were selected for the intervention, which consisted of one-time endoscopy, while 10 villages (6200 patients) formed the controls. Ultimately, 48.6% of the intervention group underwent endoscopy, and, with a follow-up of 10 years, the mortality from esophageal cancer was 3.35% in the intervention group compared with 5.05% in the controls ($p < 0.001$), with a reduction in incidence as well.[261]

Nasopharyngeal carcinoma is a common cancer in certain parts of China and is associated with exposure to Epstein–Barr virus (EBV). A screening study from Shanghai screened 20,174 subjects for plasma EBV DNA; 5.5% tested positive, of whom about one quarter were persistently positive. They underwent further testing with endoscopy and 34 were found to have

nasopharyngeal carcinoma, mostly early stage. Only one carcinoma developed among those who were EBV-negative. [262]

KEY POINTS

- The PLCO study and the NLST have revolutionized our knowledge and approach and yielded new data on screening for four cancers. Taken together, the data have (1) shown that while chest x-ray screening is ineffective for lung cancer screening, low-dose CT scan screening is effective; (2) confirmed that sigmoidoscopy is effective in reducing mortality from colorectal cancer; (3) provided definitive evidence that CA125 and transvaginal ultrasound screening for ovarian cancer are not effective; and (4) provided negative data on PSA screening for prostate cancer.
- Although mammography screening for breast cancer among women older than age 50 is supported by evidence showing a mortality reduction, screening in women younger than age 50 remains controversial. Recent changes by the ACS reflect a more conservative approach to the use of mammography. Similarly, PSA screening among men for prostate cancer remains controversial. In both circumstances, the absolute mortality reduction is small and the number needed to screen is large, making the risk:benefit ratio a major concern from a policy standpoint.
- Low-dose spiral CT screening is an established new approach to reducing lung cancer mortality among heavy smokers.
- The use of HPV DNA testing in conjunction with Pap smear testing for women age 30 or older can allow the prolongation of the interval between screenings for cervix cancer to extend to 5 years.
- Randomized trial data are substantial enough to support the use of both fecal occult blood testing and sigmoidoscopy as screening modalities for colorectal cancer.
- There is now evidence to support the use of colonoscopy for colorectal cancer screening, albeit the benefits are modest over sigmoidoscopy and possibly over fecal occult blood testing, and the evidence for colonoscopy is not based on randomized trials.

CANCER SURVIVORSHIP

It is estimated that there are currently 15.5 million cancer survivors in the United States, representing approximately 4.8% of the population,[263] and this number is likely to grow in the coming years. This is a good thing, of course, to the degree that it reflects the increasing success of treatment in curing (or at least prolonging life for) those diagnosed with cancer. The number of cancer survivors is also increasing because of the aging of the population, with a concomitant increase in cancer cases, and because of the increased use of screening and diagnostic tests, and thus the increased diagnosis of subclinical disease.

Cancer survivors share a substantial number of issues and problems that are the subjects of intensive research efforts, including their psychologic needs, employment issues, appropriate surveillance, and management of long-term toxicities of treatment. It is also critical to note that they are at increased risk for second malignancies as an overall group. Thus, multiple primary

cancers constitute as much as 16% of tumors nowadays.[264,265] Some survivors may be at increased risk for certain specific cancers.[266] They require, at the least, special attention to make sure that they obtain the screening studies that are recommended for the general population. For those who have special risks, particular screening protocols may be required. Certain adverse effects of treatment can manifest themselves in the long term. Both thoracic radiotherapy and certain chemotherapy drugs, notably anthracyclines, may cause cardiotoxicity, usually manifesting as long-term congestive heart failure or ischemic heart disease, both of which have been described following certain treatments.[267] Peripheral neuropathy from taxanes or platinum drugs can also cause long-term issues for survivors.[268] Other toxicities include pulmonary and renal effects. There has also been growing recent interest in so-called financial toxicity: the consequences that cancer and its management have on the fiscal status of a patient and his or her family. This toxicity has become particularly stressful in an era of shifting insurance plans and growing cost of chemotherapeutic agents.[269,270]

It is mandatory that a good working relationship be established between the oncologist and the primary care physician.[271] Some studies have shown that regular wellness care may be neglected for cancer survivors under the stress and pressure of a cancer diagnosis and its treatment.[272-274] The standard protocols of good medical care, including hypertension, lipid, and other screening and vaccination protocols, should be followed for cancer survivors as they would be for any other adult. In addition, there is increasing evidence that improved lifestyle and other prevention activities, such as weight loss, tobacco-use cessation, increased physical activity, and a moderate diet, may reduce the risk of second malignancies and the risk for recurrence of the initial primary cancer. In the coming years, the medical oncologist is likely to play an increasing role as a primary and secondary prevention expert, similar to the ways in which cardiologists counsel their patients on tobacco cessation, weight loss, physical activity, and lipid management.[275]

MOLECULAR BIOLOGY

Bruce E. Clurman, MD, PhD, and Jonathan E. Grim, MD, PhD

Recent Updates

- A new section outlining the molecular features of “Infectious Agents as Drivers of Cancer”
- An expanded discussion of “Emerging Concepts on Tumor Heterogeneity and Evolution”
- A discussion of the use of emerging liquid biopsy techniques in studies of cancer biology and therapy

OVERVIEW

Molecular oncology is evolving rapidly. Many of the genes that drive tumorigenesis, and the biologic pathways and processes affected by oncogenic mutations, have now been identified. Moreover, new molecular approaches have enabled the development of therapeutics that target specific oncogenic mutations, and advances in large-scale molecular biology are providing comprehensive descriptions of cancer genomes and allowing targeted therapies to be rationally applied to treat individual cancers. The goal of this chapter is to outline a framework for the molecular basis of cancer, and to describe established and emerging technologies being used to aid in cancer diagnosis, prognosis, and therapy.

BASIC PRINCIPLES OF MOLECULAR BIOLOGY

DNA is a macromolecule composed of four nucleotides—adenine (A), guanine (G), cytosine (C), and thymine (T) (Fig. 2-1).[1,2] Each nucleotide base is connected to a deoxyribose sugar, and phosphodiester bonds between the sugar moieties form the DNA strand. The nucleoside components of one DNA strand form hydrogen bonds with nucleosides on the complementary strand (C pairs with G; A pairs with T) to create a double-stranded DNA molecule. When DNA is replicated, the strands separate and each provides a template for an exact complement to be synthesized. The human genome contains approximately 3 billion nucleotides partitioned among 23 chromosomes. Most human cells contain a complete genomic copy of DNA, but there are exceptions. For example, erythrocytes contain no genomic DNA, mature lymphocytes delete fragments of DNA within either immunoglobulin (Ig) or T-cell receptor genes to generate antigen-recognition proteins, and megakaryocytes contain extra copies of the genome that results from the process of endoreduplication.

Although its definition continues to evolve, in its most basic form a *gene* can be thought of as a DNA sequence that encodes a protein or a functional ribonucleic acid (RNA).[3] Most genes are discontinuous and arranged in segments called “exons” and “introns.” The first step in protein

synthesis is transcription of the DNA template into a linear RNA copy; the introns are subsequently spliced out to generate a messenger RNA (mRNA) that contains a continuous coding sequence comprised of exons (Fig. 2-2). The mRNA is a template for the attachment of ribosomes, and nucleotide triplets, termed “codons,” specify which amino acids will be incorporated into a nascent polypeptide chain (translation). The 5′ and 3′ extremities of mRNA extend beyond the coding regions and have regulatory functions, such as determining mRNA stability and translational efficiency. As a result of alternative splicing, genes may encode multiple mRNAs, each of which specifies a different protein, termed an “isoform.”

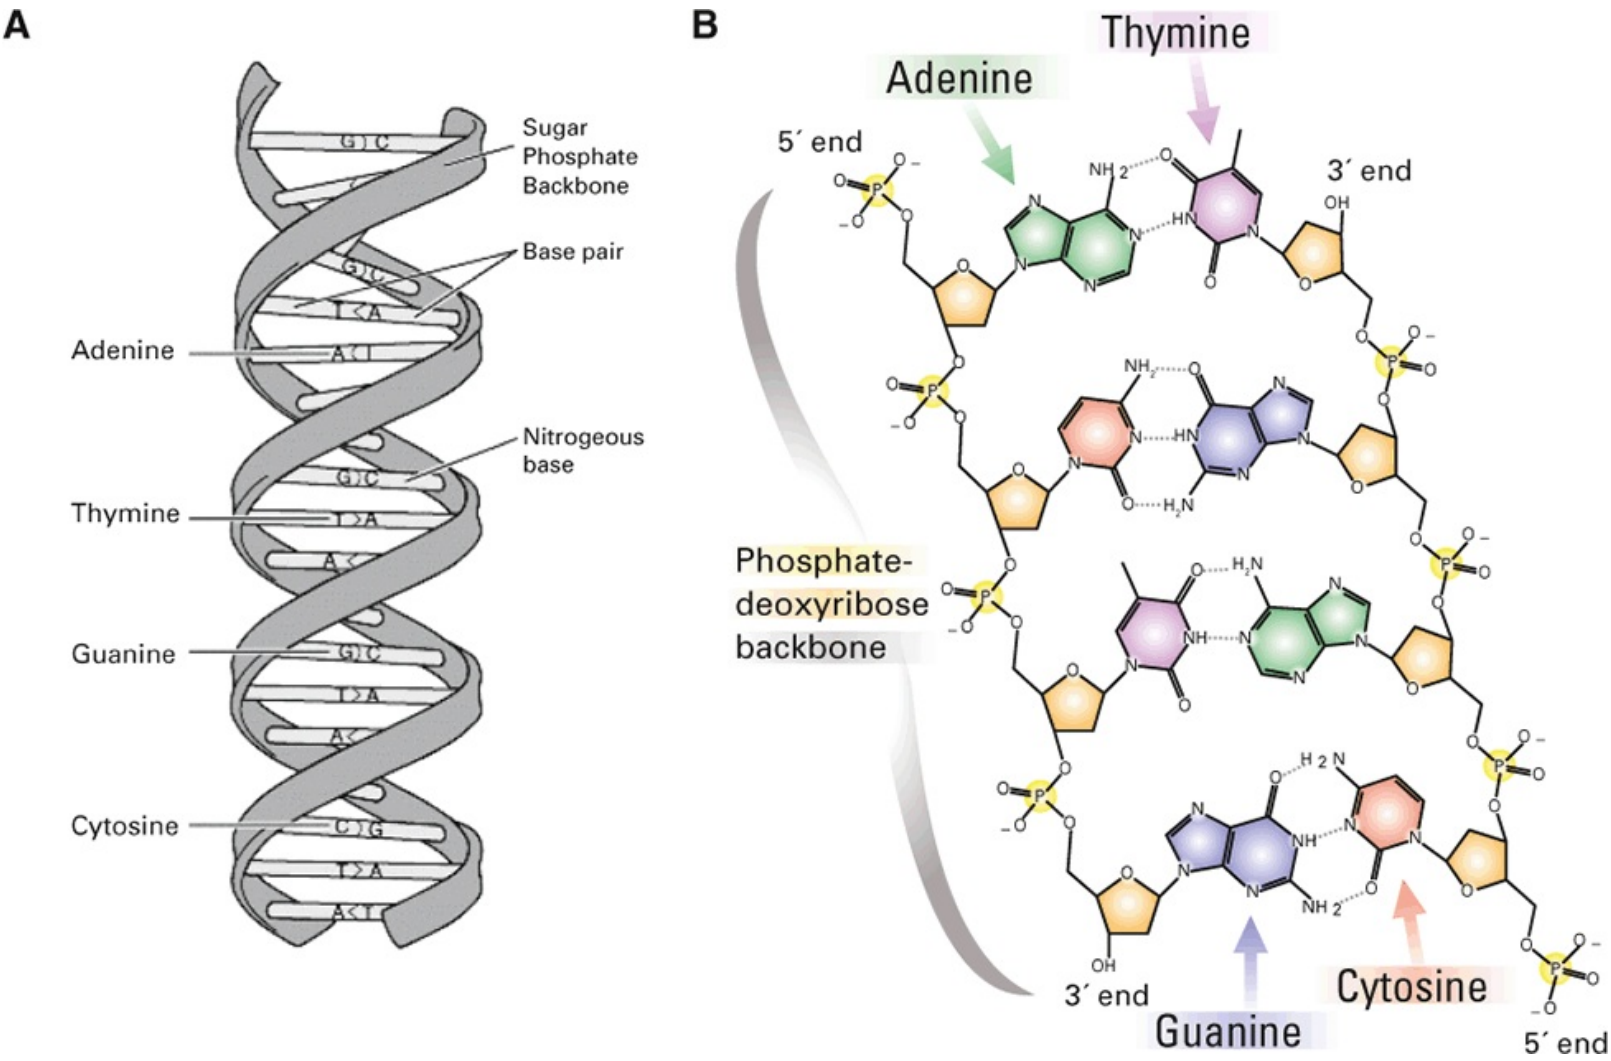

Fig. 2-1 The double helix structure of DNA includes hydrogen bonding between adenine (A) and thymine (T) bases and between guanine (G) and cytosine (C) bases.

(A) The DNA double helix. (B) A close-up of the molecular structure of DNA, showing hydrogen bonds between the two pairs of bases and the phosphodiester bonds between sugar molecules.

Numerous DNA regulatory elements such as promoters (which direct the site of transcription initiation) and enhancers (which increase transcription) control mRNA expression (Fig. 2-2).[4] These regulatory elements are recognized by proteins, called “transcription factors,” which establish the timing and tissue-specific characteristics of gene expression. Many transcription factors bind directly to these DNA elements and, subsequently, recruit additional regulatory proteins into the transcription complex. Proteins that mediate the assembly of active transcription complexes by recruiting factors or facilitating chromatin changes that promote

transcription are termed “coactivators,”[5] and those that inhibit transcription are termed “corepressors.”[6] Individual cell types express only a subset of the full complement of genes. Specific gene expression programs, thus, fundamentally drive many biologic processes, including growth and development, cellular differentiation, and neoplastic transformation.

Although the Human Genome Project was “completed” in 2003, the exact number of human genes remains unclear, and most estimates are in the range of 21,000. However, because most genes express alternatively spliced mRNAs leading to multiple different protein isoforms, the number of mRNAs and proteins far exceeds the number of genes. It is estimated that the full set of human proteins, known as the proteome, contains 250,000 to 1 million distinct proteins.

Epigenetic gene regulation, or *epigenetics,* refers to heritable, higher-order processes that can profoundly influence gene expression without mutating DNA. Chromatin is highly dynamic and undergoes remodeling via two central epigenetic processes, histone modification and DNA methylation.[7] DNA is compacted into chromatin by winding around proteins called “histones,” which maintain the DNA in nucleosomal complexes (Fig. 2-3A). Histones are modified covalently (e.g., acetylation, methylation, phosphorylation, and ubiquitylation) by changes in subunit composition (e.g., replacement of core histones by specialized histones) and by repositioning. Each of these modifications renders DNA more or less accessible to RNA polymerase (Fig. 2-3B).[8,9] Histone methylation occurs on lysine residues and is controlled by opposing methylating and demethylating enzymes: methylation on some sites facilitates transcription, whereas on others transcription is repressed.[10] Histone acetylation is also regulated by groups of opposing enzymes: acetylation is found in actively transcribed genes, whereas histone deacetylation correlates with repression. Epigenetic regulation also involves DNA modifications, most commonly cytosine methylation within cytosine–guanosine (CG) dinucleotides.[11] DNA regions that contain many CGs are termed “CpG islands,” and their methylation represses transcription. Indeed, promoter methylation is one way that cancer cells inactivate tumor suppressor genes. There is widespread cross talk between epigenetic modifications of DNA and histones, and genomewide analyses are revealing how complex epigenetic “marks” establish differential gene expression.[12,13]

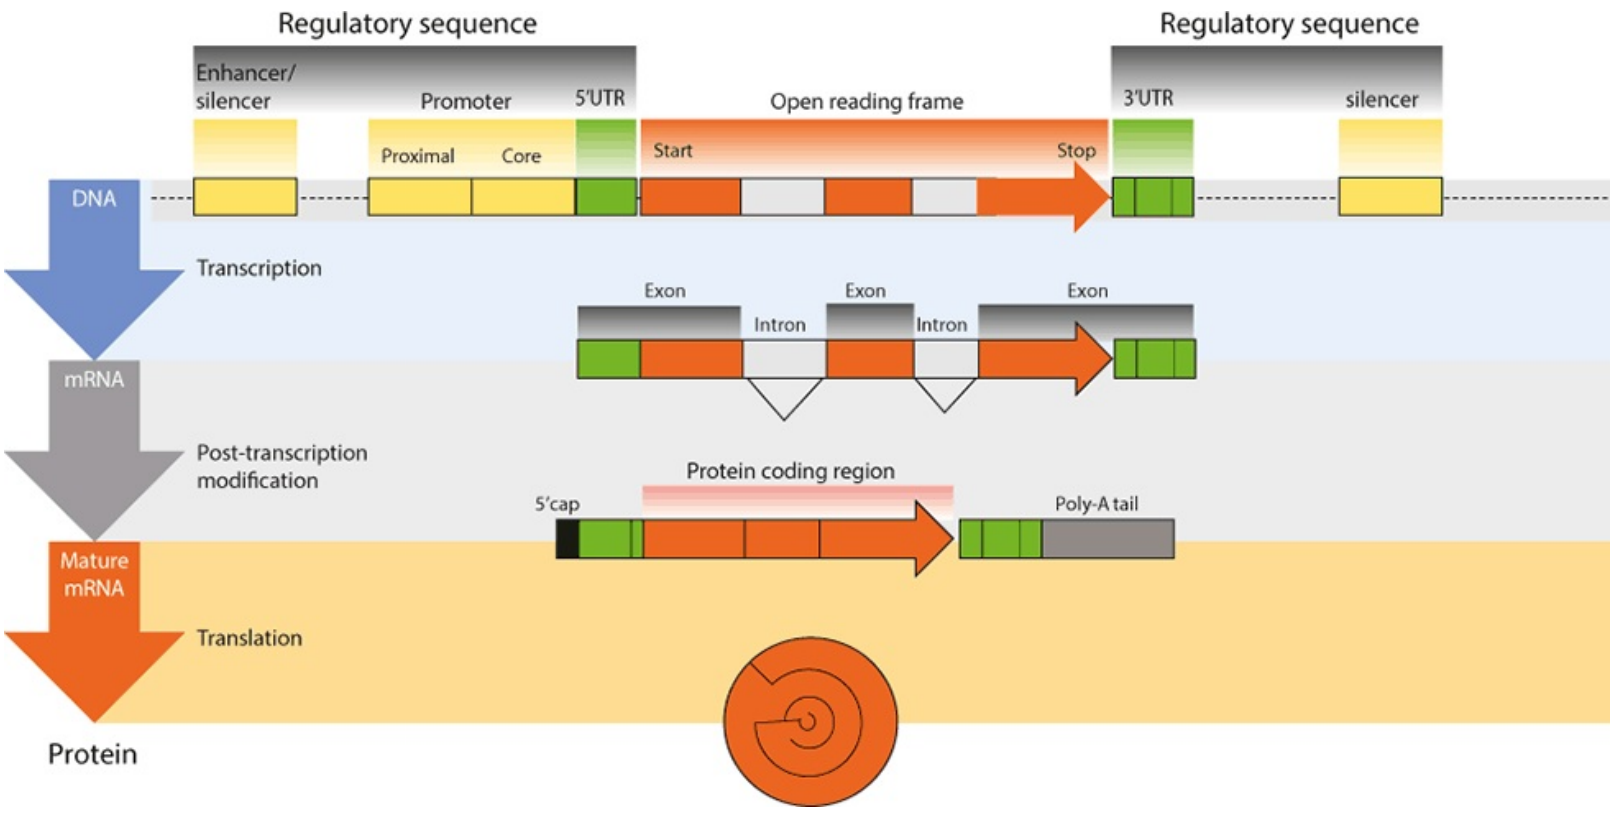

Fig. 2-2 Schematic diagram of an idealized gene, including promoter elements, an enhancer, and the transcribed region of the gene.

Promoter, enhancer, and silencer regions (yellow) regulate the transcription of the gene to generate a pre-mRNA, which contains 5' and 3' untranslated regions (green), protein coding regions (orange), and introns (light gray). Further modifications, including addition of a 5' cap (black) and 3' poly-A tail (dark gray) and removal of introns, results in a mature mRNA. The untranslated regions regulate translation of the mRNA to produce the protein product.

Because of their influence on gene expression, the enzymes that catalyze epigenetic modifications are important targets for cancer therapeutics.[14,15] For example, histone deacetylase inhibitors are approved for the treatment of T-cell lymphoma and multiple myeloma,[16,17] and inhibitors of the histone methyltransferase EZH2 are in clinical trials.[18-20] DNA methylation is another important drug target: 5-azacytidine and 5-aza-2′-deoxycytidine, which are approved for treatment of myelodysplastic syndrome, inhibit DNA methylation and reestablish expression of genes that were repressed by methylation.[21]

KEY POINTS

- Genes are functional units contained within DNA that specify the production of RNAs and proteins.
- Cells express only a subset of the genes contained within their genomes. Genes are transcribed into mRNA, and this is controlled by regulatory DNA elements (e.g., enhancers, promoters, and insulators).
- Gene expression is regulated by epigenetic modifications of DNA and histones. Chromatin modifications, which include methylations and acetylations, play a major role in determining the timing and extent of gene expression. The enzymes that catalyze epigenetic modifications are important targets for the development of cancer

therapeutics.

ANALYZING NUCLEIC ACIDS AND DETECTING CANCER-ASSOCIATED MUTATIONS

DNA

Polymerase Chain Reaction

The polymerase chain reaction (PCR) is a technique that can synthesize large quantities of specific DNA sequence fragments from minuscule quantities of template.[22,23] In its most basic form, PCR relies on: (1) annealing synthetic DNA primers to DNA sequences that flank the target DNA to be amplified, and (2) DNA polymerase enzymes isolated from thermophilic bacteria that can survive high temperatures. Multiple cycles of DNA-strand synthesis, heat denaturation, and primer reannealing allow for the repeated replication of the target sequence, resulting in exponential amplification of the DNA fragment (Fig. 2-4). For example, 20 PCR cycles produce approximately 1 million double-stranded copies of the original DNA, whereas 30 cycles produce more than one billion copies. A wide variety of PCR-based techniques have revolutionized virtually all methods used to manipulate, detect, and analyze nucleic acids.

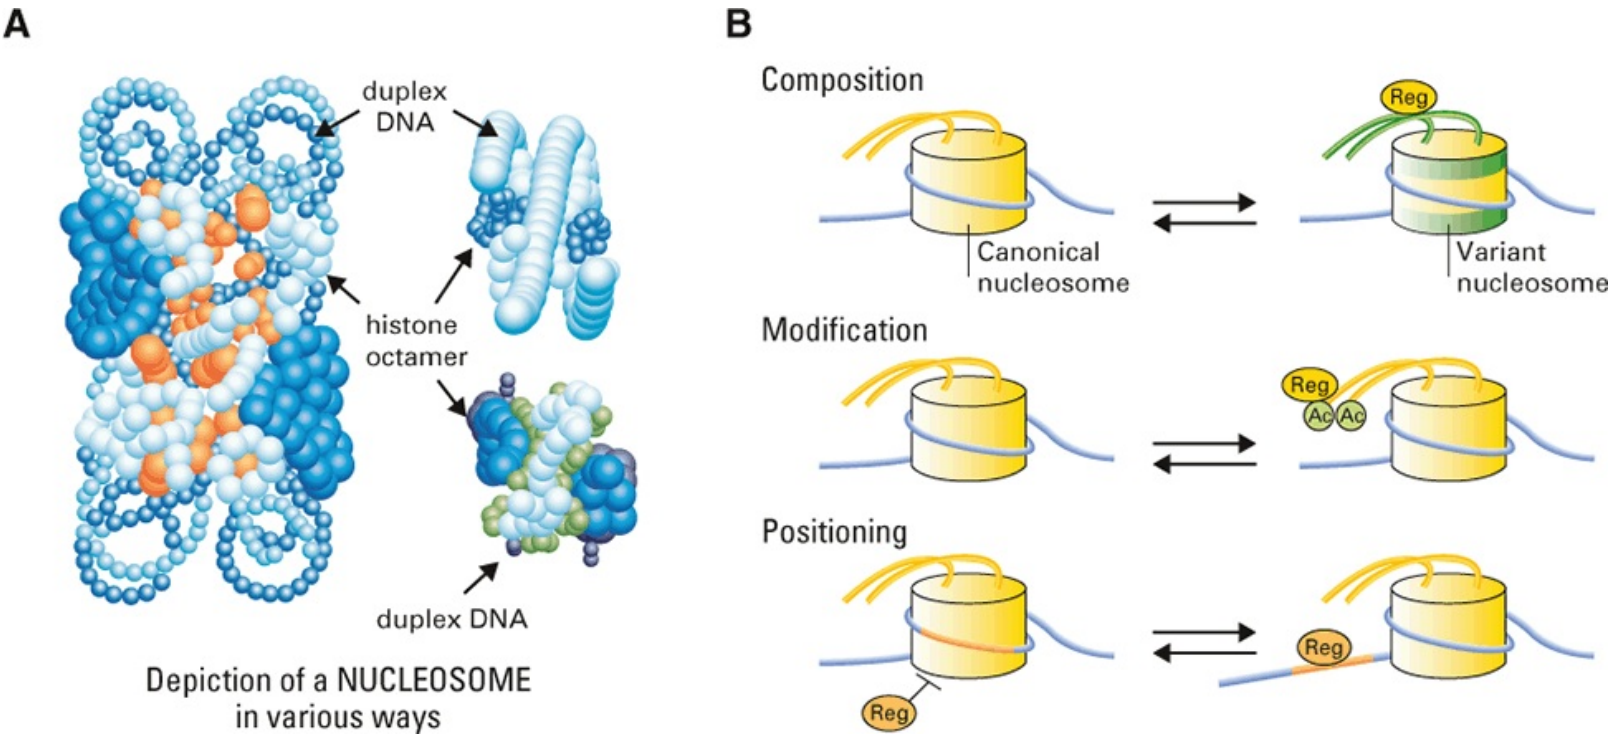

Fig. 2-3 Nucleosome structure and regulation.

(A) Nucleosome structure. The view is down the molecular 2-fold axis; DNA is represented by a tube that almost completely occludes the protein. (B) Nucleosome regulation. (top) Remodeling complexes can remove the canonical H2A–H2B dimers and replace them with variant histones (indicated in green), forming a variant nucleosome with unique tails that might bind unique regulatory proteins. (middle) Nucleosome modification (only acetylation [Ac] is depicted for simplicity) allows the binding of regulatory factors, which have specialized domains that recognize acetylated histone tails. (bottom) Nucleosome repositioning allows the binding of a regulatory factor to its site on nucleosomal DNA (orange segment).

DNA Polymorphisms Facilitate Genetic Analyses of Complex Diseases

DNA sequences that exhibit substantial variability in a population are termed “polymorphisms” and distinguish between alleles (gene variants). Genomewide maps of polymorphic markers

were important tools in many previous analyses of genetic traits, such as cancer predisposition. Through linkage analysis of pedigrees in which early-onset cancer did or did not develop, the genetic polymorphisms that segregated with the cancer-development phenotype identified many hereditary cancer genes. Single-nucleotide polymorphisms (SNPs) are the most common polymorphisms; they represent approximately 1% of any individual's human genome sequence. Current approaches use microarray-based chips and/or DNA sequencing methods to analyze SNPs on a genomewide scale, as discussed below.[24-26] With this large volume of genetic variants, geneticists can now apply more complex methods of analysis to large populations of people who do and do not have specific phenotypes. Agnostic techniques such as genomewide association studies (GWAS) can identify the relationships among specific genes and genetic variants and health traits of interest. Alternatively, some common polymorphisms have been shown to affect phenotypes in vitro, such as metabolism of cancer therapeutics, and the relevance of these findings to clinical care can be confirmed in small patient-oriented studies.

Cytosine–adenine (CA) dinucleotide repeats, called "microsatellites," are another type of polymorphism. These regions are susceptible to imperfect replication, thus leading to variability in length. DNA mismatch repair (MMR) enzymes normally suppress these errors, but they are mutated in some familial cancers, such as hereditary nonpolyposis colon cancer (HNPCC)/Lynch syndrome. Loss of expression of MMR proteins causes altered microsatellites that form the basis of some diagnostic tests.

Next-Generation DNA Sequencing: Beyond the Human Genome Project

The completion of the Human Genome Project in 2003 heralded a new era in molecular medicine. Obtaining the human genome with 99.9% accuracy took 13 years and nearly $3 billion. The technology used to obtain the reference human genome sequence required large-scale automation and an international consortium of scientific teams. Although a remarkable achievement, the methods used for the Genome Project were not practical to apply toward goals such as sequencing cancer cell genomes to guide treatment decisions. Newer technologies, termed "next-generation sequencing" (NGS), have increased the speed and dramatically reduced the expense of genome-scale DNA and RNA sequencing.

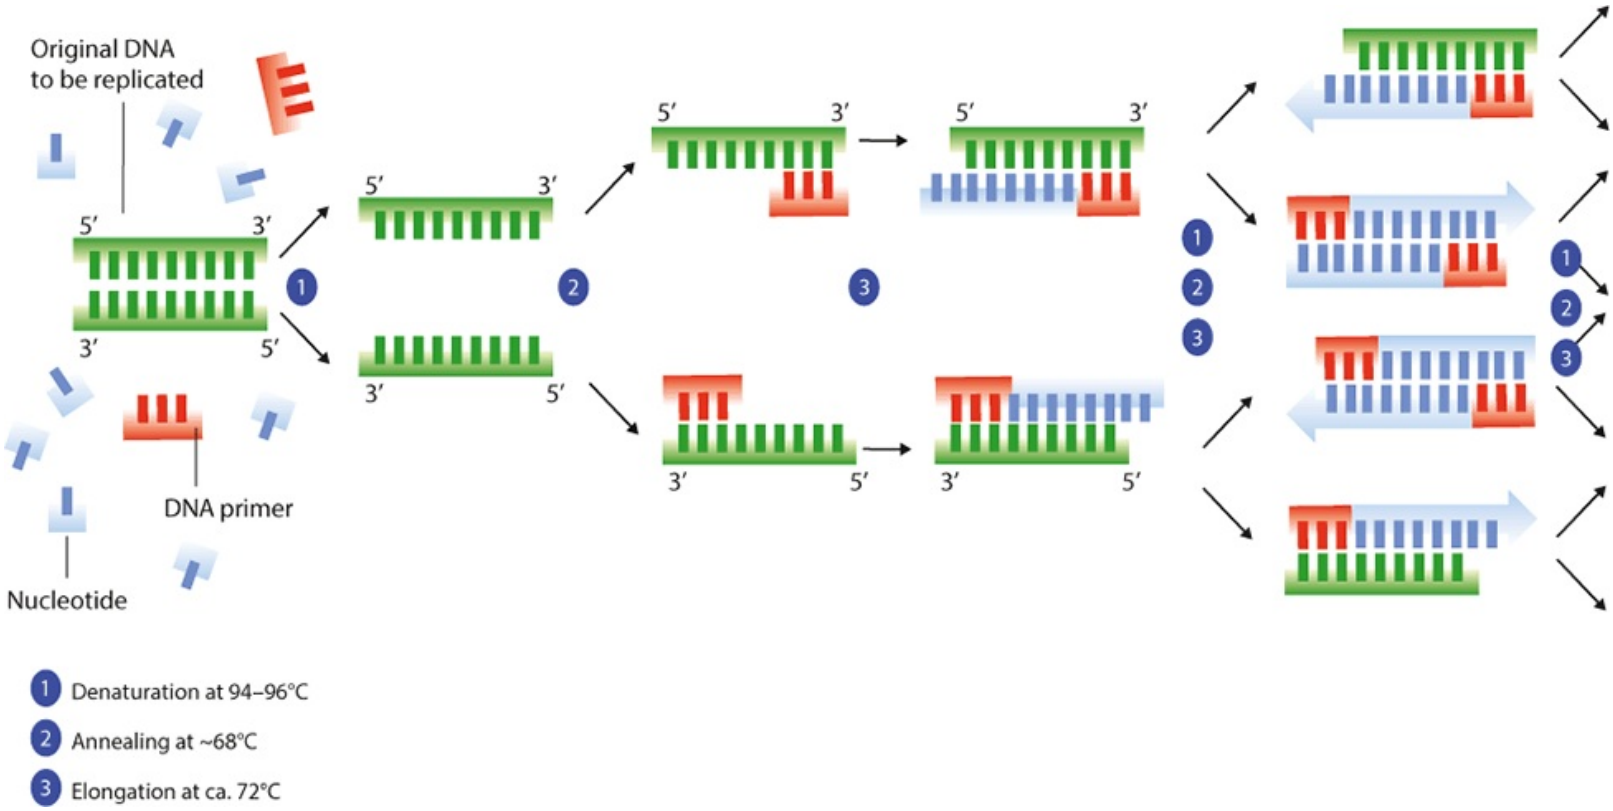

Fig. 2-4 Polymerase chain reaction (PCR).

The DNA (target) to be amplified is shown as a double-stranded DNA molecule with complementary segments (in green, far left). Also shown are sequence-specific primers (red) and nucleotides (blue). The temperature changes required for each step are indicated. The DNA is denatured and then allowed to reanneal to the primers. Taq DNA polymerase then extends from the primer using supplied nucleotides, making perfect complementary copies of the segments of DNA (in blue), yielding two copies of the target DNA after cycle 1. In subsequent cycles, the DNA is denatured and reannealed and the steps in cycle 1 are repeated, yielding exponentially increasing copies of target DNA such that with *n* cycles the yield of DNA is 2^n.

Source: *Wikipedia. Public Domain, https://en.wikipedia.org/wiki/Polymerase_chain_reaction.*

NGS methods apply massively parallel sequencing technologies to obtain millions of DNA sequence reads simultaneously using a single instrument.[27-29] Although technology platforms vary, what they have in common is that the length of the sequence read for each DNA molecule is relatively short. The power of these technologies is that they rely on sequence analysis methods that use a reference human genome sequence and sophisticated bioinformatics for positioning and alignment of millions of short reads. Because these methods are quantitative, they can also detect structural changes, such as chromosomal gains and losses and translocations in cancer cells, in addition to other types of mutations (Fig. 2-5). The cost and speed of NGS are rapidly improving. For example, in 2008, two studies reported human genome sequences that were completed in a few months, but cost approximately $1 million per genome.[30,31] As of 2016, rapid human genome sequencing was available, with costs in the range of several thousand dollars and time frames measured in weeks; this has enormous implications for understanding cancer biology, prognosis, diagnosis, and treatment. These techniques are enabling individualized treatments based on genome-scale sequence data (see the Oncogenomics and Precision Oncology section).[32]

NGS also allows epigenetic studies at a genomewide scale. For example, ChIP-Seq uses antibodies that recognize specific modifications (e.g., histone methylation) to isolate fragments of DNA associated with the modified histone; then NGS is applied to identify all DNA regions that contain the modification.[33] This strategy has produced highly detailed maps of the epigenetic marks that regulate gene expression (Fig. 2-6). Similar approaches have shown that

CpG methylation is a highly dynamic process that changes greatly during cellular differentiation.[34] The Encyclopedia of DNA Elements (ENCODE) project has used NGS approaches to catalog transcription factor binding sites as well as chromatin and histone modifications across the human genome.[35] These technologies are providing an entirely new understanding of how gene expression is regulated in health and disease.

RNA

Real-Time PCR

PCR-based methods employed for RNA analyses use reverse transcription, in which the reverse transcriptase enzyme and DNA primers first convert mRNA to a DNA copy, called "complementary DNA" (cDNA). This general strategy is termed "reverse transcription–polymerase chain reaction" (RT-PCR) to reflect both the reverse transcription and PCR steps. RT-PCR methods are widely used to precisely measure RNA abundance in cells and tissues. Real-time PCR assays use fluorescent dyes to accurately measure the amount of PCR products synthesized in various amplification cycles.[36,37] The advantages of real-time PCR include extreme sensitivity, technical ease, and the ability to accurately quantitate RNA over a very wide abundance range. Real-time PCR is often the method of choice for analyzing the abundance of specific mRNAs in tumor samples, such as monitoring the expression of the *BCR-ABL* transcript in patients undergoing therapy for chronic myeloid leukemia (CML), and for detecting minimal residual disease in leukemia and lymphoma.[38,39] RT-PCR can also simultaneously determine the expression of multiple genes. For example, one approved diagnostic test uses RT-PCR to assess the expression of 21 genes to predict recurrence risk in women with early-stage estrogen receptor–positive breast cancer.[40]

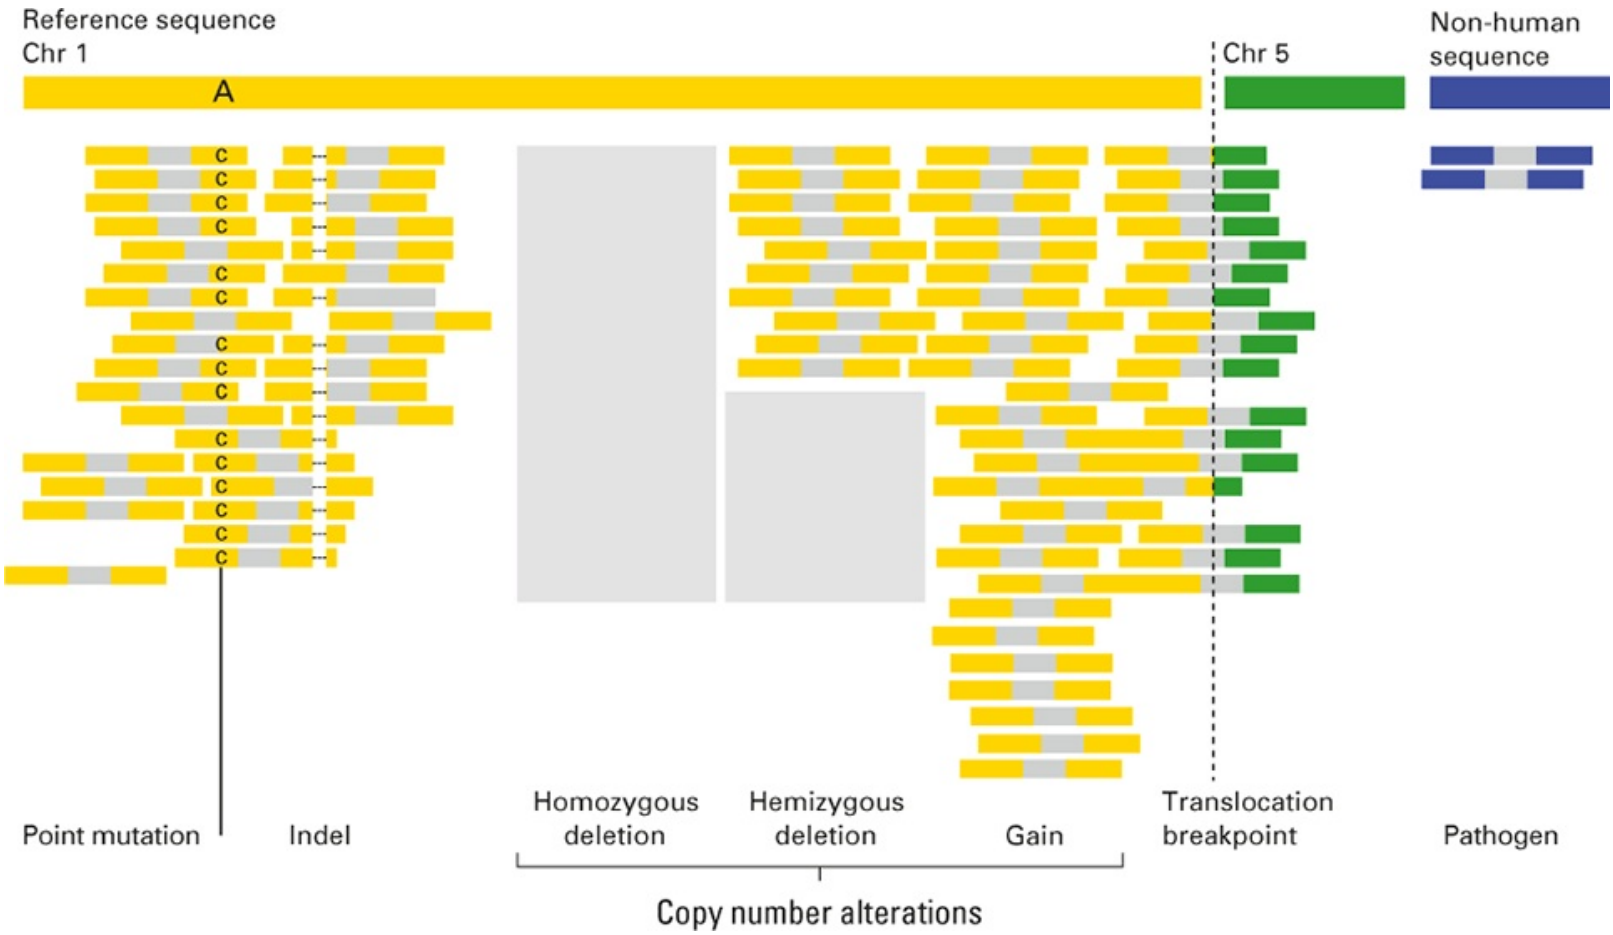

Fig. 2-5 Types of mutations discovered by next-generation genomic sequencing.

Sequenced fragments are depicted as bars, with colored tips representing the sequenced ends and the unsequenced portion of the fragment in gray. Reads are aligned to the reference genome (mostly chromosome 1, in this example). The colors of the sequenced ends show where they align with the target DNA. Different types of genomic alterations can be detected, from left to right: point mutations (in this example, A to C) and small insertions and deletions (indels; in this example, a deletion shown by a dashed line) are detected by identifying multiple reads that show a nonreference sequence; changes in sequencing depth (relative to a normal control) are used to identify copy-number changes (shaded boxes represent absent or decreased reads in the tumor sample); paired ends that map to different genomic loci (in this case, chromosome 5) are evidence of rearrangements; and sequences that map to nonhuman sequences are evidence for the potential presence of genomic material from pathogens.

Microarrays, NGS, and Global Analyses of Transcription

Some RNA analysis approaches measure the expression of thousands of genes simultaneously, and these typically utilize either microarrays or NGS. Microarray chips are small slides on which either oligonucleotides or cDNAs are spotted in a defined array.[41] Hybridization of cDNA made from tumor and control cells, each labeled with a different fluorescent dye, can show relative differences in gene expression between samples. In some cases, small amounts of RNA from limited clinical specimens are first amplified by PCR prior to hybridization. Microarray analyses of the set of genes expressed in a tumor sample, termed the “transcriptome,” have been used in diagnostic and prognostic applications. Examples include separating morphologically indistinguishable large cell lymphomas into high- and low-risk groups on the basis of their gene expression patterns (which reflect their cell of origin) and predicting risk for metastases in women with node-negative breast cancer (Fig. 2-7).[42-44] Because NGS is quantitative, it provides new ways to assess mRNA abundance at the genome scale, termed “RNA-Seq,” that are not prone to many of the technical limitations of microarrays. Thus, as NGS becomes more widely available, these approaches will replace microarrays as the method of choice for quantitating mRNAs in tumors. Indeed, RNA-Seq is becoming a vital component of cancer diagnosis and treatment.[45]

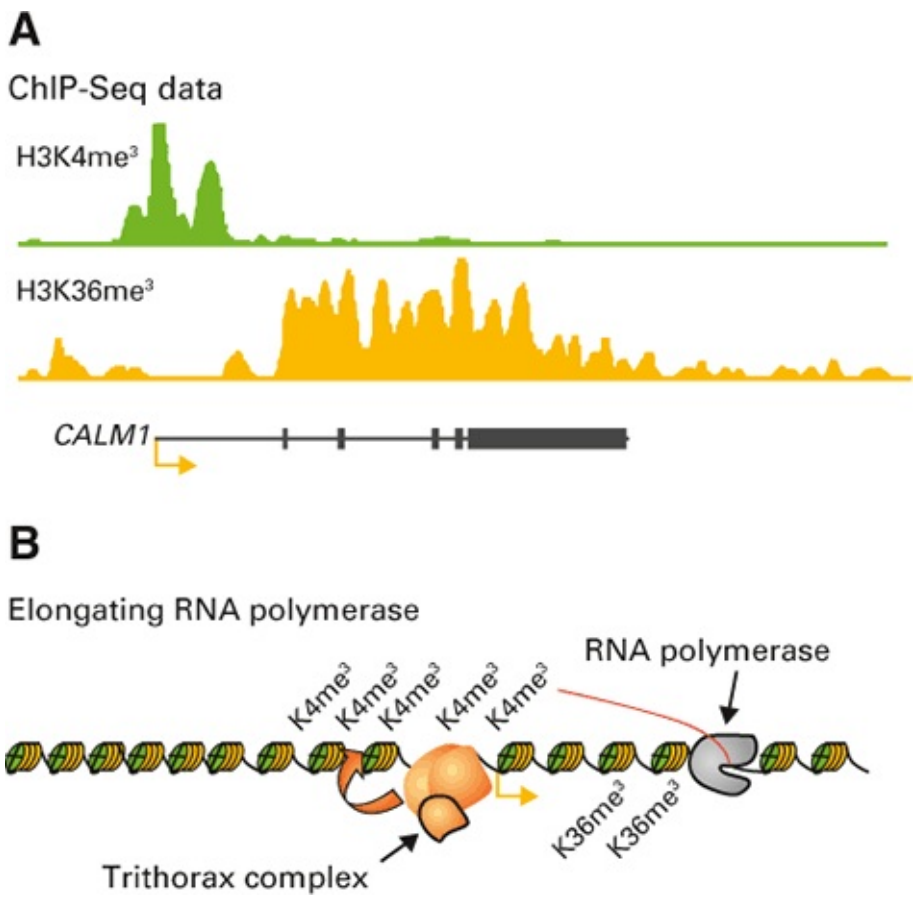

Fig. 2-6 Chromatin state maps reveal a stereotypical pattern at active genes.

(A) In mouse embryonic stem cells, the transcription start site for the *CALM1* gene (orange arrow) is marked by H3K4 trimethylation, a trithorax-associated mark, while the remainder of the transcribed region is marked by H3K36 trimethylation. (B) Evidence from model systems supports a central role for initiating and elongating RNA polymerase II in recruiting the relevant histone methyltransferase enzymes.

MicroRNAs, Small Interfering RNAs, and CRISPR/Cas9 Genome Engineering

MicroRNAs (miRNAs) are small RNAs (18 to 24 nucleotides) that regulate the expression of other genes by base-pairing to their target mRNAs and inhibiting their expression (Fig. 2-8).[46] Most miRNAs are encoded within longer primary transcripts that are processed to form the final miRNAs. More than 400 miRNA genes regulate most human cellular processes.[47,48] Individual miRNAs target many genes simultaneously (dozens to hundreds), and many human genes are controlled by multiple miRNAs. Aberrant miRNA expression is thought to play causal roles in human neoplasia, and miRNA deregulation causes cancers in mouse models.[49-51] Because specific cancers exhibit characteristic and abnormal patterns of miRNA expression that can be detected in tissues such as blood, miRNA analyses could become another important molecular tool in cancer diagnosis and prognosis.[52]

Small interfering RNAs (siRNAs) are synthetic double-stranded miRNAs that have become common tools for molecular oncology research. Because siRNAs efficiently catalyze the degradation of their cognate mRNAs, researchers can design siRNAs that inhibit the expression of any desired mRNA transcript. These techniques, termed “RNA interference,” facilitate powerful studies of gene function, and genomewide siRNA screens are extensively used to dissect biologic pathways to ascertain gene function and identify drug targets in cancer cells.[53,54] The recent development of simple and robust genome-editing technologies using the Clustered Regularly Interspaced Short Palindromic Repeats/Cas9 (CRISPR/Cas9) system

provides a second valuable tool for whole-genome genetic screens or drug screens. While siRNA techniques can downregulate gene expression, CRISPR/Cas9 readily mutates genes such that there is a complete loss of gene expression. Thus, CRISPR/Cas9 techniques are now complementing or supplanting RNA interference in many genetic and drug screening applications.[55-58]

KEY POINTS

- DNA analysis with NGS methods, which utilize computational analysis of short nucleic acid sequence reads aligned with reference genome sequence information, can define near-complete mutational landscapes of individual tumor samples.
- Analyses of mRNA can quantitate the expression of specific genes in tumor samples, which provides insights into cancer biology as well as important diagnostic and prognostic information.
- Whole-genome genetic screens using siRNA or CRISPR/Cas9 technologies can identify genes that promote or suppress cancer or that mediate resistance to chemotherapy.

CHROMOSOME ANALYSIS

KARYOTYPING, FLUORESCENCE IN SITU HYBRIDIZATION, AND ARRAY COMPARATIVE GENOMIC HYBRIDIZATION

Cancer cells often exhibit chromosome abnormalities that are pathognomonic for specific diseases. Karyotype analyses examine an individual's entire chromosome complement, and classical analyses identify chromosomes in metaphase spreads based on banding patterns and morphology. Although these techniques are still widely used, particularly to classify hematologic malignancies, they are often augmented with newer techniques that are more sensitive and/or comprehensive. Several cytogenetic methods employ fluorescence in situ hybridization (FISH). Fluorescently labeled synthetic, prespecified sequence, nucleic acid probes are incubated with fixed metaphase or interphase cells. The probes hybridize to their complementary sequences, which allows visual inspection of the structure of specific genes. For example, chromosome- and gene-specific probes are used to determine the copy number of specific oncogenes, such as the *HER2* gene in breast cancers and gastroesophageal cancers, because significant amplification of this gene predicts sensitivity to anti-HER2 therapies. Another common FISH technique uses probes that detect gene fusions and chromosome translocations. For example, presence of the *BCR-ABL* fusion is diagnostic of CML and is sometimes found in acute leukemias. Similarly, the *EML4-ALK* gene translocation defines a subgroup of non-small cell lung cancers. Importantly, the identification of these translocations is clinically relevant, as it confers sensitivity to small molecular tyrosine kinase inhibitors. The ability of FISH-based methods to identify rare cells with abnormal karyotypes makes them useful for detecting residual disease when malignant cells harbor a cytogenetic marker. Spectral karyotyping is another FISH method for characterizing chromosome aberrations that cannot be appreciated by classic techniques; it uses a panel of chromosome-specific fluorescent probes that allow the identification of subtle and/or complex chromosomal rearrangements (Fig. 2-9).

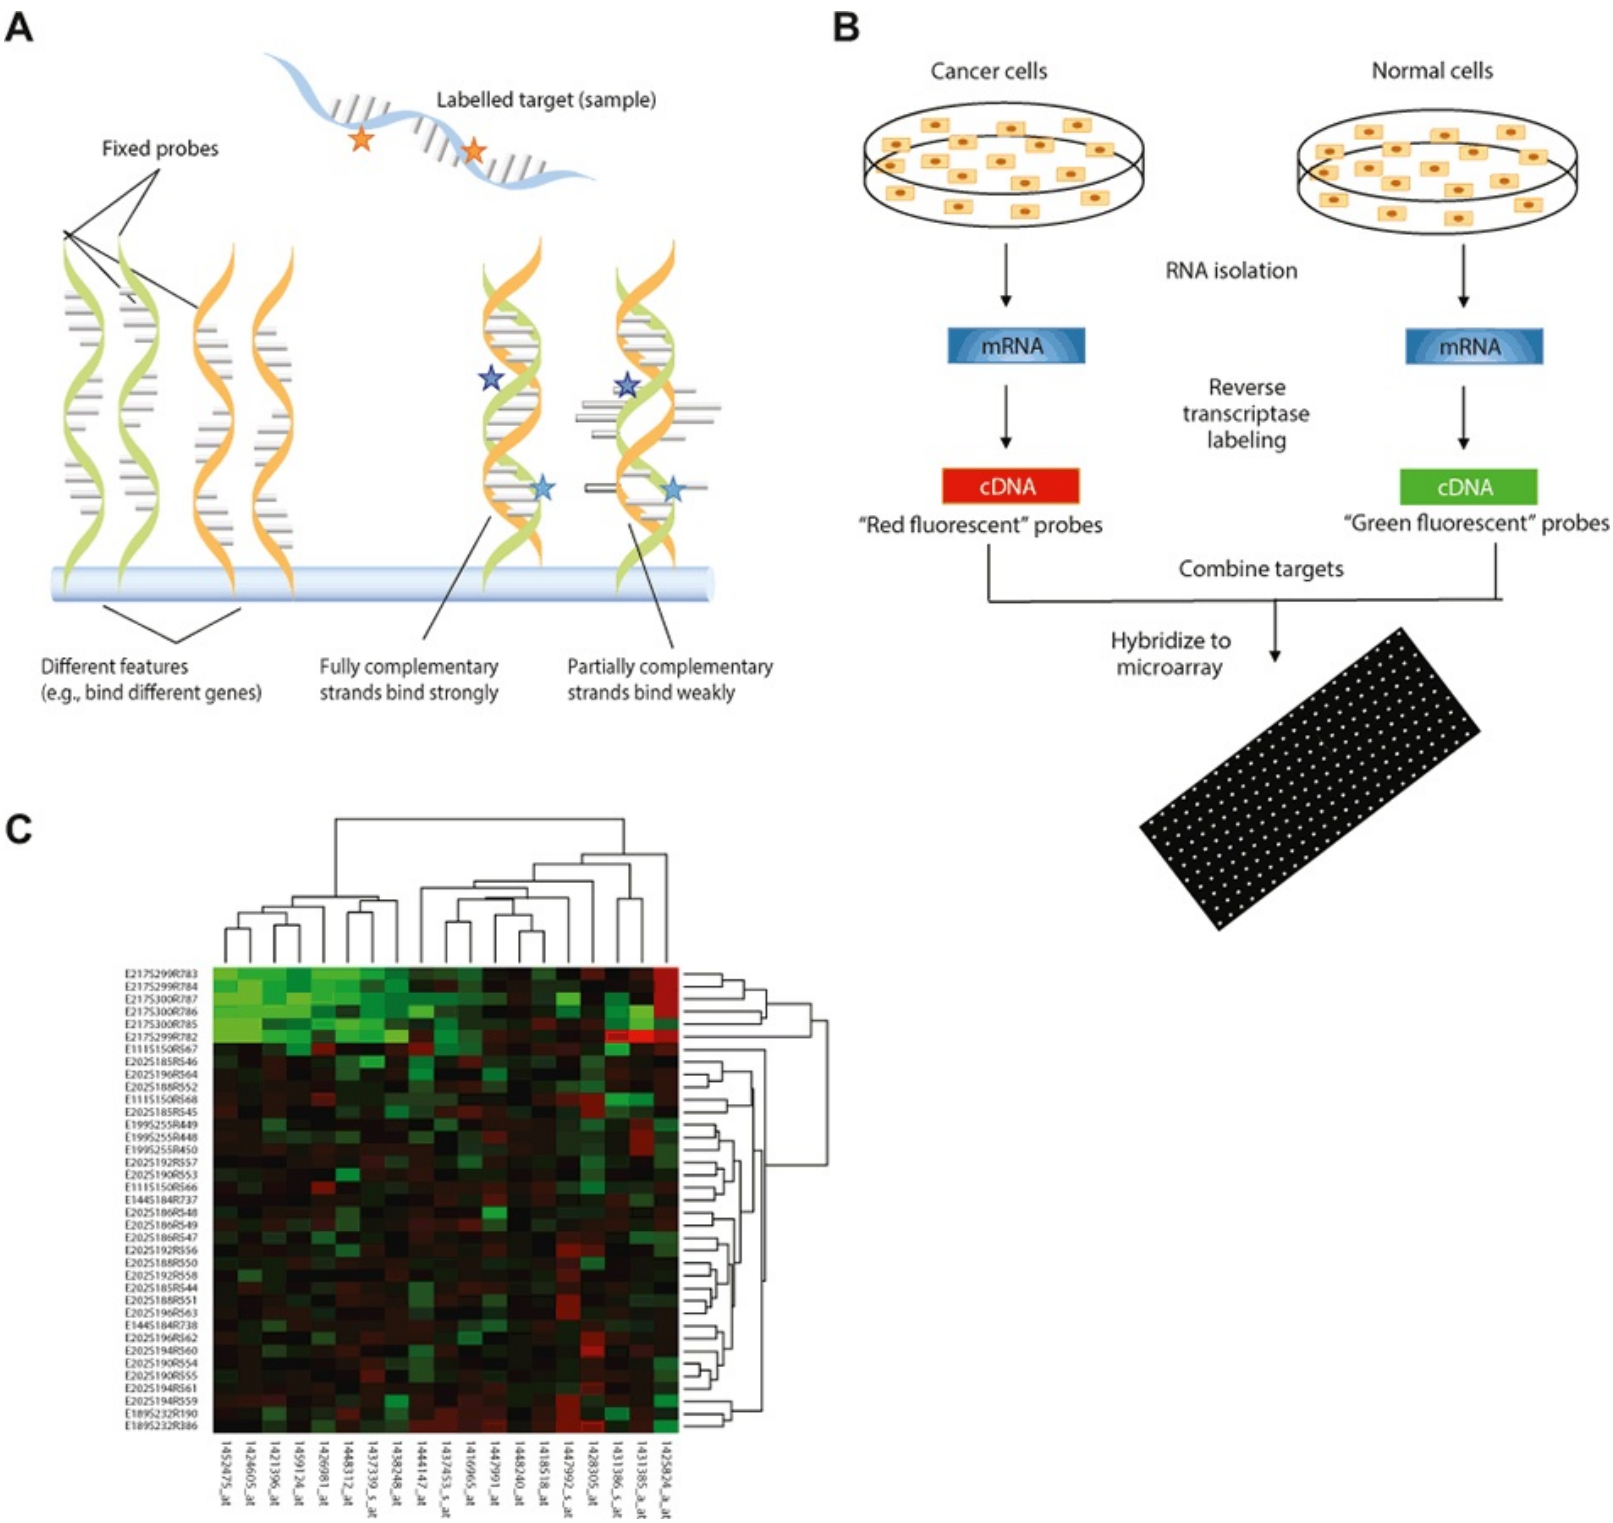

Fig. 2-7 Gene expression microarray.

(A) Microscopic dots of nucleic acid probes representing different genes are fixed to chips, where they can hybridize to labeled DNA from tissue samples. (B) Standard RNA and tumor RNA are isolated from respective samples, converted to cDNA, labeled with different fluorescent probes, and hybridized to microarrays. (C) The resulting array of fluorescent signals is read electronically and the output compares gene expression of a subset of genes between the two samples. A typical gene expression heat map is shown, where genes in green are upregulated and genes in red are downregulated.

Many DNA losses or gains in tumors involve regions that are too small to be visualized by cytogenetic methods. Comparative genomic hybridization (CGH) can identify DNA gains and losses in a tumor by using DNA hybridization to compare it with a normal sample. In array CGH, labeled tumor and normal DNA are hybridized to chips containing arrays of DNA fragments representing entire genomes.[59] Because array CGH detects copy-number changes in DNA

fragments too small for detection by cytogenetic techniques and at the genome scale, it provides unique insights into the complex genomic gains and losses that drive neoplastic transformation. However, as previously discussed, NGS approaches are now becoming the preferred means of detecting copy-number changes in cancers.

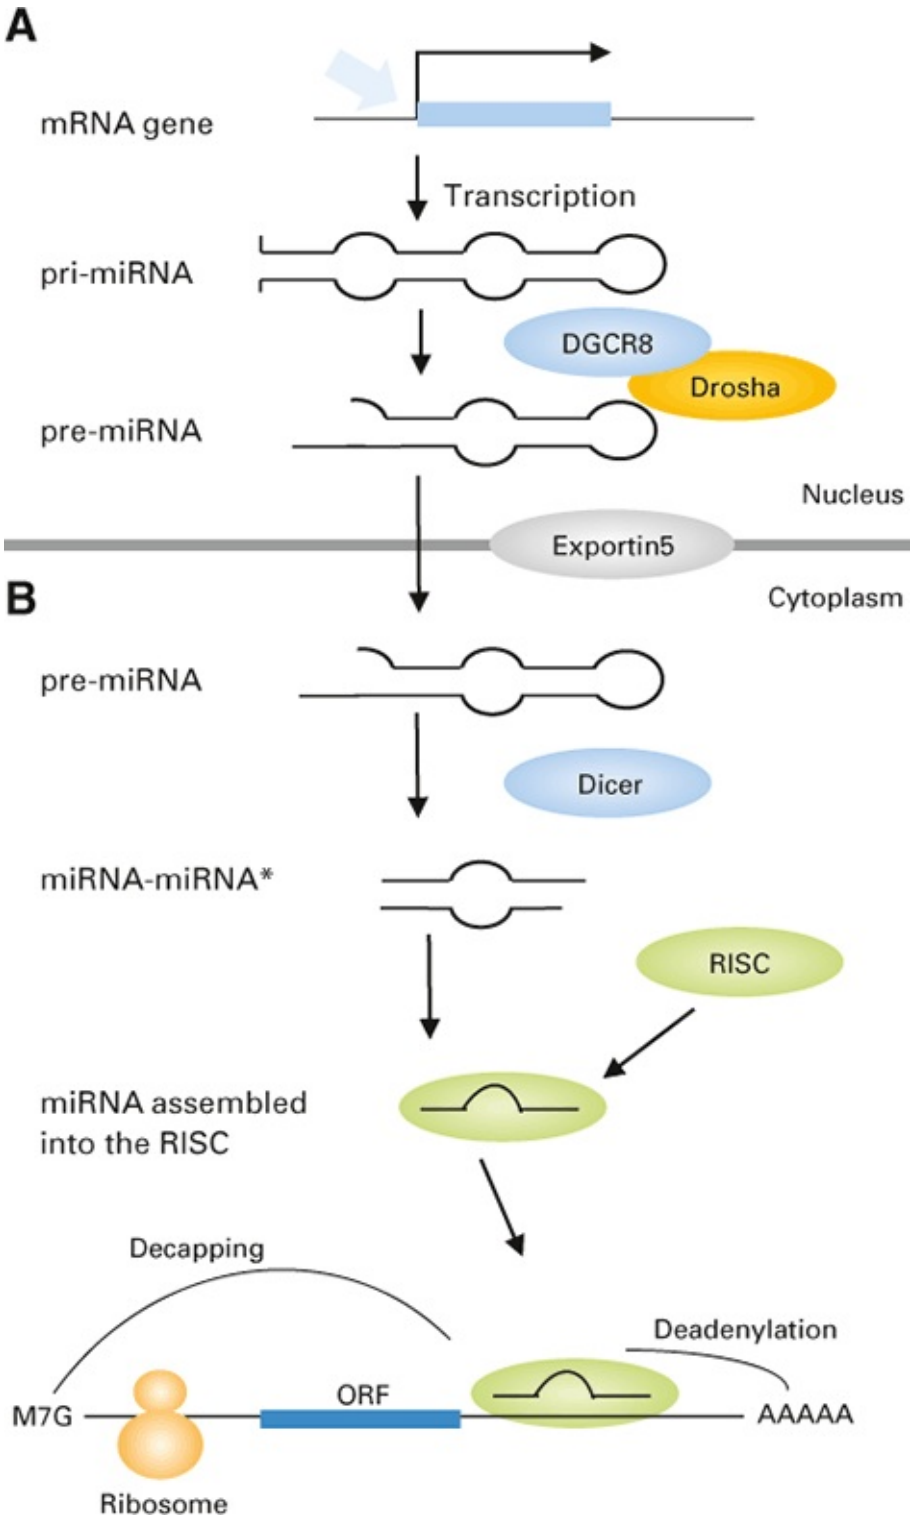

Fig. 2-8 Model of small-RNA-guided post-transcriptional regulation of gene expression.

(A) Primary miRNA transcripts are processed to miRNA precursors in the nucleus by the RNase-III-like enzyme Drosha. (B) The miRNA precursor is subsequently exported to the cytoplasm by means of the export receptor exportin-5. The miRNA precursor is further processed by Dicer to small interfering RNA (siRNA)–duplex-like intermediates. The duplex is unwound while assembling into miRNA ribonucleoproteins/RNAinduced silencing complexes (miRNP/RISC). The incorporated miRNA serves to target these complexes to mRNAs with similar sequences. This ultimately results in regulation of gene expression through translational repression or mRNA cleavage.

KEY POINTS

- Karyotyping reveals gross DNA structural anomalies in tumor cells, such as translocations and chromosomal deletions.
- FISH techniques detect structural abnormalities in tumor DNA, such as translocations, deletions, and copy-number variations. Genome alterations identified by FISH are clinically relevant, as they can predict sensitivity to molecularly targeted therapies and can be used to detect residual disease in hematologic cancers.
- Comparative genomic hybridization increases the sensitivity and resolution of cytogenetic analyses.

ANALYSIS OF PROTEINS: ANTIBODY-BASED METHODS

WESTERN BLOTTING, IMMUNOHISTOCHEMISTRY, AND FLOW CYTOMETRY

As previously noted, despite having ~21,000 genes, the human genome encodes >250,000 distinct proteins. Methods to study large sets of proteins simultaneously, collectively termed "proteomics," enhance the understanding of cancer and offer the potential for diagnostics that might advance cancer care beyond that achieved with NGS.

Protein-detection methods have been in common use for decades. Antibody-based methods are well established; low- to intermediate-throughput assays are routinely used in experimental and clinical laboratories to study protein expression and function. Lysis of cells or other tissue samples solubilizes proteins. These lysates can be separated by gel electrophoresis and transferred to membranes, which can then be exposed to detection probes, most commonly antibodies (Western blotting); this can detect changes in protein size, posttranslational modifications (e.g., phosphorylation), and abundance.[60] Analogous methods are used in fixed- and fresh-tissue specimens. To aid in diagnosis, pathology departments routinely employ antibody-based immunohistochemistry (IHC) methods to detect the expression of specific proteins in tumor cells, including panels of cellular markers that help to define the origins of poorly differentiated cancers or to differentiate squamous cell carcinoma and adenocarcinoma in lung cancers. Furthermore, IHC is frequently used to subclassify human tumors to refine prognosis and determine treatment. For example, p16INK4A overexpression is a surrogate for human papillomavirus (HPV)–associated head and neck cancers, which have a more favorable prognosis as compared to non–HPV-associated cancers. Ongoing studies are using HPV status to develop risk-adapted treatment algorithms for this disease. Likewise, HER2 is overexpressed in a subset of breast and gastroesophageal cancers. This overexpression has both prognostic and therapeutic significance, as these cancers frequently respond to anti-HER2 therapies. Finally, IHC for MMR proteins is commonly used to identify cancers associated with Lynch syndrome.

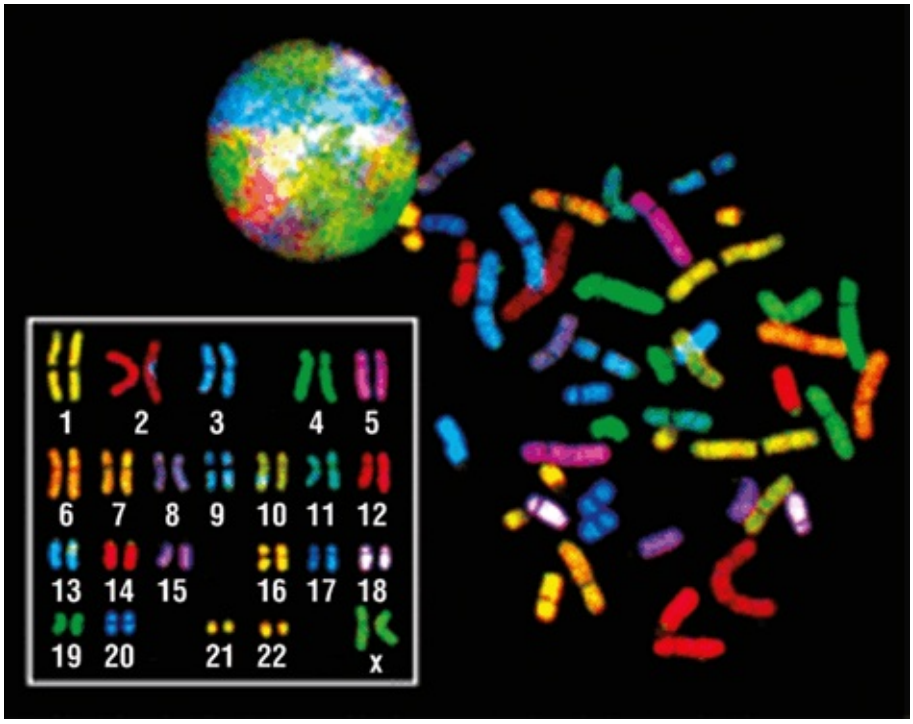

Fig. 2-9 Spectral karyotype showing different dyes characteristic for each chromosome.

This technique allows for rapid analysis of metaphase spreads for subtle chromosomal losses, gains, and translocations.

Another important antibody-based diagnostic technique, particularly for hematologic cancers, is flow cytometry, which detects multiple cell-surface markers in complex cell populations, such as bone marrow or peripheral blood. This process, known as "immunophenotyping," can classify leukemias and lymphomas based on their cell-surface proteins. Because flow cytometry has high sensitivity and throughput it can detect small numbers of tumor cells, such as residual leukemia in normal bone marrow. Finally, flow cytometry can determine eligibility for the rapidly expanding array of monoclonal antibody–based therapies, including those targeting CD20 (for lymphoma and leukemia), CD30 (for Hodgkin and other lymphomas), CD33 (for acute leukemias), and CD38 (for multiple myeloma).

MASS SPECTROMETRY–BASED PROTEOMICS

Antibody-based methods are limited by their low throughput. Analogous to the large-scale genomic analyses of DNA sequence or RNA expression, mass spectrometry (MS) is a high-throughput technology that can assay thousands of proteins simultaneously. MS forms the core of modern proteomics and is used in combination with bioinformatics to quantitate and identify the large numbers of proteins present in complex biologic samples.[61,62] These methods are informed by genomewide sequencing that allowed construction of the comprehensive databases used to identify the peptides analyzed by MS. MS can also interrogate protein modifications, such as protein phosphorylation and ubiquitylation, on a very large scale. MS of cancer samples or serum from cancer patients can be used to generate proteomic signatures that may influence selection of therapy.[63,64] One intense area of proteomics research involves early cancer detection based on defining protein signatures indicative of early-stage cancers in tissues, such as peripheral blood.[65] Proteomic methods likely will be an important tool in cancer detection, diagnosis, and prognosis in the near future. A related area of MS that will have a

large effect in cancer biology and treatment in the near future is metabolomics, in which MS is used to measure hundreds of cellular metabolites, thus, revealing metabolic changes that have critical roles in carcinogenesis,[66] as well as potential therapeutic vulnerabilities.[67]

KEY POINTS

- Protein analyses reveal protein abundance, functional modifications such as phosphorylation and acetylation, and information such as subcellular localization.
- Immunological techniques that detect protein expression are used for a wide variety of diagnostic tests, including immunohistochemical identification and sub-classification of solid tumors and immunophenotyping for diagnosis and monitoring of hematologic malignancies.
- Mass spectrometry–based proteomics allow for large-scale analyses of protein expression and modifications in tumor tissues.

ONCOGENES AND TUMOR SUPPRESSORS: ACCELERATORS AND BRAKES ON THE ROAD TO CANCER

Transforming a normal cell into a malignant cell requires a series of mutations in genes, termed "oncogenes," which contribute to neoplasia when their functions are altered.[68,69] To date, perhaps several hundred human genes have been implicated as proto-oncogenes—genes that have the potential to be converted into oncogenes. Dominant oncogenes sustain gain-of-function mutations in cancers, whereas tumor suppressors are recessive oncogenes that sustain loss-of-function mutations in cancers.

IDENTIFICATION OF ACTIVATED DOMINANT ONCOGENES

Dominant oncogenes are activated by numerous mechanisms. Many of the first known oncogenes were discovered in experimental cancer models and subsequently found to be activated in human cancers by mechanisms such as translocation, amplification, and point mutations. These different types of mutations lead to distinct functional outcomes and often provide important diagnostic and prognostic information.

Classical Experimental Cancer Models: Retroviruses and Transfections

Many oncogenes were first discovered through studies of animal cancers induced by retroviruses, called "RNA tumor viruses." One class of RNA tumor viruses carry viral oncogenes within their viral genomes, and several dozen viral oncogenes were identified in the 1970s and 1980s. The major breakthrough with respect to human cancer came with the realization that viral oncogenes represent mutated versions of host proto-oncogenes that were captured by the viral genomes during their life cycle. Many viral oncogenes are the counterparts of extremely important human oncogenes, and the identification of their cellular homologs established the framework within which we understand the role of dominant oncogenes in tumorigenesis. A second class of RNA tumor viruses causes cancers in animals by insertional mutagenesis, in which the integration of a viral genome into a host chromosome activates a cellular proto-

oncogene. Insertional mutagenesis remains a powerful genetic tool for oncogene discovery.[70]

Another classic strategy used to identify oncogenes is DNA transfection. In this approach, DNA is extracted from tumor cells and introduced into recipient cells, which undergo morphologic and growth alterations (transformation) when they incorporate a tumor-derived oncogene. The transfected tumor cell DNA is subsequently isolated and sequenced from the transformed cells, allowing the identification of the transferred oncogene. Many critical human oncogenes, including *RAS,* were originally isolated from transfection experiments.[71]

Chromosome Translocations

Cancers often contain recurrent chromosome translocations; this is particularly true for hematologic malignancies, which are often characterized by chromosome translocations that involve Ig and T-cell receptor genes.[72] Specific translocations have important diagnostic and prognostic implications and serve as molecular markers for the detection of residual disease and relapse. The regions of DNA commonly involved with translocations are termed "breakpoints," and these often contain proto-oncogenes that are activated by the DNA rearrangement.

Chromosome translocations activate proto-oncogenes in two general ways.[73] The most common mechanism involves the creation of fusion genes when the translocation joins two genes normally found on separate chromosomes in the same translational reading frame and results in a novel protein encoded by the two fused genes. Fusion proteins often involve transcription factors or tyrosine kinases and have biologic activities that differ from the parental proto-oncogene. Indeed, several examples of this type of translocation are highly relevant to cancer biology and therapy. The *BCR-ABL* fusion that results from the reciprocal exchange of DNA between chromosomes 9 and 22, t(9;22), is known as the Philadelphia chromosome (Fig. 2-10). This translocation juxtaposes the 5′ end of the *BCR* gene on chromosome 22 and the 3′ end of the *c-ABL* oncogene on chromosome 9. The resultant novel gene produces a hybrid mRNA that codes for the BCR-ABL oncoprotein, which deregulates the tyrosine kinase activity normally associated with the c-ABL protein. This translocation is the key driver of CML and is present in other leukemias as well. Indeed, many hematologic cancers are characterized by pathognomonic chromosomal translocations that produce fusion proteins.[73]

Recurrent chromosome translocations also occur in solid tumors. In Ewing sarcoma, translocations fuse the *EWS* gene on chromosome 22 to the *FLI-1* gene on chromosome 11, and this creates a transcription factor containing a DNA-binding domain derived from *FLI-1* and a transcriptional activation domain from *EWS*.[74] Alveolar rhabdomyosarcomas also contain a pathognomonic translocation, which in this case fuses the *PAX3* and *FHK4* transcription factors. Translocations that join the androgen-responsive *TMPRSS2* gene with two *ETS* transcription factors, *ETV1* and *ERG,* occur frequently in prostate cancer and result in abnormal *ETS* expression driven by the androgen-responsive regulatory elements in the *TMPRSS2* gene.[75]

Other translocations activate proto-oncogenes by deregulating their expression without altering their protein structure. An example of this type of translocation is found in Burkitt lymphoma, which is characterized by translocations that cause the *MYC* oncogene, located on chromosome 8, to be juxtaposed to Ig genes that are located on chromosomes 14, 2, and 22 (Fig. 2-10). In each case, the translocation deregulates *MYC* expression by placing it under the control of transcriptional elements contained within the Ig locus. Other examples of proto-oncogenes that are activated by translocations involving Ig genes include *CCND1* which encodes the protein cyclin D1 (found in mantle cell lymphoma and multiple myeloma) and *BCL-2*

(in follicular lymphoma).

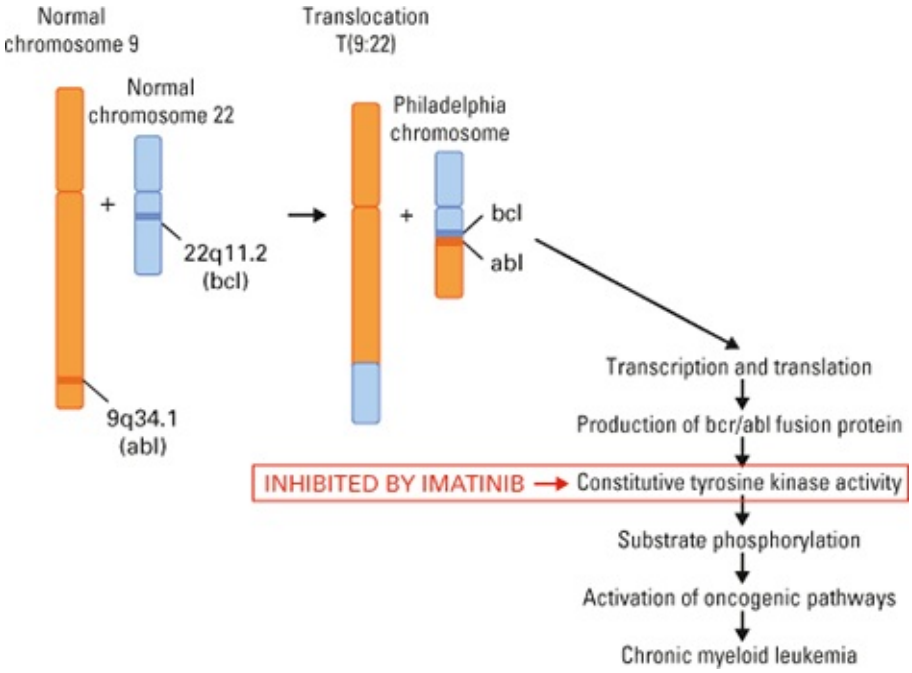

Fig. 2-10 Translocation leading to the Philadelphia (Ph) chromosome and the role of BCR-ABL in the pathogenesis of chronic myeloid leukemia.

The Ph chromosome is a foreshortened chromosome 22 resulting from an exchange between the long arms of chromosomes 9 and 22. This leads to the production of a BCR-ABL fusion protein that has constitutive kinase activity and promotes the development of chronic myeloid leukemia. The tyrosine kinase inhibitor imatinib inhibits this constitutive kinase activity and can lead to long term control of this leukemia.

Source: *Wikipedia. Public Domain, https://en.wikipedia.org/wiki/Philadelphia_chromosome.*

Other genomic rearrangements, such as chromosomal inversions, also create fusion proteins with important therapeutic implications. For example, inversions of chromosome 2 that fuse the *ALK* gene with the *EML4* gene identify a subset of patients with non–small cell lung cancer that respond to therapy with ALK inhibitors.[76]

DNA Amplification

DNA amplification results in the increased copy number of a gene and is another mechanism by which cancer cells increase the expression of a gene product, and many solid tumors exhibit proto-oncogene amplifications.[77] Gene amplification can be directly detected by many methods, including CGH, FISH, and NGS, as well as by surrogate markers, such as protein expression by IHC. In some cases, the detection of amplified genes provides important prognostic and treatment-related information, as in the case of *HER2* amplification in breast cancer and gastroesophageal cancer and *MYCN* amplification in neuroblastoma.

Point Mutations

While point mutations in cancer genes can inactivate or impair protein function, many recurrent mutations activate dominant oncogenes. Examples of this mechanism of oncogene activation include mutations of amino acids that alter *KRAS* function in colorectal cancers and activating mutations of the epidermal growth factor receptor (*EGFR*) in lung cancer. Neomorphic mutations change the function of the targeted oncoprotein, such as the altered specificity of the enzyme isocitrate dehydrogenase caused by *IDH1/2* mutations in glioma (see the

Oncogenomics and Precision Oncology section for discussion of these specific mutations). Because some common oncogenes, such as *KRAS* and *NRAS*, are activated by only a few specific point mutations, these genes were some of the first that were routinely screened for in cancer specimens. However, NGS can now identify most potentially oncogenic point mutations in primary tumor samples, and in time frames that allow genomics-based treatment decisions.[78] One common strategy uses targeted sequencing to interrogate panels of commonly mutated and actionable proto-oncogenes; this may provide genomic data with a time frame (and cost) that is more concordant with clinical interventions than broader approaches that sequence all protein coding regions or even whole genomes.

IDENTIFICATION OF INACTIVATED TUMOR SUPPRESSOR GENES

Many tumor suppressor genes were first identified by virtue of their association with hereditary cancer syndromes. Importantly, the genes responsible for familial cancers often are the same tumor suppressor genes that are inactivated in sporadic cancers. In most familial cancer syndromes, a mutant copy of a tumor suppressor gene is inherited, followed by mutation or loss of the remaining normal allele, termed “loss of heterozygosity,” in cancers that develop in these individuals. These types of recessive oncogenes, in which disruption of both alleles is associated with cancer formation, are known as two-step (Knudson) tumor suppressors, named after classic studies of the *RB1* tumor suppressor in retinoblastoma.[79]

There are important exceptions to the Knudson model that expand our understanding of how tumor suppressor genes are mutated in cancers. In some cases, loss of a single allele of a tumor suppressor is sufficient to confer cancer susceptibility or contribute to neoplastic progression, even when a normal allele persists. This is termed a “haploinsufficient tumor suppressor gene.”[80] Another situation in which a tumor suppressor will not conform to the Knudson model is when tumor suppressors are inactivated by epigenetic mechanisms, such as when the *CDKN2A* cell-cycle inhibitor is silenced by DNA methylation in cancers. So-called “dominant negative mutations” also result in noncanonical tumor suppressor inactivation because they inhibit the function of the wild-type protein produced by the normal allele, thereby removing the selective pressure to mutate both alleles. In this case, only one allele of the tumor suppressor gene will contain a mutation, such as seen with the *FBXW7* and *SPOP* ubiquitin ligases or *TP53*.

Loss of tumor suppressor gene alleles occurs commonly in cancers.[81] In classical studies, delineating a locus involved by allelic loss in a tumor type was often the first step toward identifying a tumor suppressor gene, such as the breast cancer susceptibility gene *BRCA1.*[82] Sites of allelic loss were thus determined by analyzing polymorphic markers or CGH, and disease genes were localized to within the smallest common region of allelic loss. However, this is another area of cancer genetics that is greatly affected by NGS-based technologies, which are becoming the method of choice for detecting allelic losses in tumors. NGS approaches also detect numerous other mechanisms that disrupt tumor suppressor gene function, including point mutations, deletions that lead to premature termination and/or nonfunctional proteins, and promoter methylation.

KEY POINTS

- Proto-oncogenes are normal cellular genes that can be converted into oncogenes by

mutation or by epigenetic mechanisms, which alter their normal functions or expression.

- Dominant oncogenes encode proteins that are activated in tumors by mechanisms such as amplification, point mutations, and translocations.
- Tumor suppressor genes are recessive oncogenes that are inactivated in tumors by diverse mechanisms, including deletions, point mutations, and gene silencing.

CELLULAR FUNCTIONS OF ONCOGENES AND TUMOR SUPPRESSORS

Proto-oncogenes normally function in a remarkably wide array of biologic processes. Many dominant oncogenes are found within the pathways that normally govern cell division and differentiation in response to specific signals. Other areas, cellular pathways, and/or processes are also commonly targeted by oncogene mutations in cancers, including programmed cell death (apoptosis) and protein degradation. Tumor suppressors also function within most of these cellular pathways, where they serve to counter the effects of oncogenes. Tumor suppressors also have a particularly important role in the control of DNA repair and of cellular responses to DNA damage. The major cellular pathways that contain dominant oncogenes and tumor suppressor genes, and important examples of oncogenic mutations within these pathways, are summarized below.

MITOGENIC SIGNAL TRANSDUCTION PATHWAYS

Cell division is triggered by signal transduction pathways that are stimulated when growth factors bind to specific cell-surface receptors, and these pathways contain proto-oncogenes throughout the signaling chain.[83,84] Most growth factor receptors are anchored in the cell membrane such that an extracellular domain is available for growth factor (ligand) binding and an intracellular domain interacts with downstream signaling molecules. The intracellular portion of a class of growth factor receptors—receptor tyrosine kinases (RTKs)—catalyzes the addition of phosphate to tyrosine residues. Ligand binding causes RTKs to dimerize and autophosphorylate, which recruits signaling proteins that transmit the mitogenic signal down several parallel pathways, including the phosphatidylinositol-3 kinase (PI3K) and mitogen-activated protein kinase (MAPK) pathways (Fig. 2-11). Cytoplasmic tyrosine kinases also transduce these mitogenic signals, including the c-ABL protein. The gene encoding this protein is fused with the *BCR* gene in CML. Dominant mutations in these signaling kinases found in cancer subvert the normal growth factor signals needed to stimulate these pathways.

RAS proteins transduce mitogenic signals, and their activity is regulated by whether they are bound to guanosine triphosphate (GTP) or guanosine diphosphate (GDP).[85-87] Thus, RAS activity reflects a balance of guanine nucleotide–exchange factors (GEFs), which activate RAS, and guanosine triphosphatase–activating proteins (GAPs), which hydrolyze RAS-bound GTP to GDP (Fig. 2-11). Oncogenic *RAS* mutations affect amino acids that interface with GAPs, which results in overactivity of proliferative signaling pathways. Furthermore, GAPs themselves can function as recessive oncogenes. For example, the *NF1* gene is a GAP that acquires a loss-of-function mutation in neurofibromatosis.[88]

RAS drives three parallel signaling pathways: the MAP kinase pathway (which activates transcription factors), the RAL/CDC42 pathway (which regulates membrane and cytoskeletal changes), and the PI3K pathway (which affects many cellular functions, including protein synthesis and apoptosis) (Fig. 2-12). The MAP kinase pathway is stimulated by the RAF

serine/threonine kinase, and signals to additional downstream cytoplasmic serine/threonine kinases, which ultimately activate MAP kinases and other effectors. Mutations of the *BRAF* gene are found in approximately 50% of melanomas. MAP kinase signaling ultimately activates nuclear proto-oncogenes that encode transcription factor proteins, such as *FOS, JUN,* and *MYC.* Each of these oncogenic transcription factors promotes carcinogenesis by binding to target genes and affecting their expression.

The phosphtidylinositol 3-kinase/protein kinase B (PI3K/AKT) pathway stimulates transcriptional and translational responses that affect incredibly diverse cellular processes, including cell growth and division, apoptosis, protein synthesis, and cellular metabolism (Fig. 2-13).[66,89-92] Each of these processes may be abnormal in cancers with *PI3K* mutations, which are among the most common mutations found in cancer cells.[93] AKT is a protein kinase that is downstream of PI3K and is often amplified and/or overexpressed in cancers.[94] Moreover, cancers exhibit elevated AKT activity caused by mutations in genes that regulate AKT. For example, the phosphatase and tensin homolog tumor suppressor (PTEN), which is commonly deleted in cancers, opposes PI3K and prevents AKT activation.[95] AKT phosphorylates many substrates that regulate cell division, apoptosis, and protein synthesis, and the PI3K/AKT pathway has enormously complex and important roles in controlling normal and neoplastic cellular homeostasis.[94]

Targeting Mitogenic Kinases in Cancer Chemotherapy

The concept of specifically inhibiting mutant oncoproteins in cancer falls under the umbrella term “targeted therapy” and has been heavily applied to mitogenic kinases in cancer. In cases in which the roles of individual kinases in specific cancers have been recognized for a long time, such as HER2 in breast cancer and BCR-ABL in CML, targeted therapies are already mature. However, the NGS-driven revolution in molecular oncology is now allowing these approaches to be directed against a much larger number of cancers that contain sensitizing mutations in genes that can be therapeutically targeted. Although targeted therapies will be discussed in detail in subsequent chapters in the context of specific organ sites and therapies, a general overview of these concepts is provided in this section.

Several therapeutic strategies that target aberrant RTKs are in clinical use. One approach utilizes antibodies that bind to and inhibit RTKs. Examples include trastuzumab, which antagonizes HER2 activity and is used in the treatment of breast cancers with *HER2* amplification,[96] and cetuximab, an inhibitory antibody that binds to the EGFR and is approved for use in metastatic colon cancer and head and neck cancers.[97,98]

Another important strategy to target RTKs and mitogenic kinases in cancers utilizes small-molecule inhibitors, such as imatinib, erlotinib, and crizotinib, which bind to specific kinases and inhibit their catalytic activity. These inhibitors have the greatest efficacy in tumors that contain mutations within the target kinase. For example, the efficacy of erlotinib and related tyrosine kinase inhibitors is closely associated with mutations in *EGFR* that are found in a small fraction of patients with lung cancers.[99,100] Another example is the use of BRAF inhibitors to treat patients whose melanomas harbor *BRAF* mutations.[101] The concept of directing small-molecule inhibitors against individual tumors with specific mutations is the very crux of precision oncology.

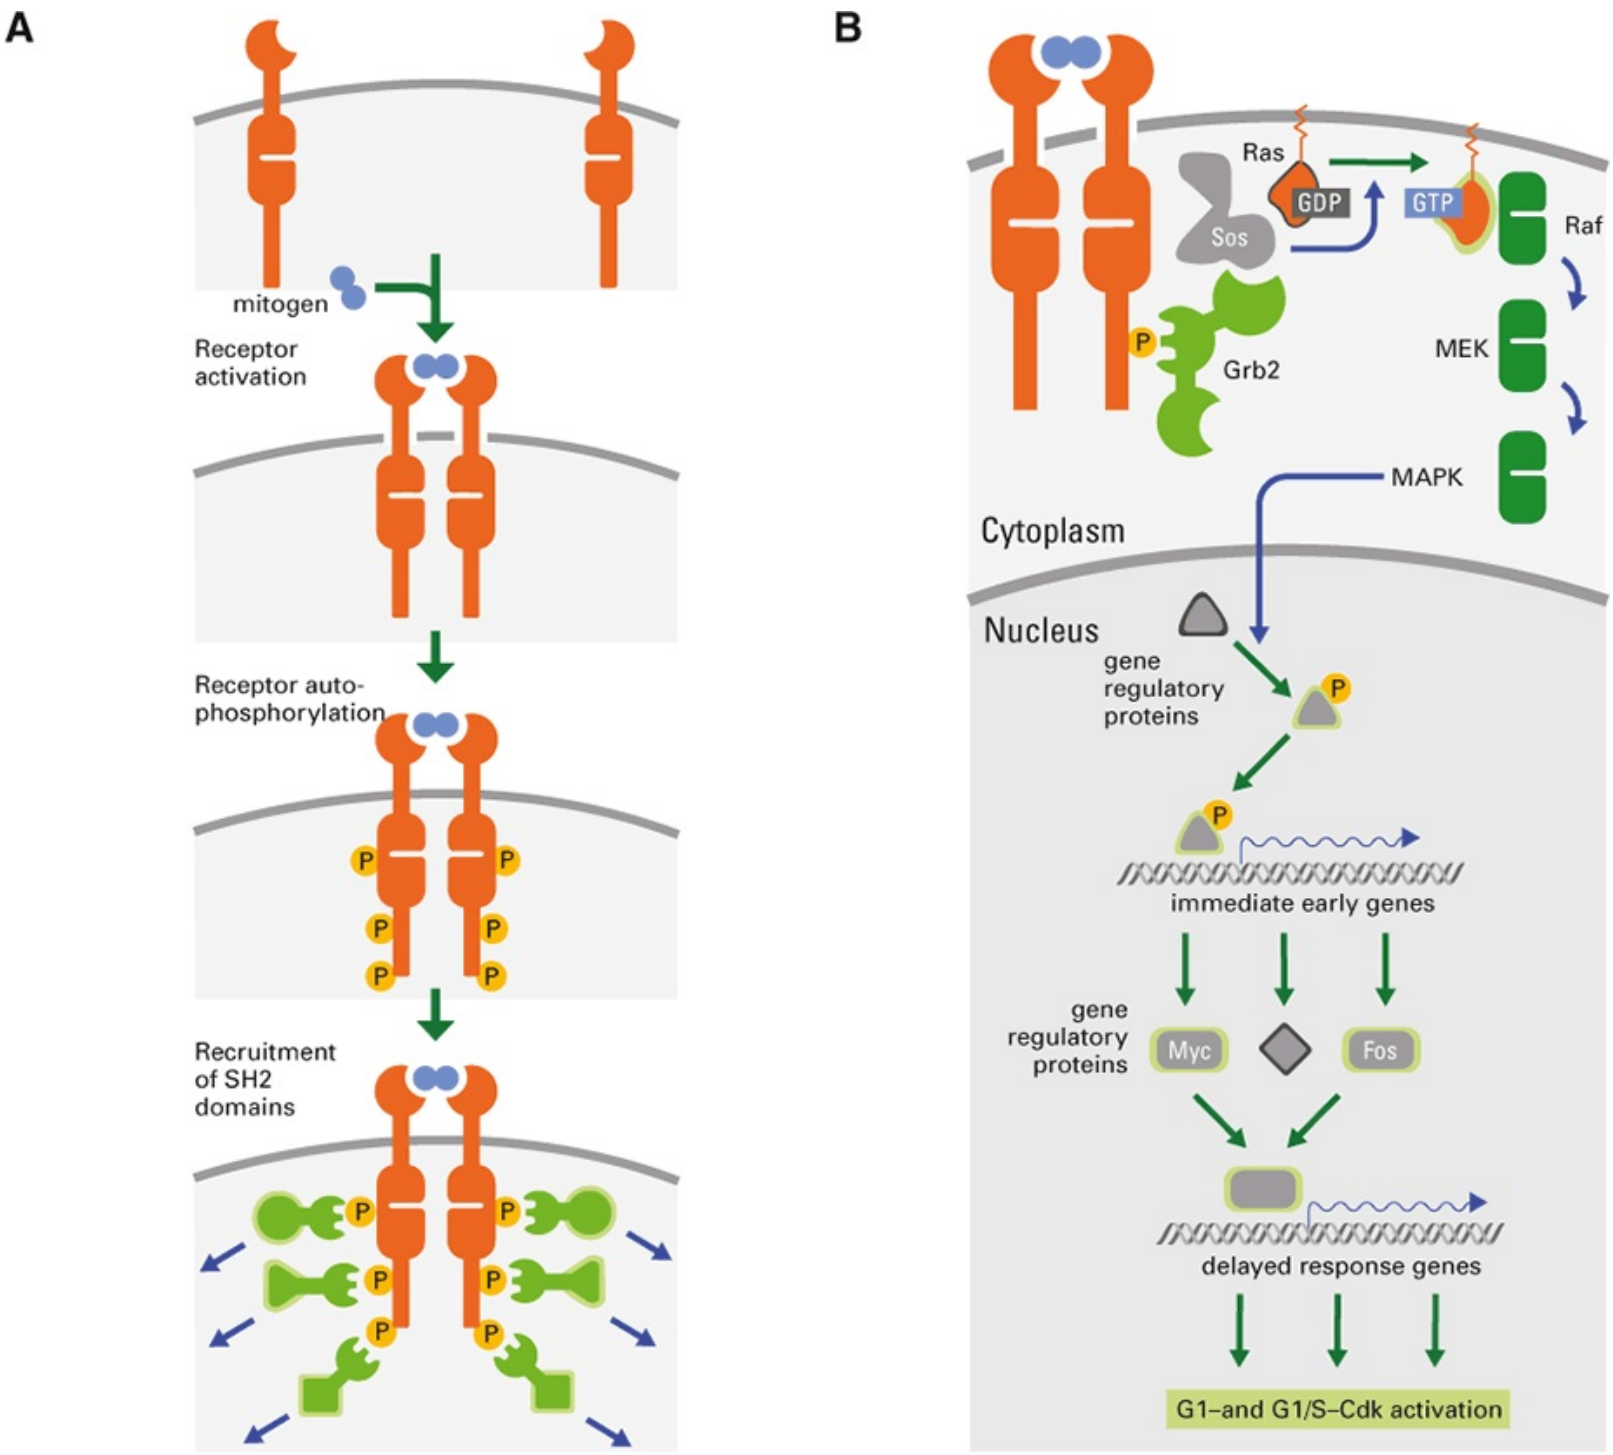

Fig. 2-11 Mitogenic signaling.

(A) Origin of the mitogenic signal at the cell membrane. The binding of growth factors to receptor tyrosine kinases causes receptor dimerization and autophosphorylation. The receptor tyrosine phosphorylation then recruits binding proteins that contain SH2 domains, and these transmit the mitogenic signal (see text). (B) Mitogenic signaling by the RAS pathway. RAS activation stimulates the mitogen-activated protein kinase pathway, which leads to the activation of downstream transcription factors such as JUN and MYC (see text).

Kinase inhibitors can also be used to treat tumors that depend on the activity of a kinase pathway but do not have mutations in the kinase itself. Examples of this approach include the treatment of chronic lymphocytic leukemia with idelalisib (which inhibits PI3K-δ) and the use of ibrutinib (which inhibits Bruton tyrosine kinase) to treat mantle cell lymphoma and chronic lymphocytic leukemia.[102] Despite their remarkable activities, the development of resistance against small-molecule kinase inhibitors limits the durability of clinical responses and may be

inevitable in solid tumors. An exception to this is the use of imatinib and related drugs to inhibit BCR-ABL in CML, for which responses are extremely durable, lasting years. In most other cancers, such as the use of BRAF inhibitors in melanoma, resistance develops much more quickly, despite impressive initial responses.

Tumors acquire resistance to kinase inhibitors in several ways. One mechanism involves mutations in the target kinases themselves, such that they are no longer inhibited by the targeted therapy. In some cases, the mutant kinases can still be effectively inhibited by related small molecules, whereas other mutations confer wider drug resistance. An example of this mechanism is the acquisition of *BCR-ABL* mutations in CML that prevent its inhibition by imatinib, but which can still be inhibited by related agents, such as nilotinib.[103,104]

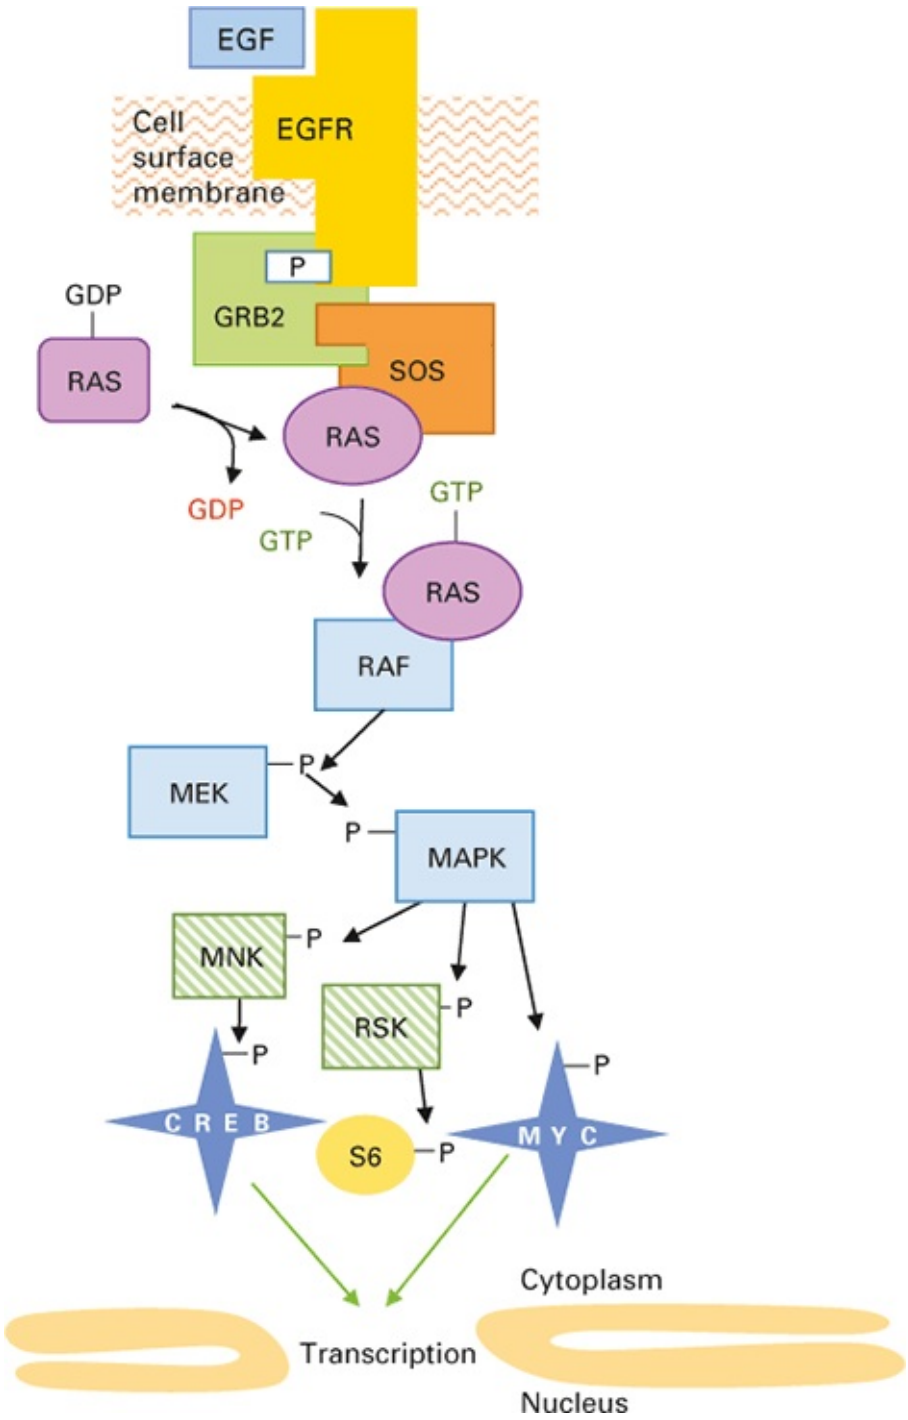

Fig. 2-12 RAS upstream and downstream signaling.

Extracellular stimuli signal through cell-surface plasma membrane receptors, for example, RTKs (EGF/EGFR shown). Through a variety of adaptor proteins, these signals cause guanine nucleotide exchange factors to replace the GDP bound to inactive RAS with GTP. GTP-bound RAS binds to a plethora of downstream effector molecules to stimulate intracellular signaling of several

pathways. Those with established roles in *RAS* oncogenesis include the RAF serine/threonine kinases (shown), as well as the PI3K lipid kinases, RAL GEFs, and Tiam1. Activating mutations in *RAS* genes are present in many tumor types and lead to constitutive RAS signaling, which drives transformation, invasion, and metastasis.

Source: *Wikipedia. Public Domain, https://en.wikipedia.org/wiki/MAPK/ERK_pathway*.

However, some mutations confer resistance to an entire class of inhibitors. The second major mechanism of resistance to kinase inhibitors involves the development of bypass pathways, in which tumor cells "rewire" their mitogenic signaling to utilize alternative pathways. In this case, although the target kinase is still sensitive to the pharmacologic inhibitors, the tumors have escaped kinase inhibition through the activation of alternative signaling pathways.[105] An example of this mechanism is the activation of alternative RTKs in lung cancers being treated with EGFR inhibitors. One therapeutic approach in this case is the use of additional kinase inhibitors to block the bypass pathway, such as targeting both the BRAF and MAPK pathways in melanoma, although additional mutations also tend to render this approach ineffective over time.

CELL-CYCLE CONTROL

Cell cycles are divided into four phases that coordinate cell growth, DNA replication, and cell division. G1 phase is a period of growth between mitosis and the onset of DNA synthesis during which cells integrate mitogenic signals and commit to the onset of DNA replication. S phase is the period of DNA synthesis during which a cell replicates its genomic complement. G2 phase follows the S phase and is a second period of cell growth. In mitosis, chromosomes are segregated to daughter cells and cell division occurs. It is critically important that cells execute the cell-division cycle faithfully, and mutations in the genes that regulate the cell cycle are among the most common genetic changes in cancer cells.[106,107]

The cyclin-dependent kinases (CDKs) orchestrate cell-cycle transitions by phosphorylating protein substrates with diverse roles in cell division (Fig. 2-14). CDKs are composed of two subunits: a catalytic subunit (the CDK) and a regulatory subunit (the cyclin) that activates the CDK. The best known G1 CDK substrate is the retinoblastoma protein (pRb), and the Rb pathway is mutated in most cancers. Early in the G1 phase, unphosphorylated pRb sequesters E2F transcription factors and represses the expression of cell-cycle genes. As the cell cycle progresses, Rb becomes phosphorylated by cyclin CDKs, which releases E2F and promotes the transcription of genes that drive cell proliferation (Fig. 2-15). Two classes of CDK inhibitor proteins prevent CDK activity. The INK4 proteins inhibit only CDK4 and CDK6, whereas the CIP/KIP proteins (p21, p27, and p57) bind to most cyclin-CDKs (Fig. 2-14).

Cyclins and CDKs can act as dominant oncogenes. The cyclin D1 gene (*CCND1*) is rearranged by chromosome inversion in parathyroid adenomas, translocated to the IgG heavy chain locus in mantle cell lymphomas, and amplified in 10 to 15% of solid tumors. Similarly, the cyclin E gene (*CCNE1*) was found to be the second most commonly amplified gene in ovarian cancers[108] and the cyclin E protein is upregulated in cancers by increased *CCNE1* transcription or prolonged protein stability.[109] CDKs themselves undergo oncogenic mutation, such as a *CDK4* mutation found in familial melanomas that prevents its inhibition by INK4 proteins.[110] Abnormal CDK4 and CDK6 activity is particularly linked to tumorigenesis, and CDK4/6 inhibitors are demonstrating great promise in breast cancer and hematologic cancers, as evidenced by the recent approval of palbociclib to treat estrogen receptor–positive breast cancer.[111-113] Small molecules that inhibit other cell-cycle kinases, such as cyclin-dependent kinase 2 (CDK2) and the Wee1 kinase, which regulates CDK activity, are also in wide clinical trials.[114,115]

Genes encoding proteins that inhibit CDKs are recessive oncogenes. p16INK4A proteins, encoded by the *CDKN2A* locus, frequently exhibit allelic loss in cancers. Another potent tumor suppressor, ARF, also is contained within *CDKN2A* and contributes to the biologic selection for its allelic loss.[116] Deletions and point mutations of the *CDKN2A* locus occur commonly in cancers such as glioblastomas.[117] *CDKN2A* is also epigenetically inactivated in tumors by promoter methylation, most notably in colon and lung cancers.[118] The p27KIP1 CDK inhibitor is a tumor suppressor whose abundance has prognostic significance in cancers.[119] This protein, encoded by the *CDKN1B* gene, is an example of a tumor suppressor that is rarely mutated, but instead is inactivated by mutations in the pathways that regulate its degradation and/or subcellular localization. *RB1* is the prototype tumor suppressor, and its role in hereditary retinoblastoma provided the basis for the Knudson two-step model.[79] Importantly, *RB1* is mutated in many sporadic cancers, including small cell lung cancer, bladder cancer, and other common tumors.[120,121]

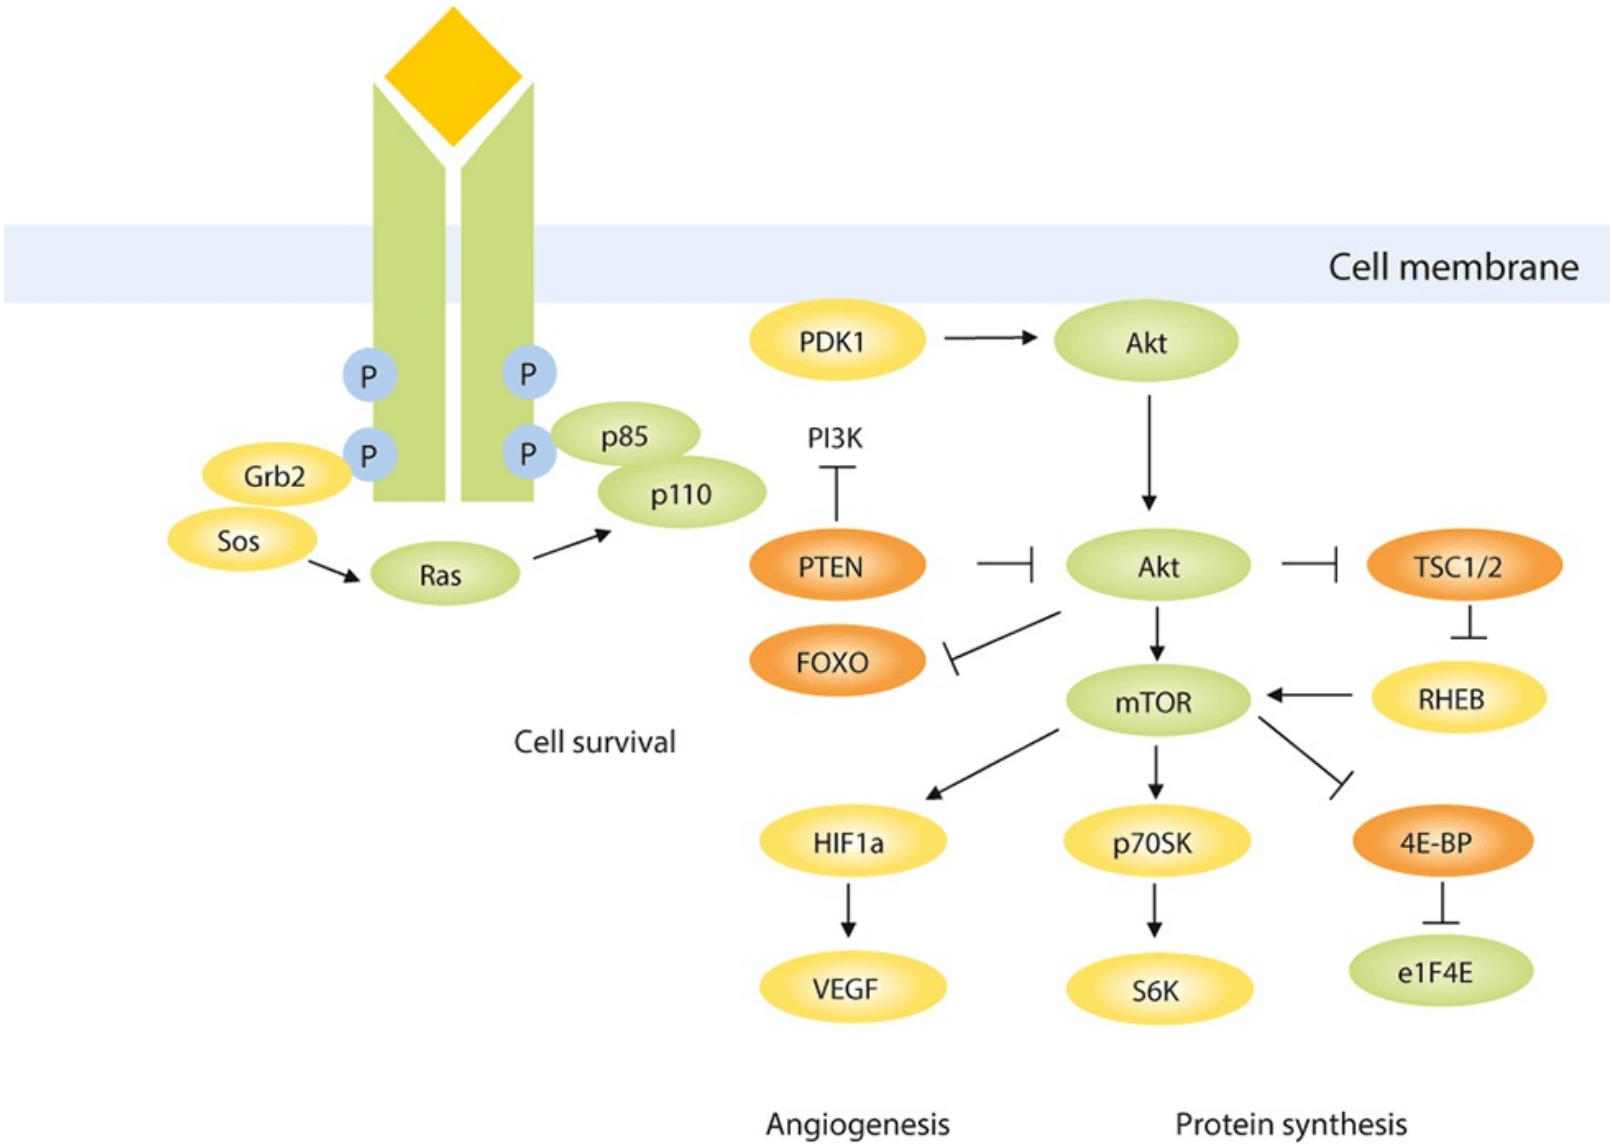

Fig. 2-13 Alterations of the AKT pathway in human cancer.

Activation of growth factor receptors such as EGFR, either by ligand stimulation or receptor overexpression/mutation, is one of the major mechanisms responsible for upregulation of AKT signaling. Other common mechanisms include activation of oncoproteins and inactivation of tumor suppressors intersecting the AKT signal transduction pathway. Proteins shown in green indicate oncoproteins for which overexpression and/or activating mutations have been implicated in many sporadic human cancers. Proteins in orange are tumor suppressors whose loss and/or inactivation have been found to contribute to deregulation of the AKT pathway and tumor formation. FOXO transcription factors have also been implicated as tumor suppressors (see text), although, to date, mutations have not been observed in any hereditary cancer syndrome. AKT signaling contributes to cancer

development by activating multiple processes, including cell survival, angiogenesis, and protein synthesis.

APOPTOSIS

Tumor growth is a consequence of both unrestrained cell division and decreased cell death, and the pathways that mediate cell death contain proto-oncogenes that are mutated in cancers. Apoptosis is a physiologic process whereby complex biochemical pathways mediate cell death; it is triggered by two distinct pathways (Fig. 2-16).[122,123] Cell death through the extrinsic pathway is signaled when ligands, such as tumor necrosis factor-alpha (TNF-α) and Fas ligand, bind to cell-surface death receptors, such as TNF-R1 and Fas. Ligand binding to death receptors initiates a sequence of events leading to activation of proteases, termed "caspases," which execute the apoptotic response. In contrast, the intrinsic or mitochondrial pathway results from a number of stimuli, such as radiation therapy or chemotherapy, and involves changes in the mitochondrial membrane that affect the release of cytochrome C into the cytoplasm. The intrinsic pathway also activates a caspase cascade that ultimately leads to DNA fragmentation and cell death.

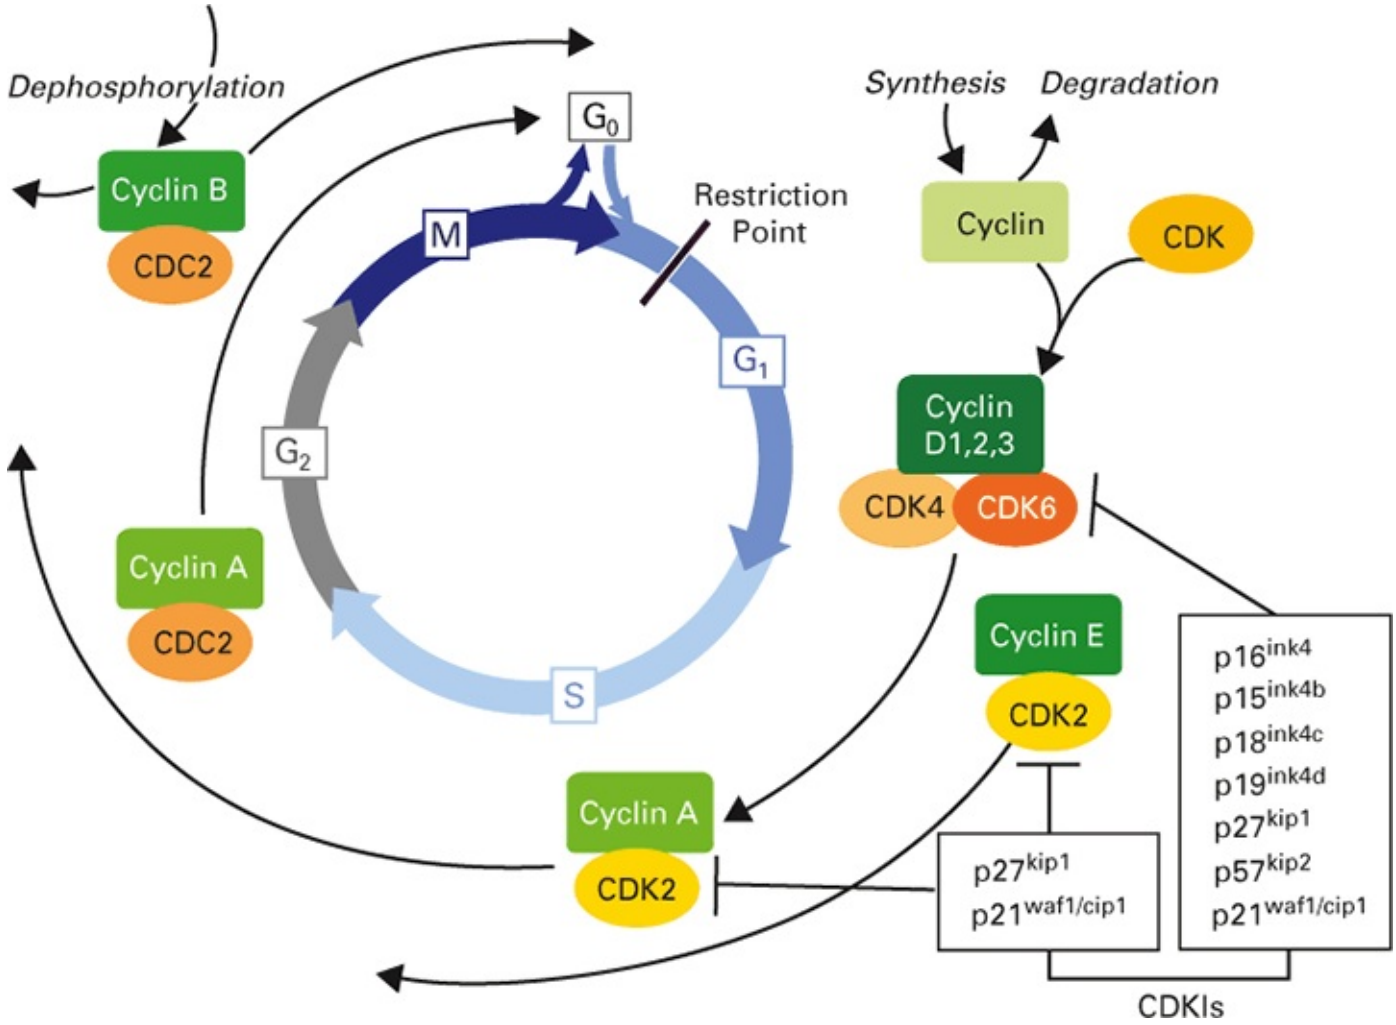

Fig. 2-14 The cell cycle.

The cell cycle is divided into four phases (G1, S, G2, and M). Progression through the cell cycle is promoted by cyclin-dependent kinases (CDKs), which are regulated positively by cyclins and negatively by CDK inhibitors (CDKIs). The restriction point is the point at which cells progress through the cell cycle independently of external stimuli.

Reproduced with permission from Schwartz G, Shah M. Targeting the cell cycle: A new approach to cancer therapy. J Clin Oncol. *2005;23:9408–9421. PMID: 16361640.*

The BCL-2 family comprises proteins that regulate apoptosis; they are either proapoptotic (promote cell death) or antiapoptotic (promote cell survival).[124] *BCL2* is antiapoptotic and was first identified as the gene activated by the t(14;18) translocation found in follicular lymphomas. The precise mechanisms by which BCL-2 prevents cell death are not fully elucidated, but they involve interactions with proapoptotic family members, as well as mitochondrial functions. One important consequence of BCL-2 overexpression in tumorigenesis is that it prevents the apoptosis normally triggered by dominant oncogenes, such as *MYC,* and this likely underlies the aggressive behavior of "double-hit" lymphomas, which contain activating translocations of both the *MYC* and *BCL2* genes.[125] The realization that BCL-2 prevents apoptosis was pivotal in the evolution of understanding the relationship between apoptosis and cancer. Because of their potential to induce apoptosis in tumor cells, drugs that target the BCL-2 family are being widely studied in clinical trials.[126-128]

Many oncogenes interact with the core apoptotic pathways. The most common mutations that impair apoptosis in tumors involve the *TP53* tumor suppressor gene. Apoptosis is one outcome of *TP53* activation by cellular stresses, and impaired cell death is an extremely important consequence of *TP53* loss in cancer. Another frequently mutated pathway that negatively regulates apoptosis is the PI3K/AKT pathway. AKT's interactions with apoptotic signaling is complex and includes direct effects on the mitochondrial membrane, as well as functional interactions with BCL-2 family members, FOXO transcription factors, nuclear factor-kappa B, and p53.

KEY POINTS

- Mitogenic signaling pathways contain many broadly acting proto-oncogenes. Many of these proteins are tyrosine kinases that can be targeted clinically by small-molecule kinase inhibitors and antibody-based therapeutics.
- The genes that regulate the cell-division cycle are commonly mutated in cancer cells.
- Many oncogenic mutations disrupt normal apoptotic responses.

UBIQUITIN-MEDIATED PROTEOLYSIS

Many short-lived proteins are degraded in a proteolytic structure called the "proteasome." Conjugation of a protein to ubiquitin is the signal for its delivery to the proteasome, and this is catalyzed by a multistep reaction in which ubiquitin is transferred to lysine side chains of the target protein (Fig. 2-17).[129-131] Ubiquitin, a 76–amino acid protein, is first attached to an ubiquitin-activating enzyme (E1), and then transferred to ubiquitin-conjugating enzyme carrier proteins (E2). In most cases, protein ubiquitylation requires an ubiquitin ligase enzyme (E3), which facilitates transfer of ubiquitin to the protein substrate. Cells contain hundreds of E3s, and these often recognize their targets after they have been modified by specific signals (e.g., phosphorylation). A family of deubiquitinating enzymes provides an additional layer of control by removing ubiquitin moieties from protein substrates. The multienzyme and signal-regulated ubiquitin–proteasome system provides an enormous amount of specificity over which proteins are degraded in various contexts. In addition to protein degradation, which is signaled by a specific type of polyubiquitin linkage to proteins, ubiquitylation also regulates processes such as

protein–protein interactions and cellular signaling, and specific types of polyubiquitin and monoubiquitin linkages mediate these alternative outcomes.

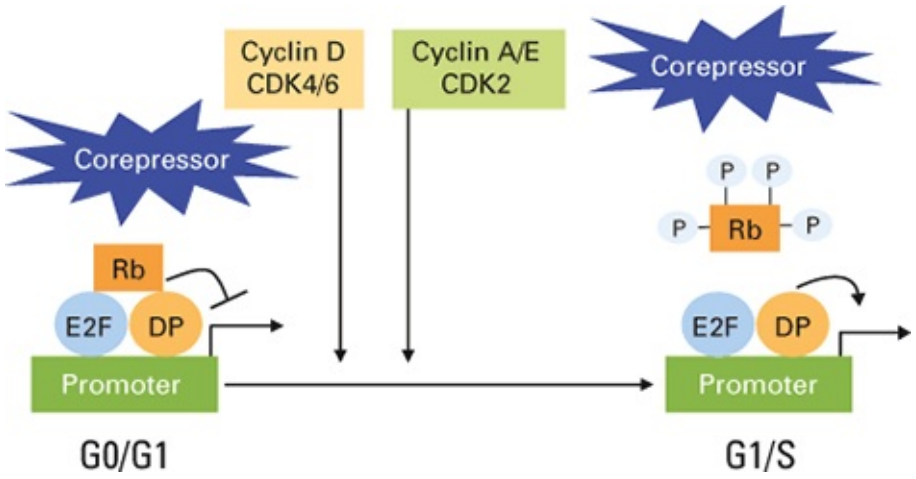

Fig. 2-15 Rb and E2F function.

Rb binds the transcription factor E2F and its associated subunit DP. Rb represses E2F-mediated transcription by recruiting chromatin remodeling complexes to the promoter in resting cells. At the G1–S-phase transition, Rb is thought to be phosphorylated by CDK2, CDK4, and CDK6. Hyperphosphorylated Rb releases E2F, allowing it to activate transcription of its target genes.

E3 ubiquitin ligases are important oncogenes and tumor suppressors. *FBXW7* encodes an E3 ubiquitin ligase and is one of the most commonly mutated tumor suppressor genes across the cancer spectrum.[132] Fbxw7 targets numerous key oncoproteins for degradation, including cyclin E, c-Myc, Notch, and c-Jun, and inactivating *FBXW7* mutations promote tumorigenesis through the unrestrained activity of its oncogenic substrates. Cancer of some organ sites, such as T-cell acute lymphoblastic leukemias and endometrial cancers, exhibit particularly high *FBXW7* mutation rates. SPOP is another ubiquitin ligase protein recently implicated in carcinogenesis. Prostate and endometrial cancers show recurrent mutations in *SPOP* that lead to deregulation of cancer drivers, including androgen and estrogen receptors.[133,134] SPOP also appears to be involved in the DNA repair gene process, and *SPOP* mutation may predict sensitivity to DNA-damaging agents.[135] Interestingly, SPOP may act as an oncogene in clear cell renal cancer, and as such, is an example of the rare genes that can act as both tumor drivers and tumor suppressors, depending on cellular context.[136] Inactivating mutations of the Von Hippel–Lindau (*VHL*) E3 ubiquitin ligase are the cause of VHL syndrome; in this syndrome renal cell carcinomas, central nervous system hemangioblastomas, pheochromocytomas, pancreatic tumors, and other neoplasms develop. VHL syndrome is diagnosed by the presence of germline inactivating *VHL* mutations, and the remaining allele is inactivated in tumors by mutation. Inactivating *VHL* mutations are also found in most spontaneous renal cell carcinomas.[137] One critical VHL target is hypoxia-inducible factor-1 alpha (HIF1A), a transcription factor that regulates genes in response to hypoxia, including an angiogenic transcriptional program that contributes to the highly vascular tumors associated with VHL loss. In other cases, E3s are overexpressed and act as dominant oncogenes. One example of this involves MDM2, a ubiquitin ligase that degrades the p53 protein, and whose abundance is increased in cancers by mechanisms such as gene amplification.[138]

Proteasome inhibitors have emerged as important antineoplastic agents, particularly for the

treatment of hematologic cancers.[139,140] Bortezomib was the first pharmacologic proteasome inhibitor in clinical use and is approved for the treatment of patients with multiple myeloma and mantle cell lymphoma. Carfilzomib is a second-generation proteasome inhibitor approved for the treatment of multiple myeloma. However, the mechanism(s) that account for the therapeutic index associated with general proteasome inhibitors still remains unclear because these compounds affect a large number of proteins normally degraded by the proteasome. The ubiquitin–proteasome system also contributes to the actions of other chemotherapeutics, such as the striking finding that thalidomide and related drugs cause the Cereblon E3 ubiquitin ligase to abnormally degrade Ikaros B-cell–specific transcription factors and casein kinase 1 alpha and that this accounts for their efficacy in multiple myeloma and myelodysplastic syndromes with chromosome 5q deletions.[141-143] In addition to general proteasome inhibitors, activators or inhibitors of specific components of the ubiquitin ligase pathway are of great clinical interest.[144] For example, inhibitors of the SPOP ubiquitin ligase have been developed and show activity in kidney cancer models.[145]

WNT/BETA-CATENIN SIGNALING

The Wnt/beta-catenin pathway has vital roles in development and cellular self-renewal.[146] Consistent with these functions, abnormal Wnt signaling is implicated in many cancers. Reduced to their essential components, soluble Wnt proteins bind to membrane-bound receptors, and this prevents the ubiquitin-dependent degradation of beta-catenin by the proteasome. Beta-catenin then translocates to the nucleus, where it stimulates a transcriptional program in concert with members of the TCF family of transcription factors. The regulation of this pathway is quite complex, and many proteins augment or restrain Wnt pathway activation. The best-characterized role of Wnt pathway activation in human cancer is in familial adenomatous polyposis, a hereditary colon cancer syndrome caused by deletion of the *APC* tumor suppressor. *APC* loss in cancers upregulates Wnt signaling by increasing beta-catenin abundance. Although first described in familial adenomatous polyposis, *APC* mutations are found in most sporadic colon cancers, and they are an early step during the progression of colorectal cancer.[147] Many other cancers also have aberrant Wnt signaling, including uterine cancers, brain cancers, and leukemia.[120] Inhibitors of the Wnt pathway are being actively studied for use in cancer therapy.[148] For example, the finding that colorectal cancers require persistent Wnt deregulation for tumor maintenance suggests that Wnt inhibitors may be efficacious in this setting.[149]

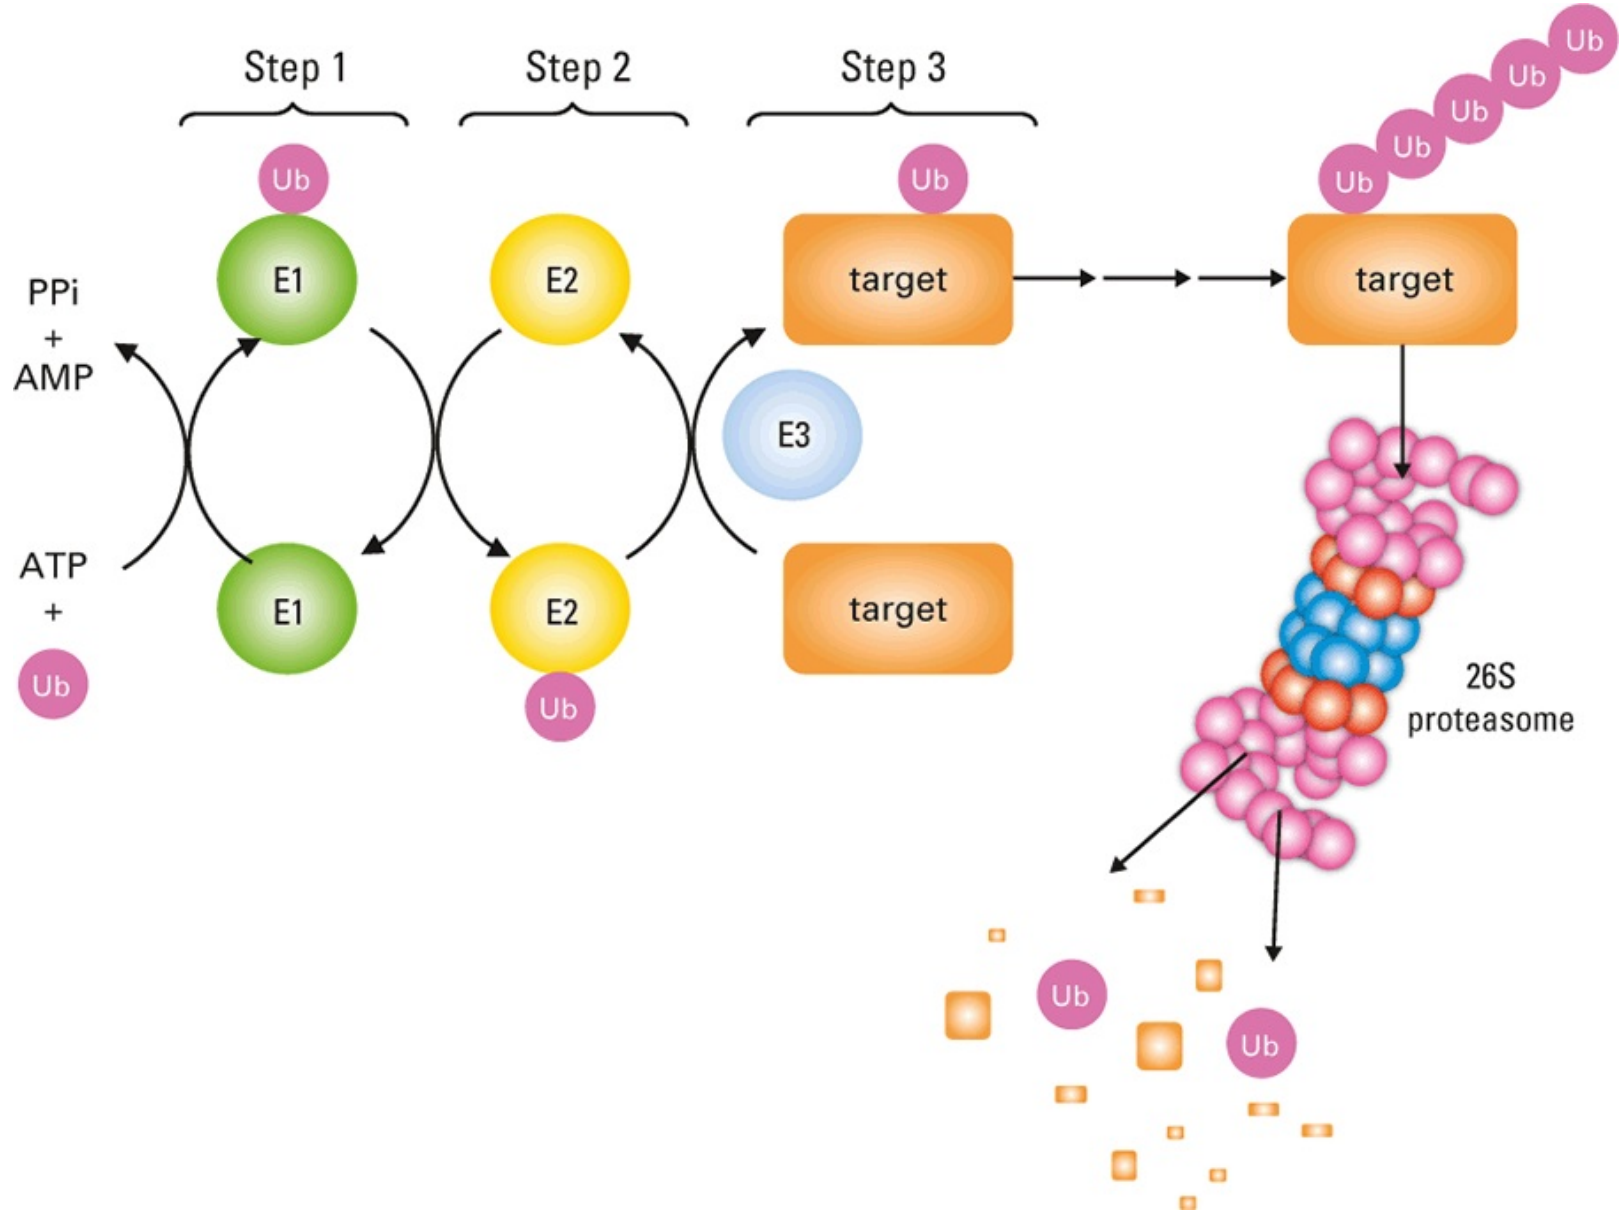

Fig. 2-17 Overview of the ubiquitin–proteasome pathway.

Ubiquitin (Ub) is a small protein that is first transferred to the ubiquitin-activating enzyme, E1, in an ATP-dependent manner. This activated ubiquitin is then transferred to the ubiquitin-conjugating enzyme, E2. Finally, the ubiquitin is covalently attached to the target protein by an E3 ubiquitin ligase, leading to formation of a polyubiquitin chain. The polyubiquitinated protein is recognized by the 26S proteasome, and is destroyed in an ATP-dependent manner.

DIFFERENTIATION

Most somatic cells are in a terminally differentiated, postmitotic state, which is established by complex transcriptional pathways. Many proto-oncogenes affect the pathways that regulate differentiation, and these often are transcription factors and/or coactivators involved in leukemias and lymphomas.[151] For example, the gene encoding retinoic acid receptor (RAR)-alpha is deregulated by several translocations found in acute promyelocytic leukemia, most commonly t(15;17), which produces a promyelocytic leukemia (PML)–RAR-alpha fusion protein. This fusion protein acts as a dominant-negative mutant that inhibits RAR-alpha target genes by recruiting co-repressors. This dominant-negative RAR-alpha fusion is targeted by all-trans retinoic acid (ATRA), which is used in conjunction with combination chemotherapy to induce remission in patients with acute promyelocytic leukemia. ATRA binds to the fusion protein and

prevents it from bringing co-repressors to RAR-alpha target genes. Thus, ATRA treatment reverses the differentiation block caused by the translocation product and allows promyelocytes to proceed down their differentiation pathway.[151] Core-binding factor (CBF) is another transcription factor that regulates hematopoietic differentiation and genes encoding both components of CBF (RUNX1/AML1 and CBF-beta) are involved in translocations found in acute leukemia. Like RAR-alpha, these translocations produce dominant-negative proteins that inhibit CBF target gene expression, which is thought to impair hematopoietic cell differentiation.[152]

The *NOTCH* genes are involved in cell-fate and differentiation pathways and are frequently altered in human cancers. *NOTCH* genes encode transmembrane receptors that stimulate transcriptional programs after they bind to ligands.[153] Ligand binding causes Notch proteins to be cleaved, forming intracellular domains that translocate to the nucleus. Notch proteins play important roles in lymphoid differentiation and are likely drivers of hematologic cancers. *NOTCH1* was first described as an oncogene by virtue of its involvement in the t(7;9) translocation found in a subset of patients with T-cell acute lymphoblastic leukemia. However, activating *NOTCH1* mutations occur in as many as 50% of patients with this disease.[154] The precise mechanisms through which Notch proteins promote leukemia are thought to involve impaired differentiation and enhanced self-renewal, and *MYC* is a critical mediator of Notch protein activity.[155] Interestingly, Notch proteins may act as tumor suppressors in some cancers, as 20% of squamous cell carcinomas show inactivating mutations in *NOTCH* genes. How this pathway promotes cancer in some clinical situations while suppressing it in others remains poorly understood.[156]

DNA REPAIR PATHWAYS

Mammalian cells use three major DNA repair pathways to maintain genomic integrity (Fig. 2-18). Mutations that disrupt these pathways cause genetic instability and are associated with diseases characterized by sensitivity to DNA-damaging agents and cancer predisposition. Ultraviolet light–induced nucleotide dimers and other DNA adducts are recognized and repaired by the nucleotide excision repair (NER) pathway. DNA-recombination repair is involved in the restoration of double-stranded breaks induced by ionizing radiation and radiomimetic agents. Finally, the DNA MMR pathways correct errors during DNA replication by removing the mismatched strand and enabling subsequent repair of the DNA.

Nucleotide Excision Repair Pathway

NER pathways correct nucleotide lesions induced by ultraviolet light and adducts induced by chemical carcinogens.[157] There are two NER pathways: a global repair pathway and a transcription-coupled repair pathway that repairs DNA damage that occurs during transcription. Mutations affecting these pathways give rise to sun-sensitive and developmental disorders, including xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy. Xeroderma pigmentosum is an autosomal-recessive disorder leading to neurodegeneration, sensitivity to ultraviolet light, abnormalities in skin pigmentation, and cancer predisposition. Patients with this disorder have a risk for skin cancer that is estimated to be 2000 times higher than the risk in the general population. Eight genes have been associated with xeroderma pigmentosum; seven of them code for excision-repair proteins, and one is a DNA polymerase that is required for accurate replication of damaged DNA. In contrast, Cockayne syndrome is associated with two genes, *ERCC8* and *ERCC6,* which are involved in transcription-coupled DNA repair. Trichothiodystrophy is caused by mutation of either *ERCC2* or *ERCC3,* which encode helicase

subunits of the TFIIH transcription complex. Neither Cockayne syndrome nor trichothiodystrophy is associated with an increased cancer risk.

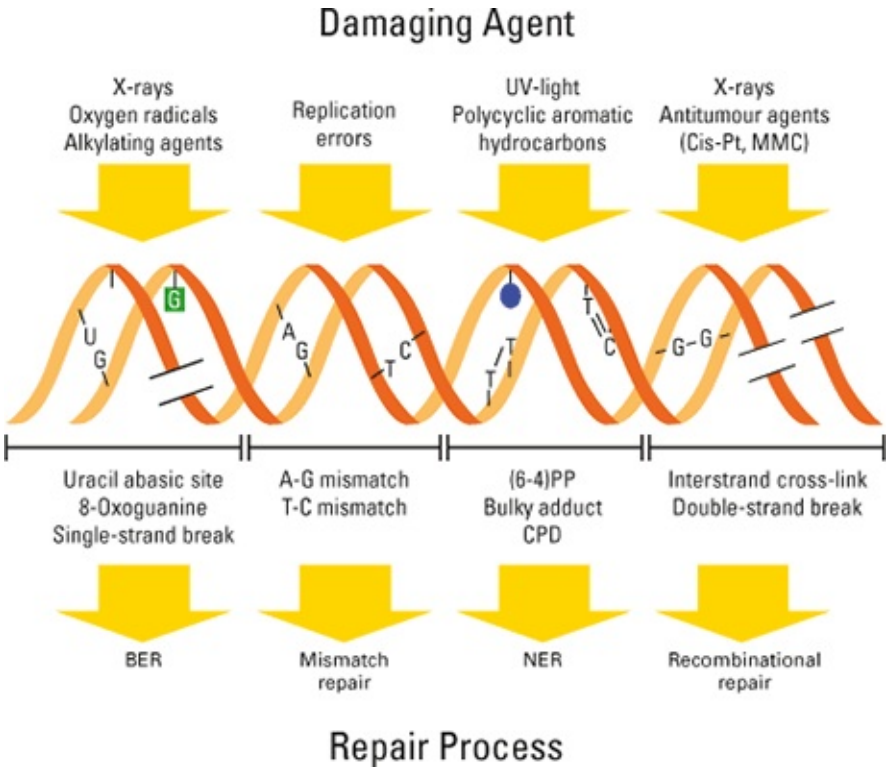

Fig. 2-18 DNA lesions and repair mechanisms.

(Top) Common DNA-damaging agents. (Middle) Examples of lesions that can be introduced into the DNA double helix by these agents. (Bottom) The most frequently used repair mechanisms for such lesions. Distinct damaging sources can induce similar types of DNA lesions, and any one agent often induces more than one type of damage. The lesion spectrum of different repair pathways may overlap.

Double-Strand Break Repair

Damage to DNA by radiation, chemicals (such as chemotherapy), and other insults produces double-strand breaks that are recognized and repaired by a coordinated response that involves the proteins encoded by a wide range of tumor suppressor genes. Mutations of some of these genes cause inherited syndromes that have highly variable clinical manifestations. Ataxia telangiectasia is characterized by progressive cerebellar ataxia, telangiectasia, immunodeficiency, and increased tumorigenesis (most commonly T-cell neoplasms). The ataxia telangiectasia gene (*ATM*) encodes a large protein kinase with homology to PI3K. *ATM* is activated by serine phosphorylation in response to DNA breaks, and it phosphorylates a number of downstream substrates with critical roles in DNA repair and checkpoint pathways, including CHK2, p53, BRCA1, and NBS1 (Fig. 2-19).[158] Cells derived from patients with ataxia telangiectasia exhibit increased DNA damage after radiation therapy, as well as defects in normal cell-cycle responses to DNA damage, called “checkpoints” (discussed in more detail Checkpoints: Crossroads of DNA Repair, Cell Cycle Regulation, and Genetic Instability).

Fanconi anemia (FA) is an autosomal-recessive disease characterized by developmental abnormalities, bone marrow failure, and susceptibility to cancers, particularly acute myeloid leukemia, squamous cell cancer of the head and neck, gynecologic cancers, and esophageal cancer. Similar to ataxia telangiectasia, cells derived from patients with FA display abnormal

chromosome breakage. However, FA cells are not hypersensitive to ionizing radiation; rather, they are hypersensitive to DNA cross-linking by agents such as diepoxybutane and mitomycin C. Classic studies defined many FA complementation groups, and 13 FA genes have now been cloned. Remarkably, many of these proteins form a complex that catalyzes the monoubiquitination of two FA proteins, FANCD2 and FANCI.[159-161] Monoubiquitinated FANCD2 and FANCI become localized to nuclear foci after DNA damage, and these foci also contain FANCD1 (identical with the *BRCA2* breast cancer gene) and other proteins, including BRCA1 and NBS1 (Fig. 2-19). The striking intersection of the BRCA1 and FA pathways underscores the central importance of this DNA damage sensing and repair mechanism in carcinogenesis.

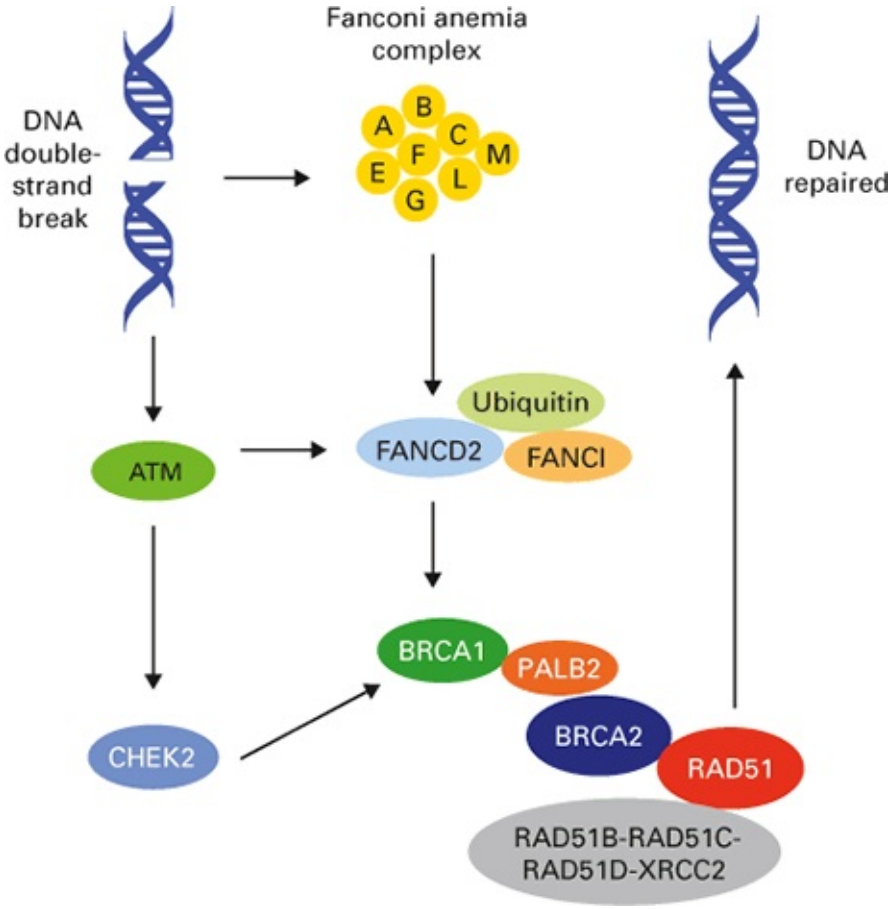

Fig. 2-19 Recombinational repair of DNA double-strand damage.

DNA double-strand breaks recruit protein kinase ATM and also activate the Fanconi anemia core complex (FANCA/B/C/E/F/G/L/M) that monoubiquitinates the downstream targets FANCD2 and FANCI. ATM activates (phosphorylates) CHEK2 and FANCD2 and in turn CHEK2 phosphorylates BRCA1. Ubiquinated FANCD2 complexes with BRCA1 and RAD51. The PALB2 protein then acts as a hub, bringing together BRCA1, BRCA2, and RAD51 at the site of a DNA double-strand break, and also binds to RAD51C, a member of the RAD51 paralog complex RAD51B-RAD51C-RAD51D-XRCC2 (BCDX2). The BCDX2 complex recruits RAD51 or stabilizes the damage sites. RAD51 plays a major role in homologous recombinational repair of DNA during double-strand break repair. In this process, an ATP dependent DNA strand exchange takes place in which a single strand invades base-paired strands of homologous DNA molecules. RAD51 is involved in the search for homology and strand pairing stages of the process.

Source: Wikipedia. Public Domain, https://en.wikipedia.org/wiki/Fanconi_anemia#/media/File:Homologous_recombinational_repair_of_DNA_double-strand_damage.jpg.

The NBS1 protein is another component of nuclear repair foci implicated in a chromosome breakage syndrome. Nijmegen breakage syndrome is an autosomal-recessive disease characterized by microcephaly, immunodeficiency, and increased frequency of hematopoietic cancers that is caused by mutations in the *NBS1* gene. NBS1 forms a complex with MRE11 and

RAD50, which binds to BRCA1 in nuclear foci. Deficiency of the NBS1 protein blocks the formation of the MRE11–NBS1–RAD50 complex, and this impairs the S-phase surveillance responses triggered by ATM. Accordingly, many of the symptoms of this disease are identical to symptoms of ataxia telangiectasia.

Mismatch Repair

DNA MMR corrects errors that occur during DNA replication, primarily single base mismatches or short insertions or deletions.[162] A complex of proteins bind to a DNA mismatch, identify the correct DNA strand, and then excise and repair the mismatch. Several of these proteins are tumor suppressors involved in hereditary nonpolyposis colon cancer (HNPCC). Patients with HNPCC/Lynch syndrome develop colon cancer at an early age, as well as cancers in many other organ sites.[163] The two most commonly mutated MMR genes in Lynch syndrome are *MSH2* and *MLH1.* MSH2 is involved with the initial recognition of the mismatch, whereas, MLH1 helps determine which DNA strand contains the correct sequence. Mutations in other MMR genes are less commonly associated with HNPCC and include *MSH6, PMS1,* and *PMS2.* Patients with HNPCC inherit a nonfunctional MMR gene allele with subsequent loss of the remaining allele in a somatic cell that will ultimately give rise to a tumor. Importantly, impaired MMR causes a hypermutable phenotype, as evidenced by microsatellite instability, which is readily detected in tumors by PCR-based assays that reveal novel tumor-specific microsatellite fragments. Although microsatellite instability is the hallmark of HNPCC, it also is found in a subset of sporadic colon cancers. However, in these cases, *MLH1* is typically silenced by promoter hypermethylation rather than by gene mutation.

CHECKPOINTS: CROSSROADS OF DNA REPAIR, CELL-CYCLE REGULATION, AND GENETIC INSTABILITY

The fidelity of the enzymes that replicate DNA and segregate chromosomes is largely responsible for the accurate propagation of genetic information. However, these enzymes have an intrinsic error rate, and the frequency of errors is increased by genotoxic insults. Normal cells continually monitor DNA replication and mitosis and stop the cell cycle if these do not occur correctly, allowing the damage to be repaired before proliferation resumes, or initiate apoptotic and/or senescence responses if the damage cannot be repaired. The pathways that link cell-cycle progression to the accurate execution of prior cell-cycle events are called “checkpoints.”[164] (Note that this section refers to *checkpoints* as molecular processes that safeguard the genome from damage; such checkpoints are wholly distinct from the checkpoints present in the immune system that are targeted by immunotherapy approaches.)

Mammalian cells have checkpoints that operate in each phase of the cell cycle and are intricately interwoven with the cell-cycle and DNA repair machinery.[165-168] The G1 and G2 checkpoints recognize DNA damage that occurs during these cell-cycle phases and initiate responses leading to either cell-cycle arrest or cell death. In addition to DNA damage, the S-phase checkpoint also is activated by stresses that inhibit the proper function of the replication machinery, including S-phase chemotherapeutics such as hydroxyurea and cytarabine.

Checkpoint pathways may be broadly viewed as being composed of sensors/mediators, signal transducers, and effectors (Fig. 2-20). The sensors and mediators detect DNA damage and comprise protein complexes that accumulate in DNA repair foci. The DNA damage signal is then transmitted by kinases, which initially include ATM and ATR, and subsequently by kinases such as CHK1 and CHK2, which ultimately activate effectors, such as p53 and Cdc25, that

directly affect cell-cycle progression, apoptosis, and DNA repair proteins. Small-molecule inhibitors of many checkpoint kinases are being evaluated as chemotherapeutics.

Checkpoint pathways are disrupted in most cancers. One consequence of impaired checkpoint function is genetic instability, which drives tumor progression through the accumulation of additional oncogenic mutations. The p53 protein plays a central role in checkpoint pathways, and *TP53* is the most frequently mutated human tumor suppressor gene.[169-171] Although this gene is mutated in up to half of all spontaneous cancers, its role as a tumor suppressor first came to light in studies of Li–Fraumeni syndrome, a rare autosomal disorder associated with the development of a wide variety of early-onset cancers, including soft-tissue and bone sarcomas, as well as breast, brain, and colon cancers. *TP53* encodes a transcription factor that is activated by many triggers, including DNA damage and replication stress. When the p53 protein is activated by signals such as DNA damage, the outcome can be cell-cycle arrest, apoptosis, or cellular senescence; these alternative outcomes depend on many factors (Fig. 2-21). p53 accomplishes these outcomes by activating transcription of its target genes and through other actions. Tumors most commonly inactivate *TP53* through loss-of-heterozygosity, which leaves a single normal copy of the gene, followed by intragenic point mutations, which inactivate the remaining allele by altering critical functional domains of the resulting p53 protein.

Another mechanism of p53 loss in tumors involves the MDM2 ubiquitin ligase.[138] MDM2 expression is induced by p53, and it functions in a feedback loop to downregulate p53 by catalyzing its ubiquitination. The normal MDM2–p53 regulatory circuit is disrupted in many cancers. MDM2 is overexpressed in a wide spectrum of neoplasms, and this leads to decreased p53 abundance and function. A second mechanism that targets this pathway involves the *ARF* tumor suppressor. As discussed previously, *ARF* is encoded within the same gene as the p16INK4A protein and is frequently deleted in cancers.[172] ARF normally binds to MDM2, which prevents MDM2 from degrading p53. However, when *ARF* is deleted, MDM2 activity is unrestrained, causing p53 to be degraded. *ARF* expression is induced by oncogenes such as *MYC* and plays an important role in p53 activation by oncogenic signaling. Thus, loss of *ARF* disables an important protective mechanism against oncogenic transformation.

There is enormous interest in developing cancer treatment strategies that target the p53 pathway. In fact, studies in model systems demonstrating the antitumor activity of p53 restoration in tumors has reenergized this active field.[173] Strategies that target the p53 pathway range from peptides that restore p53 function in cells with mutant p53 proteins to recombinant adenoviruses that selectively kill cells with *TP53* mutations. However, the scope of these approaches is too great to be covered in detail here, and there are reviews that address this large field.[174,175]

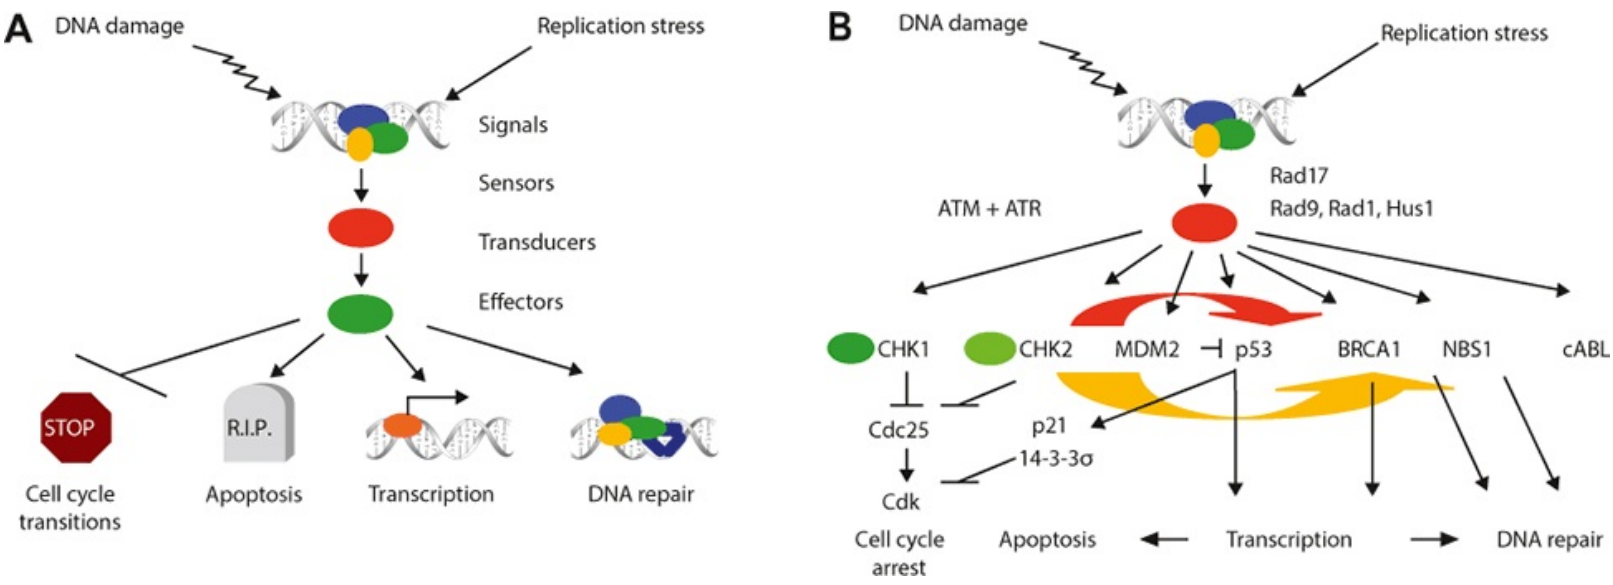

Fig. 2-20 Organization of DNA damage response pathways.

(A) A general outline of the DNA-damage response signal transduction pathway. Arrowheads represent activating events, and perpendicular ends represent inhibitory events. Cell-cycle arrest is depicted with a stop sign and apoptosis with a tombstone. The DNA helix with an arrow represents damage-induced transcription, while the DNA helix with several oval-shaped subunits represents damage-induced repair. For the purpose of simplicity, the network of interacting pathways are depicted as a linear pathway consisting of signals, sensors/mediators, transducers, and effectors. (B) Organization of the mammalian DNA-damage response pathway. Arrowheads represent positively acting steps while perpendicular ends represent inhibitory steps. Gene names are shown at the approximate positions where their encoded proteins function in the pathway. Although the general organization of the pathway is correct, some details are omitted, especially concerning the relationship between the ATR/ATM and Hus1/Rad17/Rad9/Rad1 proteins, which may participate in mutual regulation.

The mitotic or spindle assembly checkpoint ensures that chromosomes are equally segregated to daughter cells during mitosis, and it is the key safeguard against the gain or loss of whole chromosomes, also known as “aneuploidy.” The spindle apparatus is composed of tubulin and attaches to chromosomes through their kinetochores during mitosis. In a normal cell, the signal that activates the spindle checkpoint is generated by kinetochores that are unattached or have insufficient spindle tension; this delays mitosis and ensures that chromosome separation does not occur in situations in which the daughter cells may receive an abnormal number of chromosomes because of misalignment (Fig. 2-22).[176] A number of spindle checkpoint proteins accumulate at the unattached kinetochore, including BUB1, BUBR1, MAD1, and MAD2. This complex prevents mitosis by sending a signal that inhibits the anaphase-promoting complex (APC), an E3 ubiquitin ligase that regulates mitotic entry and exit. Two critical APC targets that must be degraded for mitosis to proceed are cyclin B and securins (the latter function to hold together sister chromatids). Thus, the spindle checkpoint prevents mitosis in the setting of an improperly attached spindle by blocking the degradation of APC substrates. A number of chemotherapeutic agents target the spindle apparatus (e.g., taxanes and vinca alkaloids) and trigger the spindle checkpoint in normal cells.

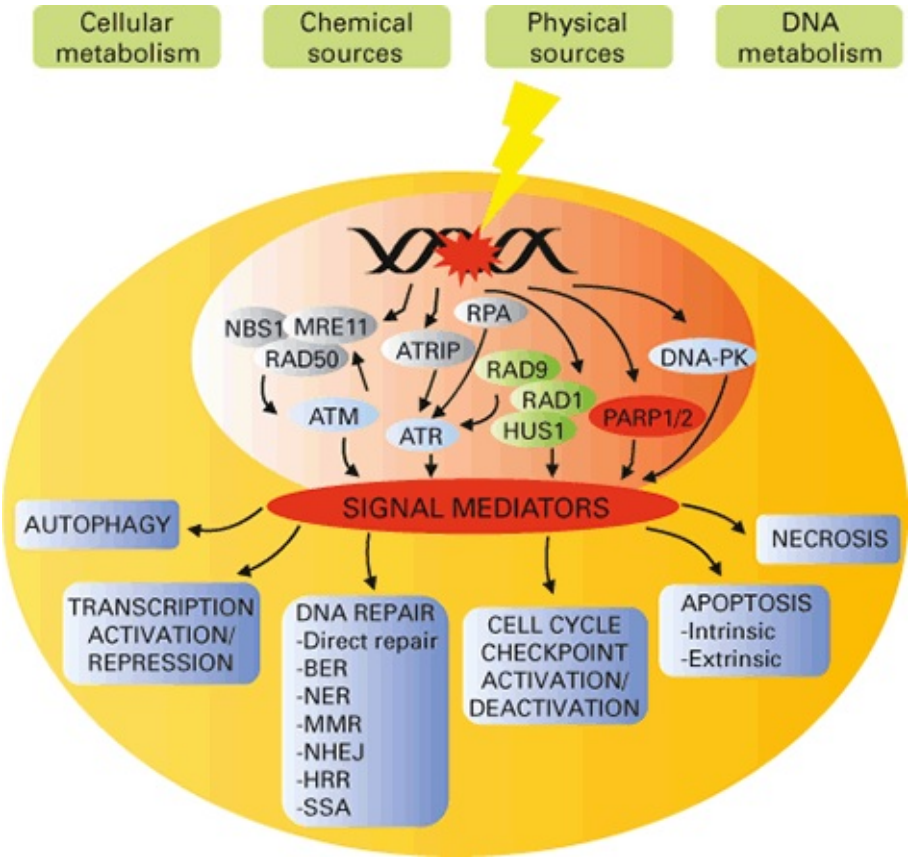

Fig. 2-21 The cellular response to DNA damage.

The activation of p53 classically occurs in response to many other cellular stresses that produce DNA damage, including oncogene-induced stress. Depending on the nature of the inducing signal, these DNA-damage responses activate myriad upstream mediators that lead to upregulation and activation of p53. This, in turn, results in activation of p53 target genes that serve to counteract the initiating cellular stress and protect the cell from further damage. When *TP53* is mutated or deleted, as it is in most cancers, these critical safeguards no longer function and cellular stress continues unabated.

KEY POINTS

- Enzymes that promote protein degradation by the proteasome can function as tumor suppressors.
- Pharmacologic proteasome inhibitors are approved for the treatment of multiple myeloma and other blood cancers.
- Genes that regulate cellular differentiation often are mutated in hematologic cancers.
- DNA repair pathways contain many tumor suppressor genes that are mutated in both familial and sporadic cancers.
- Mutations that disable different DNA repair pathways are associated with specific cancer syndromes.

MULTISTEP TUMORIGENESIS

The development of fully malignant cancers requires many independent events. Although the specific mutations that cause human cancers vary greatly between types of cancers and

individuals, the broad consequences of these mutations are abnormal phenotypes that are shared by most cancers. Hanahan and Weinberg have proposed six “hallmarks of cancer” that they define as “distinctive and complementary capabilities that enable tumor growth and metastatic dissemination” (see Fig. 2-23).[177,178] These include sustained proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis. These capabilities can be acquired in different sequences, and, in some cases, a single genetic mutation might provide more than one capability. This conceptualization provides an important framework within which to consider multistep carcinogenesis.

The first three of these “acquired capabilities” involve mutations within the mitogenic signaling, cell cycle, and cell-death pathways that have been previously outlined. The fourth category involves the acquisition of cellular immortality in tumors. Normal cells are limited in the number of times that they can divide, even when they are provided with all of the normal mitogenic stimuli required for cell division. In contrast, many cancer cells have apparently limitless potential to divide. One fundamental mechanism that limits human cell division involves the ends of chromosomes, which are called “telomeres.” Telomeres normally protect the ends of chromosomes, and they shorten with each cell division. Thus, the length of a cell’s telomeres reflects the number of divisions it has undergone. Eventually the telomeres are shortened to a point at which they can no longer protect the chromosome ends; this leads to a condition termed “crisis” and, ultimately, to cell death. Unlike normal cells, cancer cells maintain their telomere length during cell division. This usually results from expression of the enzyme telomerase that adds DNA back to the telomere. Telomerase activity can be detected in 85 to 90% of cancers, and the remaining tumors maintain their telomeres through a mechanism involving recombination.

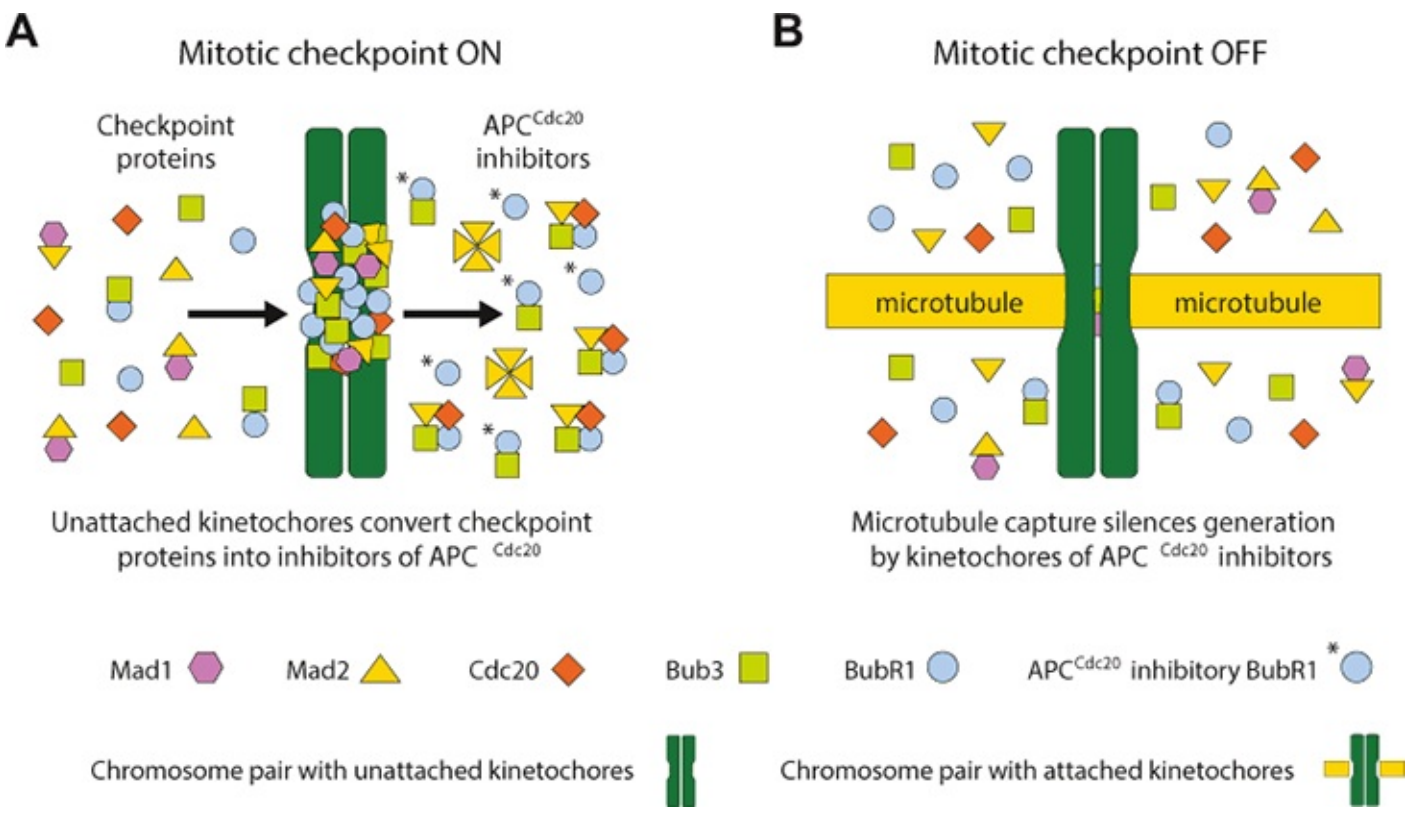

Fig. 2-22 Mitotic checkpoint signaling.

(A) Unattached kinetochores are the signal generators of the mitotic checkpoint. They recruit mitotic checkpoint proteins, including Mad1, Mad2, BubRI, and Bub3, and convert them into inhibitors of APCCdc20. (B) Once all kinetochores have made productive attachments to spindle microtubules, production of the APCCdc20 inhibitors is silenced.

The fifth capability of induced angiogenesis reflects the fact that tumors often outgrow their blood supply and must actively recruit vasculature to grow. In normal tissues, the development of new blood vessels is highly regulated by both positive and negative signals. Tumor cells promote angiogenesis by upregulating the pathways that promote blood vessel formation (e.g., increased expression of growth factors such as vascular endothelial and fibroblast growth factors) and by reducing the activity of inhibitory pathways. Some of these pathways involve transcriptional networks under the control of previously discussed genes, such as *VHL* mutations in renal cell carcinoma. The importance of these pathways in tumor cell growth has prompted the development of drugs that target angiogenesis.

The last of the six hallmarks is tissue invasion and metastasis, which is critically important because metastasis accounts for most cancer fatalities. Specific gene products are associated with the ability of tumor cells to metastasize to different organ sites. Other tissue types, such as stroma and tumor-associated cell populations, also contribute to metastasis. Elegant animal models of metastasis, as well as transcriptional profiling of human cancers, are revealing that metastasis includes alterations in genes involved in processes such as cell adhesion, integrin signaling, growth factors, chemokine signal transduction, and extracellular proteolysis.

In addition to these six hallmarks, Hanahan and Weinberg outline two emerging hallmarks and two enabling characteristics that make it possible for tumor cells to acquire the core hallmarks. The two emerging hallmarks are deregulating cellular energetics and avoiding immune destruction. The concept that tumor cells reprogram their glucose metabolism toward glycolysis, even in the presence of oxygen, was first noted more than 50 years ago. However, more recently, there has been an explosion of research into the significance and mechanisms of aerobic glycolysis in cancer, also known as the “Warburg effect.”[66] It is clear that metabolic reprogramming has critical roles in cancer cell growth and division.[179] The second emerging hallmark reflects the role of the immune system in controlling cancers and the molecular changes in cancer cells that allow them to evade immune destruction. Although discussion of immunotherapies is beyond the scope of this chapter, they are a key component of current therapy for cancer in many organ sites and are discussed in many disease-specific chapters later in this book.

The two “enabling characteristics” are properties of cancer cells that facilitate the acquisition of the hallmarks. The first of these characteristics is genomic instability, which drives the acquisition of the multiple mutations required for multistep tumorigenesis. The second enabling characteristic is “tumor-promoting inflammation,” which reflects the rapidly advancing concept that inflammatory responses can actually facilitate tumor initiation and progression. One important aspect of the “hallmark/enabling characteristics” conceptualization is that it also provides a framework for understanding the development of mechanism-based targeted therapies, which target both hallmarks and enabling characteristics. Examples of such therapies include angiogenesis inhibitors and immune checkpoint inhibitors, as previously discussed.

KEY POINTS

- Checkpoints ensure the fidelity of cell division and protect against genomic instability.

- Many tumor suppressor genes and DNA repair proteins are intimately associated with checkpoint pathways.
- The loss of checkpoint functions causes genomic instability and fosters the accumulation of multiple mutations in cancer cells.
- *TP53* is the most commonly mutated cancer gene, and it participates in diverse checkpoint responses. The p53 protein senses cellular stress and signals to pathways that regulate processes such as cell-cycle progression and apoptosis.
- Tumorigenesis is a multistep process that requires the accumulation of multiple mutations. All tumors share a number of hallmarks that contribute to their malignant phenotype, but the specific molecular events that produce these phenotypes vary greatly among tumor types and individuals.

INFECTIOUS AGENTS AS DRIVERS OF CANCER

Infectious agents contribute to the pathogenesis of approximately 15% of all cancers worldwide, affecting more than 2 million people.[180] Most of these are associated with chronic viral infection. Examples of common cancers associated with chronic viral infection include squamous cell carcinomas of the cervix, head and neck, and anus (HPV); Burkitt and other types of lymphoma, nasopharyngeal carcinomas, and some stomach cancers (Epstein–Barr virus [EBV]); and hepatocellular carcinoma (hepatitis B and C viruses). Other cancers associated with viral agents include Kaposi sarcoma and Merkel cell carcinoma. Extensive research has elucidated some of the molecular mechanisms used by infectious agents to drive carcinogenesis. As previously noted, retroviruses can cause cancer through insertional mutagenesis. Other cancer-causing viruses express proteins that interfere with the critical cancer pathways, outlined elsewhere in this chapter. For example, the HPV E6 protein promotes degradation of the tumor suppressor p53, impacting the DNA damage and repair response, while HPV E7 promotes degradation of the cell-cycle inhibitor Rb, driving cell growth, division, and proliferation. Whereas EBV-associated lymphomas are characterized by a translocation involving the *MYC* oncogene, EBV also promotes B-cell survival and transformation via molecular mimicry, as EBV gene products mimic activated cell-surface receptors and antiapoptotic proteins. Hepatitis B and C proteins promote expression of genes associated with angiogenesis, enhanced cell motility, invasion, and metastasis. In fact, many oncogenic viruses produce protein products that impact most of the hallmarks of cancer.[181] Given that viral-associated cancers frequently subvert normal cellular processes, the study of these cancers often yields insights into the biology of sporadic cancers. These insights include the identification of new oncogenes or tumor suppressor genes, as well as an increased understanding of more complex aspects of tumor biology (e.g., immune surveillance).

While viruses are most commonly associated with cancer, other pathogens also contribute to carcinogenesis. Chronic infection with the intestinal bacteria *Helicobacter pylori* is associated with some stomach cancers and low-grade lymphomas.[182] Similarly, hepatobiliary cancer, which is much more common in southeast Asian populations, is associated with endemic infection with liver flukes.[183] While less is known about the molecular mechanisms driving these cancers, chronic inflammation likely plays a major role.

Given the large number of human cancers associated with infections, there is much interest in preventing and/or treating infection with the underlying pathogen with the ultimate goal of

cancer prevention. Examples include the use of an HPV vaccine to prevent squamous cell carcinoma and universal vaccination against hepatitis B virus to decrease the incidence of hepatocellular cancers.[184] Elimination of *H. pylori* may prevent gastric cancer and often induces remission of gastric mucosa-associated lymphoid tissue (MALT) lymphomas.[185,186] As more is learned about the molecular mechanisms driving infection-related cancers, targeted agents that specifically block the function of viral gene products will likely be developed. Finally, viral proteins expressed by pathogen-associated cancers represent attractive targets for various immunotherapeutics.

KEY POINTS

- Infection-associated cancers represent a worldwide epidemic affecting more than 2 million people per year.
- Infectious agents frequently subvert molecular processes related to the hallmarks of cancer, including checkpoints, proliferation, apoptosis, and immune surveillance.
- The study of infection-associated cancers gives insights into the molecular basis of sporadic cancers.

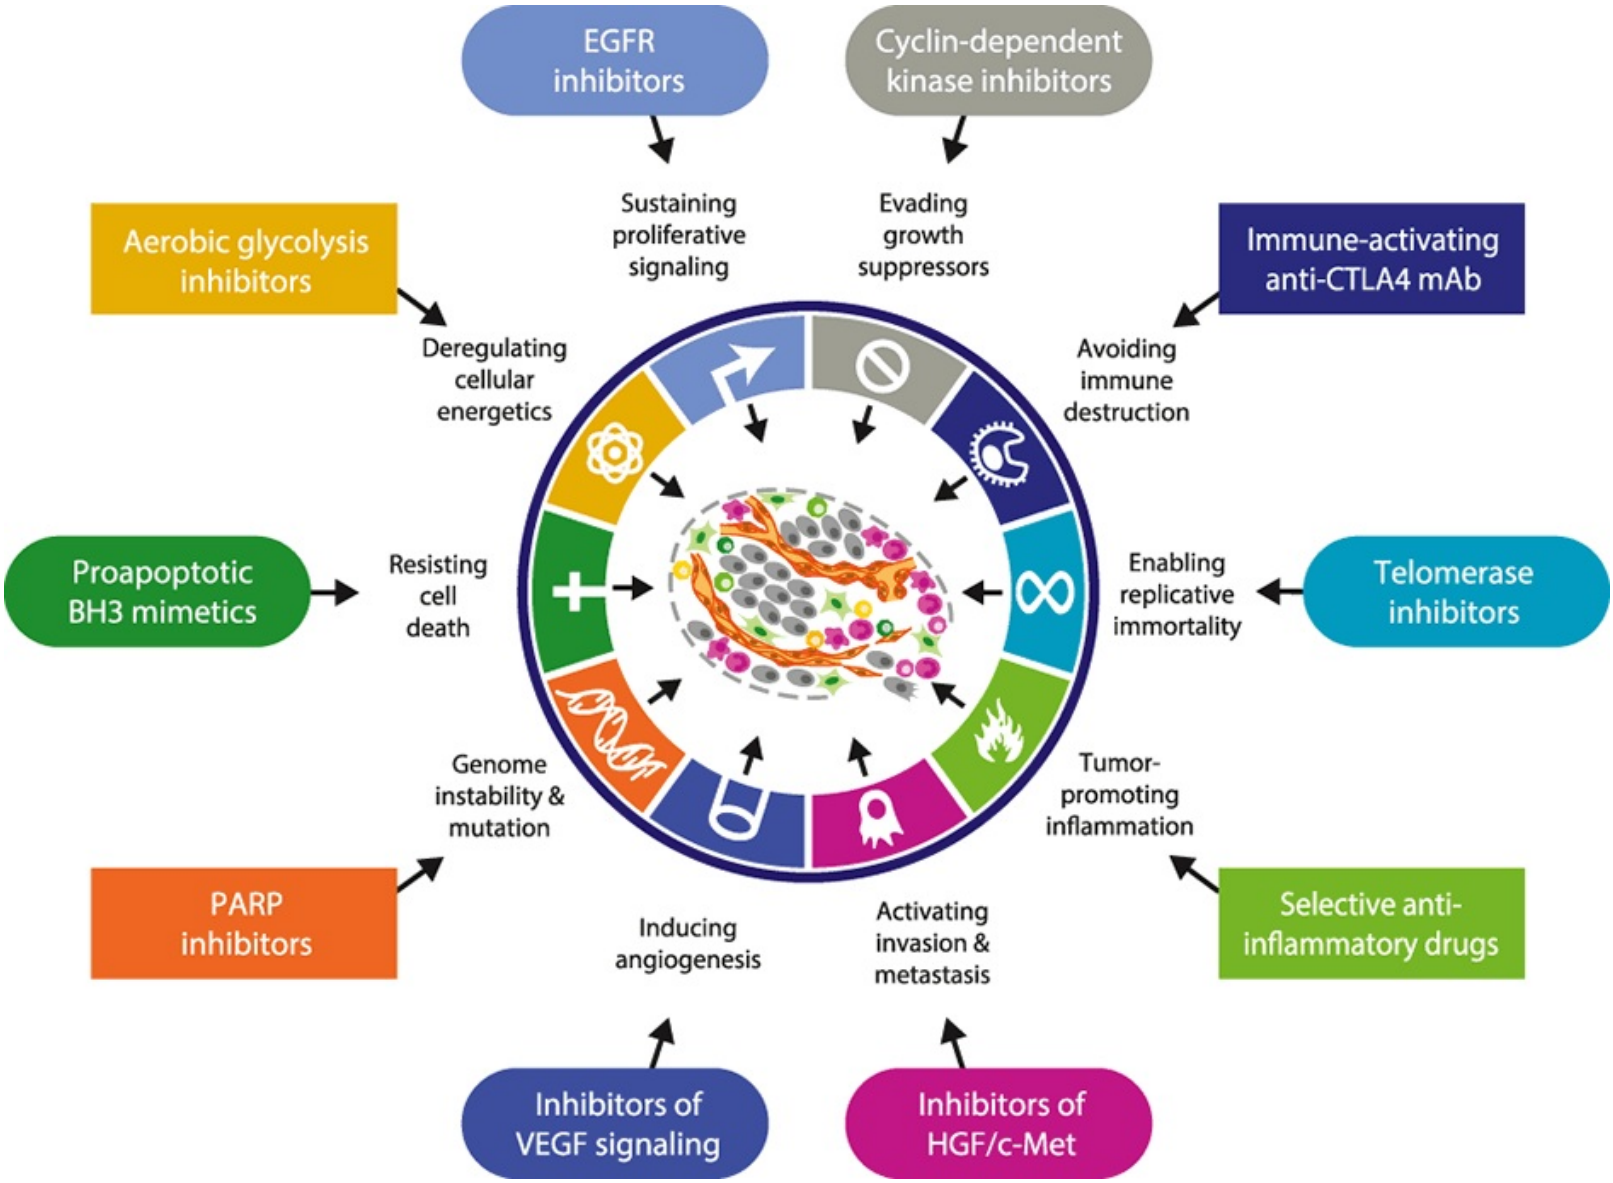

Fig. 2-23 The hallmarks of cancer.

Hanahan and Weinberg describe ten acquired capabilities necessary for tumor growth and progression (inner circle of text). Therapeutic strategies aimed at counteracting each specific hallmark are indicated. Drugs that interfere with these hallmarks have been developed and are in clinical trials, or in some cases, they have been approved for clinical use in treating certain forms of human cancer. The drugs illustrated are examples of the deep pipeline of candidate drugs with different molecular targets and modes of action in development for most of these hallmarks.

ONCOGENOMICS AND PRECISION ONCOLOGY

A plethora of studies employing NGS to study cancer genomes have radically altered our understanding of the genomic landscape of cancers and demonstrated the immediate effect of genome-scale analyses on clinical oncology. Many of these studies used integrative approaches that incorporate various types of large-scale data to discover mutations in oncogenes and cancer pathways at an unprecedented rate. This is a rapidly evolving field. A few examples are briefly described in this section to illustrate the power and importance of these approaches.

Although most current approaches to cancer genomics incorporate NGS, different strategies are used to achieve different goals. For example, when sequencing is limited to either known oncogenes or coding sequences (exomes, which comprise only 5% of the total DNA), many

tumors can be analyzed; this allows highly powered studies of genes and pathways that are targeted by mutations in cancers. Limited-sequencing approaches also rapidly characterize tumor genomes within time frames that allow treatment decisions to be made based on the presence of specific mutations; this quick turnaround is critical to the success of targeted therapies, which are often indicated only in genetically-defined subgroups of patients. In contrast, whole-genome sequencing reveals genetic alterations in regions of DNA that cannot be assessed by limited approaches and may provide entirely novel insights into the types of mutations that drive carcinogenesis. However, whole-genome approaches are more difficult to apply to large numbers of tumors, at least for the time being.

A comprehensive analysis of the explosion of cancer genomics studies enabled by NGS is beyond the scope of this chapter, but the following are some examples that highlight the power and importance of these approaches. Two examples of early studies described an integrative approach that included sequencing of protein coding regions, SNP-based array analyses of DNA copy number, and RNA-Seq to develop global views of the genes and pathways that are mutated in pancreatic cancers and glioblastomas.[187,188] The use of these combined methods helped distinguish mutations that likely played a causal role in tumorigenesis (driver mutations) from mutations that may be irrelevant (passenger mutations). Importantly, Parsons et al.[187] found that the isocitrate dehydrogenase (*IDH*) gene, previously unrecognized as an oncogene, was mutated in 12% of glioblastomas. *IDH1* and *IDH2* mutations have subsequently been found in other cancers, including acute myelogenous leukemia (AML) and chondrosarcoma. Importantly, IDH1/2 mutant proteins cause epigenetic dysregulation and DNA hypermethylation[189] and pharmacologic IDH1 inhibitors are already demonstrating efficacy in numerous clinical trials.

Dozens of large-scale cancer genomics studies, many of which have been coordinated by The Cancer Genome Atlas (TCGA; a consortium sponsored by the National Institutes of Health), have identified the molecular features of most common and many uncommon cancer types.[190] Although the data included in these remarkable publications varies among studies, the molecular features that have been cataloged include whole-exome sequencing, RNA-Seq/RNA expression, copy-number variants, DNA methylation, miRNA expression, and protein analysis. These studies have provided unprecedented insights into cancer biology and revealed many new targets for therapeutic interventions. One common theme that has emerged is that although specific organ sites exhibit unique mutational spectra, other pathways are mutated in many, or most, types of cancer.[120,191,192] Some studies have applied whole-genome sequencing to study specific cancer types, such as a TCGA analysis of adult AMLs. That work revealed that AMLs contain fewer mutations than other adult cancers, with an average of 13 mutations per sample, only 5 of which involve recurrently mutated genes.[193]

EMERGING CONCEPTS ON TUMOR HETEROGENEITY AND EVOLUTION

While initial studies from TCGA and other consortia were aimed at cataloging gene mutations and other changes in primary tumors from a wide range of organ and tissue types, more recent efforts have included multiple biopsies from the same tumor, concurrent biopsies of primary and matched metastatic lesions, or multiple biopsies over time. These data allow comprehensive studies of genetic heterogeneity within a single tumor, as well as the dynamic process of tumor evolution at various stages of disease and its treatment.[194,195] It is now apparent that tumors may exhibit heterogeneous cell populations with distinct genetic changes at their earliest stages[195] and that the idea of a linear progression of tumor evolution is overly simplistic. In one

seminal example, analysis of separate regions within a single primary renal cell carcinoma (RCC) revealed marked genetic heterogeneity.[196] While such "sampling error" has important implications for the selection of therapies based on the presence of "targetable" mutations in a single biopsy specimen, it also informs our understanding of tumor evolution. For example, this study found that inactivation of the tumor suppressor VHL was the only pathogenic genetic change present in every tumor biopsy sample taken from a presumably homogenous single RCC lesion. All other frequently mutated genes exhibited multiple and distinct mutations within different areas of the tumor. This suggests a model in which the heterogeneous landscape of primary tumors serves as the substrate for subsequent tumor evolution, during which time specific clones are enriched or lost as tumors grow, invade, and metastasize.

Molecular comparisons of metastatic lesions with their antecedent primary tumors reveals a similarly complex picture of tumor evolution, including the maintenance and/or enrichment of "founder" mutations and new mutations unique to the metastatic lesion.[197,198] Indeed, discrete metastases can have markedly different genetic profiles. Together, these types of studies are revealing complex models of tumor evolution, such as parallel evolution, in which subclones within a single tumor may evolve independently of each other, and convergent evolution, in which unique clonal populations develop molecularly distinct but functionally equivalent alterations in common cancer pathways.[195] It should be noted that many studies of tumor evolution are based on exome or genome sequencing only; thus, other molecular events, such as copy-number variation, epigenetic effects, and proteomic changes, are less well understood. Finally, large-scale genetic change, such as chromosomal instability or chromothripsis (which refers to extensive DNA rearrangements that cluster in specific genomic regions), are commonly seen in both primary and metastatic tumors. Whether these changes are a cause or a consequence of tumor evolution remains controversial, but there is much interest in targeting these processes in the clinic.[199-201]

While understanding the heterogeneity and evolution of a patient's tumor could greatly impact therapeutic decisions, serial tumor sampling via invasive biopsy techniques is generally neither feasible nor favored by patients. The emerging field of "liquid biopsy," in which circulating tumor cells or circulating tumor DNA can be isolated from routine blood draws, allows serial tumor sampling in cancer patients across the spectrum, from diagnosis, treatment, and surveillance.[202] At diagnosis, liquid biopsies may simplify the search for targetable mutations, especially when primary biopsy specimens are limited or uninformative. Because liquid biopsies allow analysis of tumor evolution in real time, they can also serve as adjuncts to standard assessments of tumor response and progression after therapy has begun. For example, Siravegna et al. used serial sampling of circulating tumor DNA from patients with *KRAS* wild-type colorectal cancer to investigate mechanisms of resistance to cetuximab.[203] This analysis showed evidence of *KRAS* mutated subclones that were enriched after prolonged cetuximab therapy. Notably, cetuximab withdrawal led to resensitization of the tumor to this agent. As the field develops, liquid biopsies are likely to become commonplace, and they should provide new insights into molecular mechanisms of chemoresistance and allow prioritization of targeted therapies based on new or evolving genetic profiles. Finally, liquid biopsy is likely to be integrated into tumor screening in asymptomatic individuals and as surveillance for recurrence following therapy, given its superior sensitivity as compared to available methods.[204,205]

MOUSE MODELS OF HUMAN CANCER

Genetic techniques developed throughout the past two decades now make it possible to create

mouse models that mimic sporadic human cancers with increasing fidelity. The first generation of genetically engineered mouse models involved expressing oncogenes from transgenes (that were injected into oocytes) or making “knockout” strains in which genes were inactivated by homologous recombination in mouse embryonic stem cells.[206] Hundreds of genes have been studied with these techniques, which led to important advances in understanding gene functions in development and tumorigenesis. In fact, these methods are still in wide use today. However, these strategies affect gene expression early in development and, in the case of knockouts, affect every cell. These characteristics limit the ability of these mouse models to replicate human cancers, which sequentially acquire rare mutations in somatic cells. Moreover, many cancer genes are lethal when disrupted in the mouse germline or lead to rapidly developing neoplasms in one tissue that preclude studies of slower-growing cancers. More recent mouse genetic engineering strategies circumvent these problems by allowing mutations to be introduced in tissue-specific and temporally controlled manners, and these have led to mouse models that much more closely resemble human cancers.[207,208] Similar to the studies in human cells previously alluded to, the use of CRISPR/Cas9 gene-editing systems to produce mouse strains with engineered oncogenic mutations is also revolutionizing the development of murine cancer models, particular in allowing the rapid development of mice with multiple mutations.[209]

In addition to murine cancers, sophisticated xenografting methods, in which human cells are grown in murine hosts, are having a major effect on cancer biology research and are already beginning to be used to help guide treatment decisions. Patient-derived xenografts (PDXs) are human tumor explants that are directly grown in immunocompetent mice, which is a much more physiologic approach than establishing tumor cell lines in vitro. PDXs can be readily subjected to sequencing and screening approaches that seek to identify therapeutic vulnerabilities. Moreover, PDX-bearing “avatar” mice can be treated with chemotherapy combinations, with the goal of determining the most effective therapy for the patient from whom the PDX was derived.[210]

KEY POINTS

- Next-generation sequencing is revealing transformative and comprehensive insights into cancer genomics.
- These technologies may allow personalized and targeted cancer therapy strategies based on specific mutations detected in a patient’s tumor cells.
- Serial tumor biopsy reveals marked tumor heterogeneity and gives insights into tumor evolution that affect the selection of cancer therapies.
- Gene targeting and transgenic methods are used to create murine models that mimic the genetic mutations found in human cancers. These models are invaluable for understanding the mechanisms underlying tumorigenesis and are used to determine the role of specific mutations in multistep tumorigenesis.

CLINICAL PHARMACOLOGY

Alex A. Adjei, MD, PhD

Recent Updates

- In a shift from tissue-based to plasma-based genomic analysis, the FDA approved a mutation test using plasma specimens as a companion diagnostic test for the detection of exon 19 deletions or exon 21 (L858R) substitution mutations in the epidermal growth factor receptor (EGFR) gene to identify patients with metastatic non-small cell lung cancer (NSCLC) eligible for treatment with erlotinib. (www.fda.gov, June 2016)
- The U.S. Food and Drug Administration (FDA) modified the indications for erlotinib for treatment of NSCLC to limit use to patients whose tumors have EGFR exon 19 deletions or exon 21 L858R substitution mutations as detected by an FDA-approved test. (www.fda.gov, October 2016)

OVERVIEW

Medical oncologists are responsible for administering anticancer therapies to patients with malignancies. Many of these drugs exhibit a narrow therapeutic window, meaning the difference between the toxic dose and the therapeutic dose is small. Traditionally, researchers have developed antineoplastic agents to be delivered at the maximum doses to optimize their anticancer activity. However, the focus of drug development has shifted away from antineoplastic therapies that target DNA and toward molecules that target a specific “molecular target,” often a protein regulating cell growth, cancer progression, or inhibition of apoptosis. These classes of drugs are commonly referred to as “targeted cancer therapies.” Regardless of the agent, drug dosing requires a balance between the anticancer benefit and the known toxic effects these agents have on normal organs. The current era of genomic medicine has resulted in the development of drugs that target actionable somatic genetic derangements in tumors, at times leading to dramatic tumor shrinkage. This has led to a diminished focus on what the patient’s body does to the drug, as well as what the drug does to normal organs. The purpose of this chapter is to address this gap by reviewing the fundamental principles of clinical pharmacology as they relate to the practice of oncology.

PRINCIPLES OF CHEMOTHERAPY

Cytotoxic chemotherapy has been a relative success story. Cancers such as Hodgkin disease, non-Hodgkin lymphomas, testicular cancer, germ cell tumors, leukemia, Wilms tumors, retinoblastomas, and others can be cured through the effective delivery of cytotoxic chemotherapy. The objective of cancer chemotherapy is to reduce the tumor cell population to zero.

Three basic principles underlie the use of systemic chemotherapy, which generally comprises a combination of agents delivered cyclically at the highest tolerable dose. First, the fractional cell kill hypothesis states that a constant fraction of tumor cells is killed per cycle of chemotherapy, regardless of total body burden. For example, if a drug kills 99% of tumor cells per cycle of treatment, the tumor burden of 10^{11} cells will be reduced to approximately 10 cells after five cycles of therapy [$10^{11} \times 0.01^6 < 10$]. Second, neoplastic tumors are assumed to have a "steep" dose–response curve, with a linear relationship between dose of drug administered and efficacy. Thus, the highest possible dose of drugs is administered at the shortest possible time intervals. Third, the Goldie–Coldman hypothesis suggests that tumors acquire a spontaneous mutation that confers drug resistance in about one cell out of 10^5 cells. At the time of detection, with current imaging, most tumors are at least 1 gram or more in size, containing 10^9 cells, and consequently contain about 10^4 clones that are resistant to a given drug. Resistance to two drugs, however, should be seen in one cell out of 10^{10}. It, therefore, follows that multidrug therapy will be more effective than single-agent therapy.

In addition to overcoming tumor resistance, combination therapy is important in limiting drug toxicity, since several agents with nonoverlapping toxicities can be utilized. One of the first curative regimens for a solid tumor (testicular cancer) comprised bleomycin/vinblastine/cisplatin; three agents with differing mechanisms of action and nonoverlapping toxicities.

Cytotoxic chemotherapy agents are administered in the adjuvant, neoadjuvant, and combined modality and metastatic settings. Adjuvant cytotoxic chemotherapy is now the standard for breast, colorectal, ovarian, and lung cancers. In these cases, chemotherapy delivered after resection of the primary cancer can suppress or even eliminate the growth of occult cancer cells that have already metastasized, ultimately leading to cures.

Additionally, chemotherapy sometimes is used in combination with radiation therapy. Combined-modality approaches (chemotherapy and radiation together) are used to shrink the tumor in many diseases to permit surgery, to control systemic disease, or both. Chemotherapy combined with radiation therapy is also sometimes used for curative intent in, for example, lung, esophageal, anal, and head and neck cancers. Chemotherapy alone may also be used to reduce the tumor burden prior to surgery in some tumors, such as breast, bladder, and lung cancers. Chemotherapy utilized in this fashion is termed "neoadjuvant therapy." It must be noted that, in general, neoadjuvant therapy has not been shown to improve survival compared with adjuvant therapy.

Despite advances in the optimization of current cancer chemotherapy for patients with malignancies such as lymphoma and testicular cancer, classic anticancer agents that target DNA have not led to cures in most solid tumors. For example, combination chemotherapy delivered to patients with metastatic disease (e.g., metastatic breast cancer) confers little or no survival advantage compared with sequential chemotherapy. In these settings, sequential single-agent chemotherapy, with or without a biologically targeted agent, is a commonly accepted approach to treatment. This is in part because, in the metastatic setting, the balance between toxicity and efficacy is particularly important, as these patients are likely to exhibit decreases in end-organ function resulting in alterations in metabolism.[1]

KEY POINT

- Combination chemotherapy remains an important component of a majority of cancer

therapy regimens in the adjuvant and metastatic settings.

PHARMACOKINETICS

Pharmacokinetics is the relationship between time and plasma concentration following drug administration; it has been best described as “what the body does to the drug.” An understanding of the pharmacokinetics of a chemotherapy drug is critical to the optimal administration of that drug. The assessment of pharmacokinetics is an objective of most early-phase clinical trials.

From these studies, clinicians learn critical information such as:

- The range of tolerable doses,
- The relationship between drug dose and systemic exposure, and
- Differences among individuals between drug dose and systemic exposure.

The study of pharmacokinetics is classically divided into four elements: absorption, distribution, metabolism, and excretion. Absorption is defined as 100% when agents are administered through an intravenous route but varies when other routes of administration are used. The choice of drug administration route is based primarily on pharmacokinetic assessment of bioavailability—the ability of the drug to reach its target in an active form—and the formulation of an acceptable dose preparation for oral (PO), intravenous (IV), intramuscular (IM), intrathecal, or subcutaneous (SC) use. Classically, oncologic drugs have been developed using the IV route, particularly for water-soluble compounds, because complete absorption is guaranteed. Another reason for the development of IV oncology drugs in the past was the lack of reimbursement for oral oncology drugs, particularly those without a parenteral equivalent. The method of administration also is highly dependent on the ability to formulate a compound into a satisfactory pharmacologic product that can be administered by the route of choice. Several common agents (e.g., paclitaxel) are poorly soluble and must be mixed in solvents, such as Cremophor EL, a proprietary castor oil and polyethylene glycol ether emulsifier. These solvents can have their own toxic effects, as seen with the Cremophor-induced hypersensitivity reaction observed with paclitaxel administration. With current technology, a number of new formulations that reduce toxicity have been introduced. Nanoparticle albumin-bound paclitaxel is not dissolved in Cremophor; therefore, hypersensitivity is not an issue.

Bioavailability is the fraction of an administered dose of unchanged drug that reaches the systemic circulation. By definition, when a medication is administered intravenously, its bioavailability is 100%. (Similar calculations can be made for intramuscular or subcutaneous dosing compared with intravenous dosing.) Bioavailability has become more important as more cytotoxic chemotherapy agents (e.g., capecitabine), as well as biologic agents, are developed for oral dosing. The oral route has the advantage of achieving a more prolonged exposure, thereby providing coverage throughout the cell cycle when toxicity allows. In addition, oral route drug delivery allows more flexible scheduling than parenteral delivery. Agents with a high first-pass metabolism will, by nature, have poor oral bioavailability. Alterations in gastrointestinal tract absorptive capacity can alter oral bioavailability as well. Previous surgery, concomitant medications, malabsorption from other causes, and changes in motility—particularly with supportive care agents such as opiates—may alter absorption of an oral chemotherapy agent. Finally, the ingestion of drugs in either a fasting or fed state can dramatically affect drug exposure. Therefore, when considering the oral administration of drugs, it is necessary to

account for these possible variations.

Distribution identifies what happens to a drug after its administration. Typically, drugs are distributed from the plasma into extracellular and intracellular fluids. The distribution phase of pharmacokinetics may be the most complicated. In the simple two-compartment model, a drug is administered to the patient and enters the plasma compartment, followed by a distribution and redistribution of the compound to the peripheral compartment. The drug concentration in this peripheral compartment is the critical value because this is where the drug–tumor interaction will occur. It is important to recognize that drug concentration in the peripheral compartment is rarely measured in clinical trials and therefore is unknown for virtually all agents used today. The degree to which drugs distribute to the peripheral compartment alters their terminal half-life—the time required to clear 50% of an administered drug. Half-life depends on the volume of distribution (V_d) and clearance (CL). Drugs that are more highly distributed to the peripheral compartment will have a longer terminal half-life.[2] This fact has important clinical ramifications for drugs such as methotrexate, which is the classic example of a drug distributing to the third space, such as pleural effusions or ascites. This scenario can lead to substantial and prolonged methotrexate-induced toxicity.

The greatest increase in research and subsequent understanding during the past several decades has occurred in the study of metabolism of therapeutic agents (Table 3-1). In addition, cellular models have been developed that enable clinicians to define the metabolic pathways for many important chemotherapy agents. Hepatic enzymes responsible for phase I (oxidation, reduction, and hydrolysis) and phase II (conjugation) reactions prepare agents for their excretion by the liver or by the kidney. Hepatic and renal functions are critical to the excretion of most cytotoxic chemotherapy agents. When choosing dosages for patients with cancer, clinicians have typically relied on hepatic enzyme function and serum creatinine levels as the primary means to assess end-organ function. However, other factors, such as age, sex, diet, and drug–drug interactions, can lead to clinically important variability in drug effect. For some drugs, genetic variation in genes that encode enzymes responsible for drug metabolism may substantially alter pharmacokinetics and thus drug effect.

Table 3-1 **Selected Drug-Metabolizing Enzymes of Importance in Oncology**

Reaction	Substrates	Polymorphic*
Phase I Reactions		
Cytochrome P450		
CYP1A1	Benzo(a)pyrene	×
CYP1A2	Theophylline, caffeine	×
CYP2B6	Cyclophosphamide	×
CYP2C8	Paclitaxel	×
CYP2C9	Phenytoin, warfarin	×
CYP2C19	Omeprazole, diazepam	×
CYP2D6	Tamoxifen, codeine, granisetron, many antidepressants	×
CYP2E1	Ethanol	×
CYP3A4/3A5	Etoposide, ifosfamide, docetaxel, irinotecan, bortezomib, imatinib, flutamide, exemestane, lapatinib, sunitinib, sorafenib, vemurafenib, temsirolimus, nilotinib vinca alkaloids	
Ketoreductase	Anthracyclines	
Aldehyde dehydrogenases	Aldophosphamide†	
Carboxylesterases	Irinotecan	
Dihydropyrimidine dehydrogenase	Fluorouracil	×
Cytosine deaminase	Cytarabine, gemcitabine	×
Phase II Reactions		
N-acetylation		
NAT2	Isoniazid	×
Glucuronidation		
UGT1A1	SN-38‡	×
UGT2B7	Morphine, epirubicin, tamoxifen metabolites	×
Methyltransferases		
TPMT	Mercaptopurine, azathioprine	×

*Known genetic variants that influence enzyme activity.
†A cyclophosphamide metabolite.
‡Active metabolite of irinotecan.

With the advent of oral drugs targeting specific proteins in cancer, the effect of food on drug absorption and metabolic drug interactions have become increasingly important.[3] Typically, in early-phase clinical trials most oral anticancer drugs are administered on an empty stomach. Only a few agents undergo a formal food-effect study. The result is that the effect of food is sometimes identified only after the drug is in clinical use. For example, concomitant food intake can increase the systemic exposure of erlotinib, as measured by the area under the curve (AUC), by 34 to 66%, nilotinib by 82%, and lapatinib by up to 167%. Conversely, food can reduce the AUC of afatinib by 39%. A number of oral agents are relatively insoluble at alkaline pH, thus their absorption is reduced when concomitant acid-reducing agents such as proton-pump inhibitors are coadministered. These agents, such as erlotinib, should be administered at least 8 hours after ingestion of a potent acid-reducing agent in order to allow for recovery of

gastric acidity. An alternative is to utilize other agents, such as sucralfate, that do not affect gastric acidity directly.

The cytochrome P450 family enzyme system is the major catalyst of oxidative biotransformation reactions, which convert lipophilic drugs to hydrophilic forms for easy elimination. The CYP3A4 isoform is the most important with regard to metabolism of anticancer agents. A number of widely used agents, such as imatinib, sorafenib, sunitinib, vemurafenib, temsirolimus, and nilotinib, are substrates (Table 3-1). Coadministration of these drugs with strong inducers such as phenytoin and phenobarbital or strong inhibitors such as ketoconazole and grapefruit juice can affect drug levels, leading to decreased efficacy or increased toxicity. A complete listing of substrates, inhibitors, and inducers of the CYPP450 enzymes can be found on the U.S. Food and Drug Administration (FDA) website (www.fda.gov).

EXCRETION

There are two major routes of excretion: the kidneys and the biliary tract. Traditionally, chemotherapy agents were and generally still are administered using body-surface area (BSA)–adjusted doses. This method of dosing was adopted on the basis of the determination that physiologic processes such as basal metabolic rate, blood volume, and drug clearance were better correlated across animal species when BSA is utilized rather than body weight. Thus, use of BSA allowed the determination of phase I starting doses from an extrapolation of preclinical animal studies.[4] Although this method of dosing in humans was assumed to reduce the interpatient variability of drug exposure and thus drug effects, the interspecies correlation of BSA with clearance and other physiologic processes is not necessarily translatable to intraspecies correlation. BSA dosing has been shown to be associated with high pharmacokinetic variability and is a poor indicator of drug exposure. For example, Baker and colleagues reviewed 33 investigational agents and found that BSA-based dosing reduced interpatient variability for only 5 (15%) agents. Interestingly, the reduction in clearance variability was between 15% and 35%, indicating that only one-third of the clearance variability was attributable to BSA.[5] Despite these deficiencies, BSA-based dosing continues to be used for most cytotoxic agents. However, for some agents, such as carboplatin, several methods have been proposed for calculating drug doses considering the AUC and its subsequent hematologic toxicity and also the direct relationship between glomerular filtration and carboplatin clearance. However, this approach has been criticized because the calculated creatinine clearance methods, which are based on random serum creatinine measurements, are not accurate. Thus, the glomerular filtration rate (GFR) used to calculate the carboplatin dose is inaccurate.

Inulin clearance is widely regarded as the gold standard for measuring GFR. The classic method of inulin clearance requires an intravenous infusion and timed urine collections, making it cumbersome. As a result, a number of alternative measures for estimating GFR have been devised. The most frequently used estimation for GFR in adults is the Cockcroft–Gault equation, which was developed for estimating creatinine clearance; its prediction of GFR has been tested widely.[6,7] Another equation for estimation of creatinine clearance, by Jelliffe, has been used extensively.[8] The Modification of Diet in Renal Disease equation provides estimates of GFR standardized for BSA.[9] The abbreviated version is easy to implement, since it requires only serum creatinine, age, sex, and race. However, no single formula for estimating GFR has been deemed accurate for carboplatin dosing to achieve an optimal therapeutic index. This is because in the past, multiple assays were used to measure serum creatinine, resulting in

considerable interlaboratory variability in the reporting of creatinine values. In 2006, in an effort to standardize serum creatinine reporting across North America, the National Kidney Disease Education Program published recommendations to recalibrate serum creatinine assays to an isotope dilution mass spectrometry (IDMS) traceable reference method. This method has been in worldwide use since 2011. For some patients with normal renal function, the new standardized IDMS method produces creatinine values that are on average 10 to 20% lower than older, non-IDMS values. Therefore, for patients with relatively low serum creatinine, the IDMS method generates abnormally low values, leading to an overestimation of creatinine clearance and consequently higher calculated carboplatin doses, which could result in significant toxicity. To avoid such potential toxicity, the FDA recommends capping the carboplatin dose for a desired AUC. The maximum dose is based on a GFR estimate that is capped at 125 mL/min for patients with normal renal function.

The clearance of an agent is an important aspect of accurate drug dosing. Clearance can be calculated as the dose divided by the AUC or the dose rate divided by concentration at steady state. Few clinicians memorize the values of clearance for agents, but it is necessary to be aware of the variability in clearance. Most of the compounds used have a variation in clearance of approximately 20 to 40%, although some agents have high variability (75 to 100%). Some of the important factors affecting variability in clearance include changes in end-organ function, drug–drug interactions, and genetic variation leading to alterations in enzymes, which activate or clear a particular drug.

Variability in the metabolic or excretory organs because of dysfunction or the concomitant administration of medications that affect enzyme function is common and must be recognized. Many agents are highly protein-bound, and variability in the amount and function of proteins involved in drug metabolism will influence clearance. Many agents currently used in clinical practice must be adjusted for either renal or hepatic dysfunction (Table 3-2). Additional variables that affect excretion include enterohepatic circulation, wherein, after biliary excretion, reabsorption of either the parent drug or its metabolites may take place in the small intestine.

Genetic polymorphisms that lead to a reduction or an increase in the function of enzymes involved in the uptake, metabolism, and distribution of drugs can account for a substantial portion of the variability in drug response phenotypes (toxicity and clinical response). Lastly, it is important to know which drugs form active metabolites (Table 3-3). Many agents are metabolized into active forms. These include antimetabolites such as 5-fluorouracil (5-FU), pemetrexed, and gemcitabine. Others are prodrugs, in which the parent compound is essentially inactive. Metabolic enzymes convert these compounds to the active moiety. These include irinotecan (activated to SN38), cyclophosphamide (phosphoramide mustard), tamoxifen (endoxifen), temsirolimus (rapamycin), and temozolomide (MTIC). An important noncytotoxic prodrug that is used widely in oncology is codeine (3-methylmorphine), which is metabolized by CYP2D6 to morphine.

Table 3-2 **Drugs Requiring Dose Modification for Organ Dysfunction**

Liver Dysfunction	Renal Insufficiency	Glomerular Filtration Rate of Less than 25%
Cyclophosphamide	Bisphosphonates	Bleomycin
Cytarabine Dactinomycin	Capecitabine Carboplatin	Cyclophosphamide
Docetaxel	Cisplatin	Daunorubicin
Doxorubicin	Etoposide	Epirubicin
Epirubicin	Fludarabine	Idarubicin
Etoposide	Hydroxyurea	Ifosfamide
Fluorouracil	Methotrexate Pemetrexed	Mercaptopurine
Gemcitabine	Pentostatin	Streptozocin
Ifosfamide	Topotecan	
Irinotecan		
Paclitaxel		
Thiotepa		
Vinblastine		
Vincristine		
Vindesine		
Vinorelbine

In summary, when choosing a drug and a dose, oncologists must consider factors known to affect the activation and/or clearance of a given drug, including (1) route of administration, recognizing factors that influence absorption (e.g., gastric motility, food effect, prior surgery); (2) organ function; (3) drug–drug interactions; and (4) pharmacogenetics. Following consideration of these factors, the clinician must then develop a plan for careful monitoring of drug-response phenotypes, namely toxicity and response. Although classic toxicities, such as myelosuppression, are not commonly seen with newer targeted therapies that do not directly target DNA, substantial toxicity (e.g., trastuzumab- or sunitinib-induced cardiomyopathy) is not rare, and therefore close observation is necessary.

TOXICITY OF SYSTEMIC THERAPIES

Cytotoxic Therapy

Most cytotoxic drugs target DNA or proteins that are commonly expressed by both malignant and normal host tissues. Therefore, their therapeutic index—the ratio of efficacious concentrations to toxic concentrations—are very narrow, leading to significant toxicity. Because of their broad effects on DNA and associated synthetic proteins, there are several common toxic effects of cytotoxics, in addition to unique effects based on specifics of their mechanisms of cytotoxicity. Commonly seen toxicities with most cytotoxic drugs related to effects on rapidly proliferating cells include alopecia, myelosuppression, mucositis, diarrhea, and fatigue. Nausea and vomiting is also common. In addition, unique toxicities that need to be noted by oncologists include cardiotoxicity with doxorubicin, pulmonary toxicity with bleomycin, renal toxicity with cisplatin, and peripheral neuropathy with the antitubulin agents and platinum compounds.

Targeted Therapy

Recent basic science advances have led to the identification and elucidation of the mechanisms of action of aberrant proteins that are differentially expressed in cancer cells compared to normal cells, and these drive malignant transformation and maintenance of the malignant phenotype. Targeting these cancer-specific aberrations with small-molecule inhibitors and monoclonal antibodies started the era of “targeted therapies.” Because of the differential expression or overexpression of these proteins in cancer cells, targeted therapies were assumed to be relatively nontoxic. However, the incidence and severity of adverse events with targeted therapy appears to be similar to those of standard cytotoxic agents. The major difference is the various types of toxicity observed. Toxic effects of these agents can be divided into “mechanism-based” effects related to inhibition of the target protein, such as hypertension with angiogenesis inhibitors, skin rash with epidermal growth factor receptor (EGFR) inhibitors, and hyperglycemia with phosphatidylinositol-3-kinase (PI3K) inhibitors. Other toxicities are structurally based or “off-target” effects. As an example, ceritinib is an inhibitor of ALK kinase with significant gastrointestinal (GI) side effects of nausea, vomiting and abdominal pain, while another anaplastic lymphoma kinase (ALK) inhibitor, alectinib, has minimal GI toxic effects. Common toxicities of targeted agents are dermatologic, vascular, coagulation, endocrine, ocular, and pulmonary (Fig. 3-1). Because of the continuous, prolonged administration of these agents, such toxicities can be challenging to manage, and are exhaustively discussed in a publication by Dy and Adjei.[10]

Immunologic Agents

Immune checkpoint inhibitors of cytotoxic T-lymphocyte antigen 4 (CTLA-4), PD-1 (programmed death 1), and programmed death ligand 1 (PDL-1) are having a significant impact on a number of malignancies (see Chapter 4: Principles of Immuno-Oncology and Biologic Therapy). The immune activation induced by these compounds have led to the advent of immune-related adverse events, which can affect any organ in the body and, if not treated quickly, can lead to death. These toxicities have included colitis, hepatitis, pneumonitis, pericarditis, hypophysitis, uveitis, rash, and activation of infections such as tuberculosis.[11] Management involves cessation of treatment and rapid institution of high-dose corticosteroids.

TREATMENT OF PATIENTS WITH TOXIC DRUG LEVELS

For some chemotherapy drugs, the drugs themselves may be intrinsically toxic to either the liver or kidneys. In this case, toxic levels of the drug can build up, leading to prolonged and severe side effects. Some drugs can be removed by dialysis. For other drugs, specific antidotes have been developed. Leucovorin has been the standard treatment for reversing methotrexate toxicity for several decades. Glucarpidase is another antidote to treat patients with toxic levels of methotrexate in their blood, defined as levels exceeding 1 µmol/L, as a result of reduced clearance because of renal impairment. Glucarpidase, a recombinant form of the bacterial enzyme carboxypeptidase G2, converts methotrexate into glutamate and 2,4-diamino-N(10)-methylpteroic acid, which are inactive metabolites that can be eliminated from the body via nonrenal pathways.[12]

Clinicians need to be aware that leucovorin should not be administered within 2 hours before or after a glucarpidase dose because leucovorin is a substrate for glucarpidase. Toxic levels of 5-FU can build up after an overdose or in patients with dihydropyrimidine dehydrogenase (DPD) deficiency who receive full doses of 5-FU. This can lead to severe neutropenia, colitis cardiac dysfunction, or encephalopathy. Uridine triacetate has been approved to treat patients after an overdose of 5-FU or capecitabine or for patients exhibiting severe toxic effects within 96 hours after the end of 5-FU or capecitabine administration. Uridine triacetate is an acetylated form of uridine. Following PO administration, uridine triacetate is deacetylated by nonspecific esterases present throughout the body, yielding uridine in the circulation.

KEY POINTS

- A broad understanding of the metabolism of cytotoxic and biologic agents is necessary.
- Bioavailability is important when using oral chemotherapy agents.
- Food can alter bioavailability and thus drug exposure.
- Drug–drug interactions are an important—but often unrecognized—factor influencing drug effects.

PHARMACOGENOMICS

Pharmacogenetics has been defined as the study of variability in drug response because of heredity. In this context, there are germline aberrations (occurring in host cells) in drug-metabolizing pathways or drug targets that are inherited and can affect individual responses to drugs, both in terms of therapeutic effect and adverse effects.[13] More recently, the term “pharmacogenetics” has been introduced. Although the former term is largely used in relation to genes determining drug metabolism, the latter is a broader term that encompasses all genes in the genome that may determine drug response.[14] These aberrations can therefore be somatic (occurring in tumor) or germline. The distinction, however, is arbitrary, and the two terms can be used interchangeably.

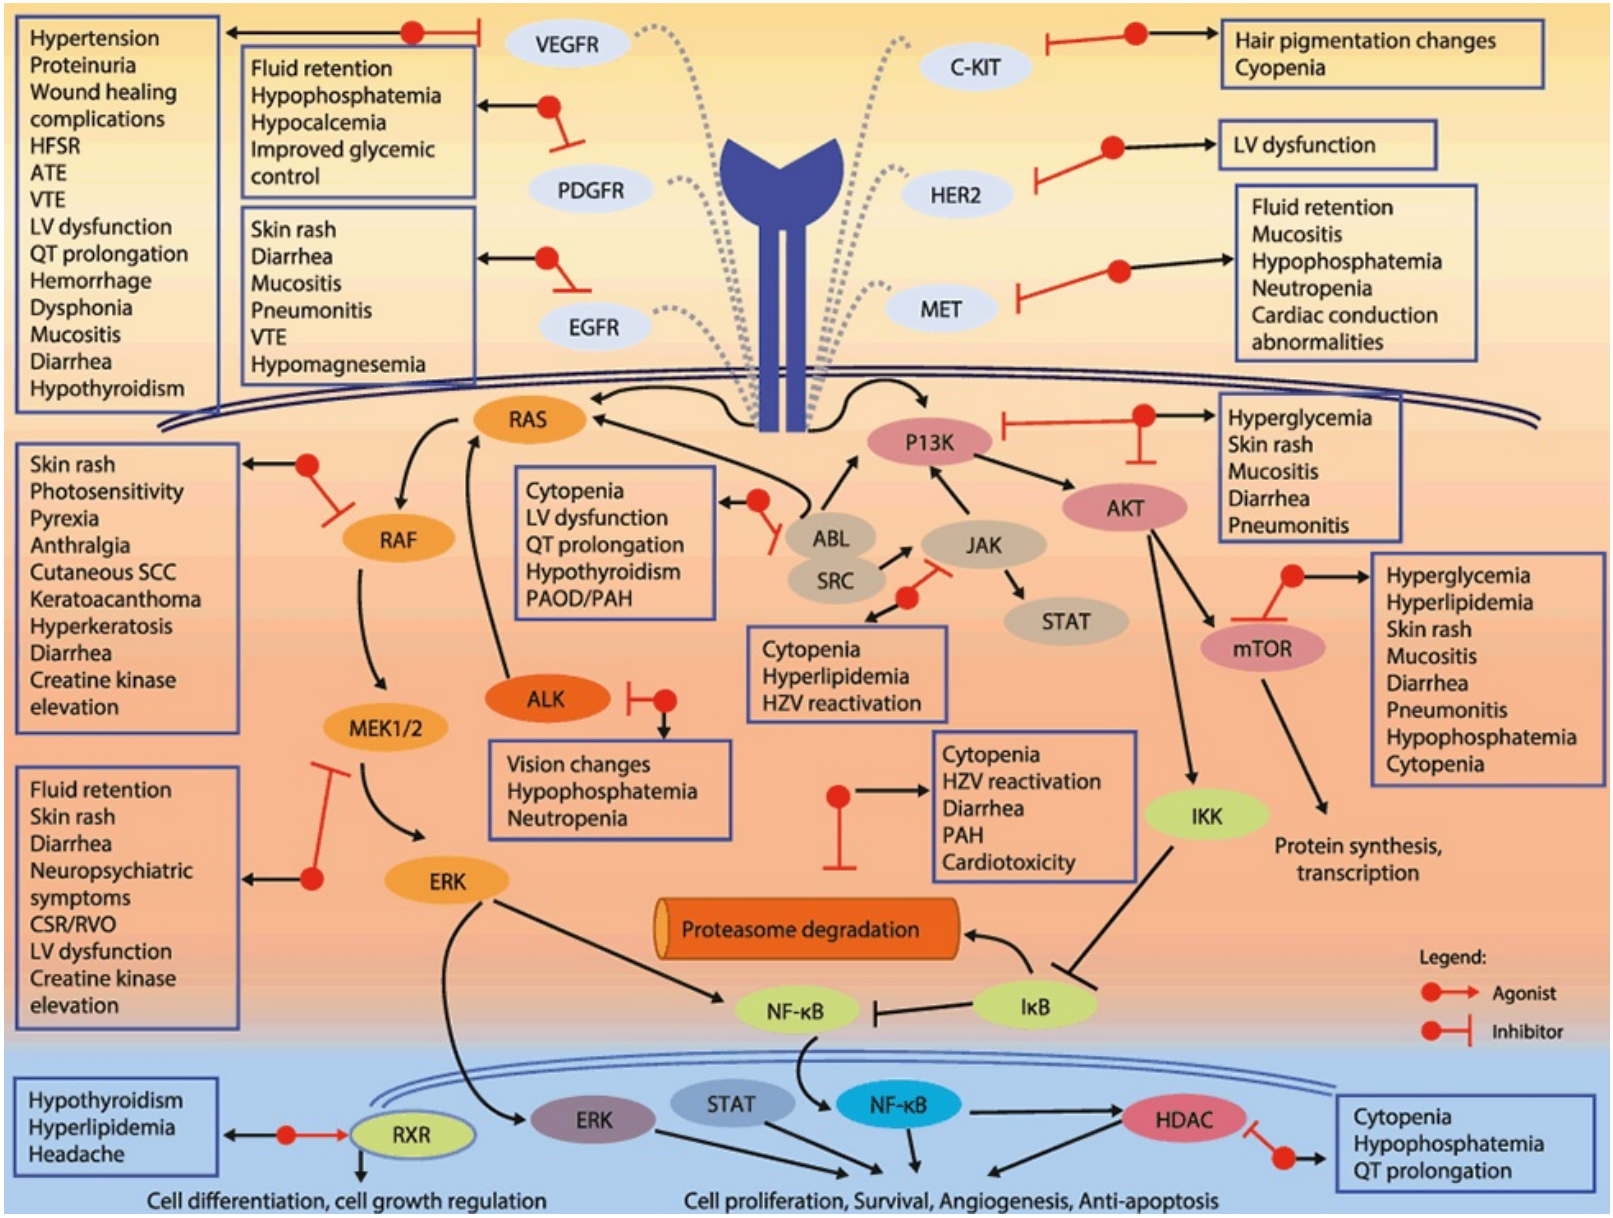

Fig. 3-1 Toxicities of targeted anticancer agents.

Much of this genetic variation is in the form of single-nucleotide polymorphisms (SNPs). SNPs are defined as variants with population frequencies of 1% or greater, which can alter the amino acid sequence of the encoded protein or alter RNA splicing, leading to altered kinetics and catalysis of the protein.

Technologic advances enable rapid and accurate assessment of tumor gene expression and deduced function, both at the level of individual genes and by global gene analysis. In the latter case, massive parallel sequencing of the entire genome is now possible (see Chapter 2: Molecular Biology). This type of research has been critical in identifying specific biologic subsets of cancer that are more or less likely to relapse (prognostic) in the absence of systemic treatment, as well as in identifying genes or gene patterns associated with response (predictive for specific therapies or agents). For breast cancer, many gene expression array tests are commercially available in which the expression patterns of a subset of genes important in proliferation identify tumors that are associated with a higher risk of recurrence (see Chapter 7: Breast Cancer).[15] This same technology may identify a subset of tumors more likely to benefit from chemotherapy.[16]

Mutations in genes that encode transmembrane receptor tyrosine kinases as well as proteins involved in downstream signaling cascades are important for response to tyrosine kinase inhibitors. For example, lung cancers that harbor mutations that activate the EGFR tyrosine kinase domain lead to high response rates to the drugs gefitinib, erlotinib, and afatinib. Similar situations exist for *ALK* gene rearrangements and response to crizotinib and ceritinib, as well *BRAF* mutations and response of melanoma to vemurafenib and dabrafenib. Furthermore, in the case of colorectal cancer, mutations in the important oncogene *KRAS* are predictive of lack of response to the EGFR-inhibiting drugs panitumumab and cetuximab. In the latter example, retrospective studies have demonstrated that monoclonal antibodies that target EGFR appear to be effective only in tumors with wild-type *KRAS.*[17]

In the specialty of oncology, clinicians must take into account all sources of genetic variation that influence drug effects. This includes both somatic and germline genetic variations. The following sections illustrate important examples in which genetic variation at the level of both the tumor and the host leads to substantial changes in drug effect.

The promise of pharmacogenetics to individualize treatment according to gene sequence variation is well illustrated in the treatment of patients with cancer. Administration of “standard” doses of chemotherapy to patients with inherited deficiencies in enzymes responsible for their metabolism and disposition can result in marked toxicity, which can be lethal. Conversely, patients who have increased enzymatic activity may be at risk for treatment failure—also an undesirable outcome when dealing with a potentially fatal illness. The traditional method by which individualized anticancer drug doses are developed and determined has involved the use of BSA measurements and weight-based dosing.[18] However, multiple studies have indicated that dosing in this manner does not reliably account for the variability in exposure to most chemotherapeutic drugs.[19]

Examples of the role of pharmacogenetics have been clearly illustrated with both cytotoxic chemotherapy and targeted therapies, including the two endpoints most important to patients with cancer: response and toxicity. The three examples discussed below have led to relabeling or hearings by the FDA to reflect the importance of pharmacogenetics.

THIOPURINES

The thiopurine drugs mercaptopurine and azathioprine (the latter of which is a prodrug that is converted to mercaptopurine in vivo) are purine antimetabolites used clinically to treat both pediatric and adult leukemias and as immunosuppressant agents.[20] Thiopurines are metabolized in part by *S*-methylation, catalyzed by the enzyme thiopurine *S*-methyltransferase (TPMT).[21,22] A group led by Richard M. Weinshilboum first identified three groups of patients on the basis of the level of TPMT activity in their red cells and found that the level of activity was inherited in an autosomal-codominant fashion.[21,23] Subsequently, it was shown that patients who received standard doses of thiopurines and who were homozygous for very low levels of TPMT activity or for no activity ($TPMT^{L}TPMT^{L}$) had greatly elevated concentrations of active drug metabolites, 6-thioguanine nucleotides, and a markedly increased risk of life-threatening, drug-induced myelosuppression.[24] As a result, the phenotypic test for the level of TPMT activity in red cells and, subsequently, DNA-based tests were among the first pharmacogenetic tests to be used in clinical practice. The result of *TPMT* gene resequencing has demonstrated that the most common variant allele responsible for low levels of activity among white populations encodes a protein with two alterations in the amino acid sequence as a result of SNPs.[25,26] These sequence changes result in a striking reduction in the quantity of TPMT,[25] at least in part

because the variant protein is degraded rapidly.[20] A series of less frequent *TPMT* variant alleles has also been described.[23]

UGT1A1 AND IRINOTECAN

Irinotecan is a prodrug, metabolized in vivo to 7-ethyl-10-hydroxycamptothecin, SN-38 (Fig. 3-1), which is a potent inhibitor of topoisomerase I.[27-29] In humans, both gastrointestinal (e.g., diarrhea) and hematologic (e.g., neutropenia) toxicities are dose-limiting following the administration of irinotecan. SN-38 is inactivated by glucuronidation to form the glucuronide conjugate (SN-38G) in a reaction catalyzed by the polymorphic hepatic enzyme uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) (Fig. 3-2).[30] A dinucleotide repeat polymorphism in the TATA box in the promoter for *UGT1A1* results in reduced hepatic *UGT1A1* expression and is considered the most common cause of Gilbert syndrome (mild unconjugated hyperbilirubinemia).[31-33] Patients homozygous for the *UGT1A1*28* polymorphism have substantially lower SN-38 glucuronidation rates and substantially higher rates of grade 4 or 5 neutropenia than those who do not carry this genetic variant.[34] In addition, it has been demonstrated in a Japanese population that 80% of patients who suffered from life-threatening irinotecan toxicities had variant sequences because of *UGT1A1*6* (211G→A) and *UGT1A1*27* (686C→A).[35] The importance of *UGT1A1* pharmacogenetics in mediating irinotecan-related toxicity was recognized by the FDA when the irinotecan label was modified to recommend a dose reduction for patients homozygous for the *UGT1A1* polymorphism. Recent studies have demonstrated that not only do patients homozygous for the *UGT1A1*28* polymorphism require lower doses of irinotecan, but also that patients who do not carry the genetic variant tolerate substantially higher doses of irinotecan.[36]

TAMOXIFEN AND CYP2D6

Tamoxifen can be considered a prodrug that requires metabolic activation to elicit its pharmacologic activity. Tamoxifen undergoes activation to metabolites that are 100 times more potent suppressors of estradiol-stimulated breast cancer cell growth (4-OH tamoxifen and endoxifen) compared with tamoxifen or its primary metabolite, *N*-desmethyl tamoxifen. Endoxifen is the most abundant active metabolite in most individuals and results from the CYP2D6-mediated oxidation of *N*-desmethyl tamoxifen (Fig. 3-3).[37] In separate studies of women treated with tamoxifen, genetic variation in *CYP2D6* and/or coadministration of CYP2D6 inhibitors were associated with a significant reduction in the mean plasma endoxifen concentrations, with the reduction in endoxifen concentrations directly related to inhibitor potency.[38,39] Multiple studies have evaluated whether genetic polymorphisms that alter CYP2D6 enzyme activity or the coadministration of CYP2D6 inhibitors are associated with disease recurrences, including conflicting data from large secondary analyses of prospective adjuvant tamoxifen trials.[40-42] One meta-analysis demonstrated that the *CYP2D6* genotype was associated with recurrence or death, but only among patients taking 20 mg/day for 5 years for the adjuvant treatment of estrogen receptor–positive breast cancer.[43] Clinicians should avoid the concurrent use of potent CYP2D6 inhibitors and tamoxifen. Ongoing prospective studies should provide definitive data as to the role of selecting hormonal therapy according to CYP2D6 genotype.

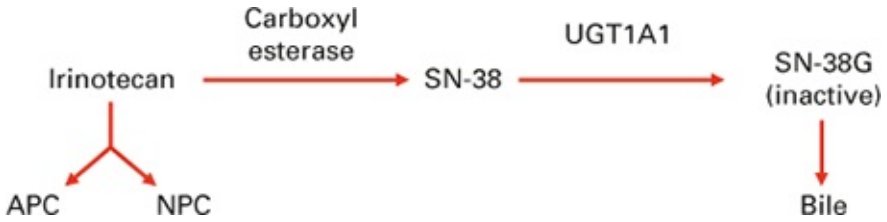

Fig. 3-2 Metabolic pathway of irinotecan, a prodrug that is activated by carboxylesterase to the active metabolite SN-38.

SN-38 is glucuronidated by uridine diphosphate glucuronosyltransferase 1A1 (*UGT1A1*), forming the inactive metabolite SN-38 glucuronide (SN-38G), which is eliminated by the bile.

Abbreviations: APC, aminopentanecarboxylic acid; NPC, 7-ethyl-20-(4-amino-1-piperidino)carbonyloxycamptothecin.

KEY POINTS

- *Pharmacogenetics* is the study of the role of genetic inheritance in individual variation in (1) drug response and (2) toxicity.
- FDA-recognized examples of oncologic drugs for which toxicity or response is influenced by pharmacogenetics, include the thiopurine drugs mercaptopurine and azathioprine *(TPMT)* and irinotecan *(UGT1A1).*

PHARMACODYNAMICS

Pharmacodynamics is the study of the effects of drugs in the body, including the drug target. It is often summarized as the study of "what a drug does to the body." In early-phase clinical research, it is important not only to define the pharmacokinetic parameters of a given drug but also to determine the effect of the drug on the tumor or on the target endpoints. These types of studies are best done in late phase I or early phase II clinical trials, in which the drug dose is fixed and the variability in target modulation can be assessed more easily. One of the greatest challenges in pharmacodynamic studies is selecting the endpoint. Ideally, endpoints can be measured reliably and are easily quantified and clinically meaningful. Also, the most reliable and relevant samples for assessing biomarkers are tumors, but access to tumors may be difficult. Clinical trials may also be designed to study changes in a circulating blood factor, to determine its correlation with disease endpoints. Determining such a relationship in early phases of clinical research simplifies the clinical development pathway for a particular agent. Examples include inhibition of phosphorylated extracellular signal regulated kinase (phospho-ERK), phosphoprotein kinase B (Akt), and retinoblastoma (Rb) phosphorylation in tumors. Additionally, a drug may exhibit effects on normal tissues, which may be associated with efficacy. Examples include, EGFR-1–induced skin rash (associated with a higher rate of tumor response) and aromatase inhibitor–induced arthralgias (associated with lower recurrence rates in the adjuvant treatment of estrogen receptor–positive breast cancer).

Activity levels of tamoxifen metabolites at the estrogen receptor and the impact of genetic polymorphisms of phase I and II enzymes on their concentration levels in plasma. *Clin Pharmacol Ther.* 2011;89:708–717.

BIOLOGIC AGENTS AND PREDICTIVE BIOMARKERS

Hundreds of novel biologic agents are in development for the treatment of cancer. Many of these agents bind a particular receptor or protein within a tumor. Therefore, the expression of the target is critical when using such an agent. Examples include *HER2*-targeting drugs such as trastuzumab, ado-trastuzumab emtansine, pertuzumab, and lapatinib, which target the *HER2* oncogene as well as critical other members of the EGFR system (*HER1* and *HER3*). In the metastatic setting, expression or amplification of the *HER2* receptor is critical for the activity of *HER2*-targeting drugs.[44] More recently, the FDA has approved biologic agents along with a companion biomarker (vemurafenib and the BRAF V600 Mutation Test; crizotinib and the Abbott Vysis ALK Break Apart FISH test).

DRUG RESISTANCE

Drug resistance has been seen as a major cause of the lack of cure with systemic cancer therapies. Cancer cell killing by a drug depends on transport of drug to the tumor and engagement with the drug target. Drug resistance could be due to any step in the process of absorption, transport, metabolism, and modification of the drug target. With classic

chemotherapy drugs, resistance mechanisms due to efflux pumps that extrude drugs from cells and multidrug resistance have been well characterized. Multidrug resistance is conferred by the expression of ATP-binding cassette family proteins that include P-glycoprotein (P-gp), multidrug resistance protein (MRP), and breast cancer resistance protein (BCRP). Tumors expressing these proteins exhibit resistance to several chemotherapeutic agents, which tend to be natural products but may have different targets. Examples are anthracyclines, vinca alkaloids, taxanes, and epipodophyllotoxins for P-gp.[45] With the dramatic clinical responses being seen with targeted agents that inhibit oncogenic kinases, the emergence of resistance has become a major problem. Multiple mechanisms of resistance, including target modification through secondary mutations, gene amplification and development of bypass tracts have been identified.[46] Based on these findings, a number of second- and third-generation kinase inhibitors have been identified that can overcome resistance to EGFR inhibitors, BCR-ABL inhibitors, and ALK inhibitors, for example (Fig. 3-4).

KEY POINTS

- Pharmacodynamics is the study of the effects of drugs in the body, including the drug target. Pharmacodynamic studies have been useful in documenting the mechanism of action of drugs, but have not been useful biomarkers.
- Predictive biomarkers such as gene mutations, translocation, and amplification have been useful in developing highly effective drugs, with a number of molecular aberrations such as *EGFR* mutations being approved as companion biomarkers to drugs.
- An emerging problem with therapy with molecularly targeted drugs is the relatively rapid development of resistance. There are several research efforts aimed at identifying and targeting mechanisms of resistance.

DRUG DEVELOPMENT: CLINICAL TRIAL DESIGN

The goals of clinical research are to expand knowledge about new anticancer agents through the conduct of well-designed clinical trials, to rapidly gain approval by regulatory bodies, and to obtain adequate clinical information for safe and effective drug delivery. The medical literature is focused on clinical research and clinical trial design, which makes the comprehension of trial design critical for practicing physicians.

NONCLINICAL DRUG TESTING

New compounds are discovered primarily by two means. First, there is rational design of new therapeutic agents. When a target is known, drugs can be tailored to fit the target (e.g., vemurafenib for V600E melanoma). Second, compounds are discovered as a result of high-throughput screening, in which multiple compounds with unknown activity are tested against a series of cancer cell lines (e.g., rapamycin, the active moiety of temsirolimus). Those with the best activity are selected for further development. From either source, new agents with promise are tested in vitro and subsequently in vivo to determine whether the drug can kill cancer cells. During in vivo testing, toxicity, dosing schedule, and route of administration are investigated. Subsequently, drugs are formulated for a specific route of administration (e.g., PO

or IV), and the administration schedule is again optimized (e.g., daily, weekly, or via infusion). Although schedules often are based on expected toxicities, mechanisms of action, and animal studies, patient and physician convenience are also factors.

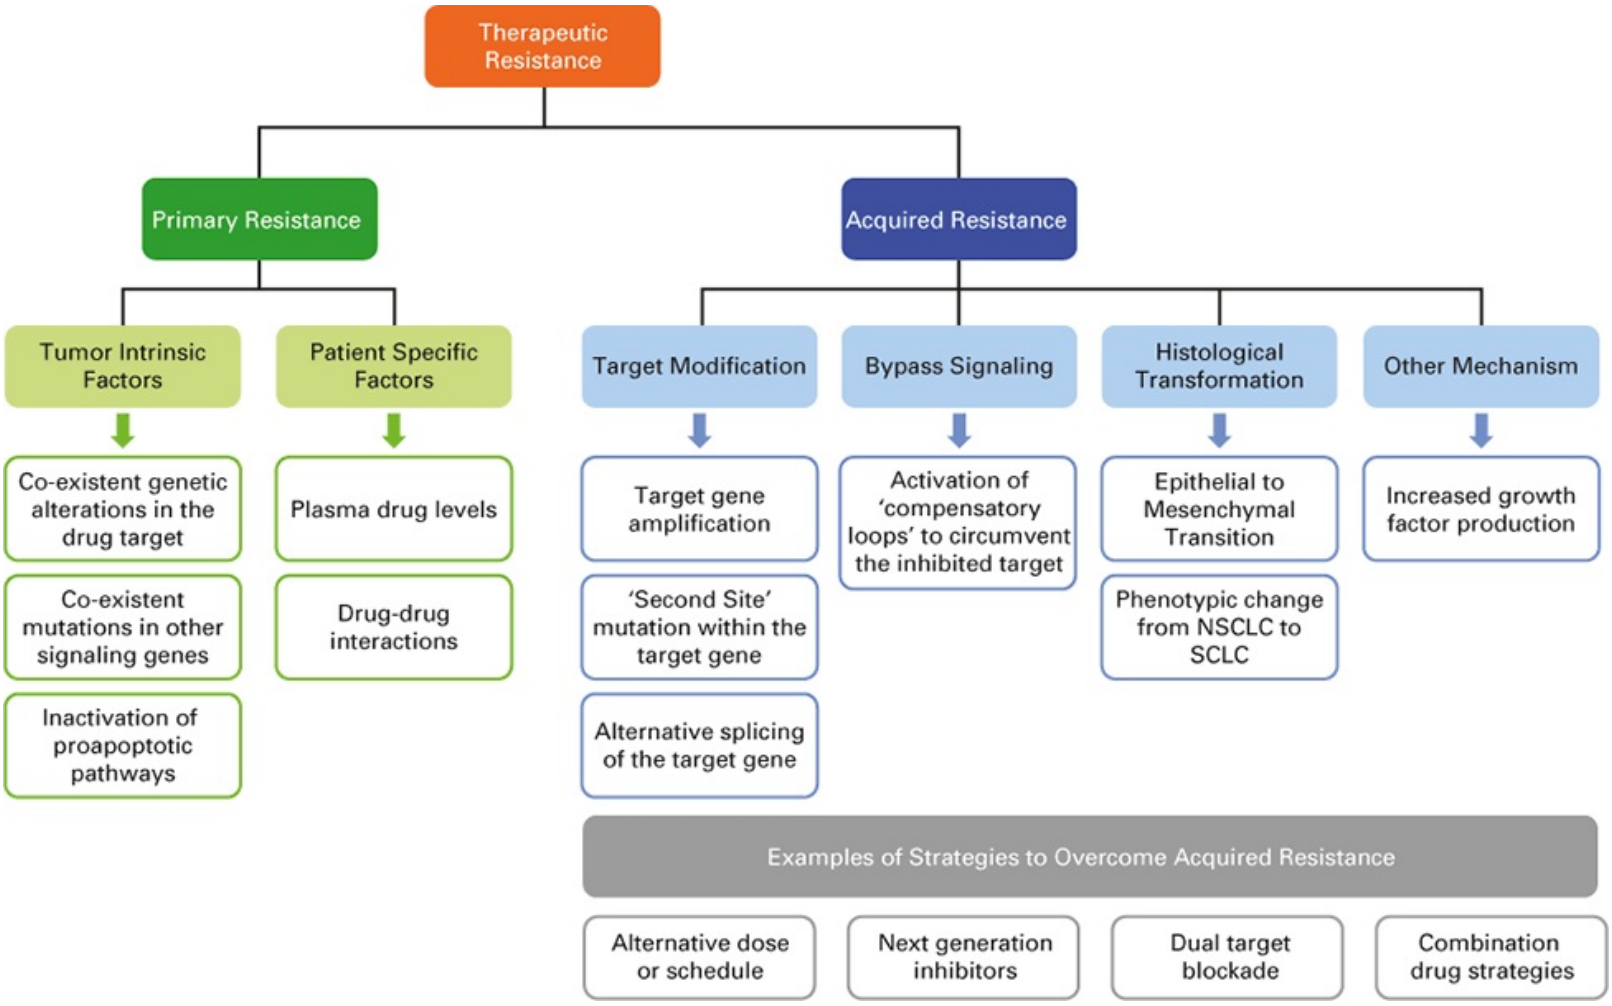

Fig. 3-4 Resistance mechanisms to kinase inhibitors.

If the agent yields positive results in nonclinical testing, clinical trials are performed. Based on toxicology studies involving animals, a starting dose is determined for phase I clinical trials using one of two standard techniques. The more common method is to take one-tenth of the dose that kills 10% of the most sensitive animal species. An alternative strategy is to use one-third of the toxic dose–low (defined as the lowest dose of a substance at which any toxic effect is produced). Once the phase I dose has been selected and appropriate regulatory measures have been met, phase I clinical trials are then performed.

PHASE I TRIALS

The primary goal of a phase I clinical trial using classic cytotoxic chemotherapy has been to determine the maximum tolerated dose (MTD): the highest dose of a drug or treatment that does not cause unacceptable side effects. However, the MTD may not be the optimal dose, especially for drugs that target a specific receptor or growth factor pathway. However, the small sample sizes in a phase I trial do not allow for an accurate assessment of an "optimal dose." This can be ascertained only through randomized dose-ranging studies. Secondary goals are to determine the optimal administration schedule, the toxicity profile of the agent, and

the pharmacokinetics and pharmacodynamics, as discussed previously, as well as to observe for any clinical activity. Typically, patients with cancer who enter phase I clinical trials have advanced cancer that has not responded to standard therapy. To be eligible for these trials, patients' disease must have a good performance status and they must have relatively normal end-organ function so that adequate pharmacology can be determined.

The classic phase I design for cytotoxic chemotherapy agents has been developed largely empirically. In this design, three patients are treated at each dose level. The first cohort is treated at a starting dose that is considered to be safe based on extrapolation from animal toxicologic data, and the subsequent cohorts are treated at increasing dose levels that have been fixed in advance. The size of the cohorts is expanded if severe (grade 3 or 4) toxicities occur. Pharmacokinetic measurements are typically obtained for all patients, as are toxicity and tumor assessments. Historically, dose escalation using this trial design typically followed a modified Fibonacci sequence, in which the dose increments become smaller as the dose increases (e.g., the dose first increases by 100% of the preceding dose, and thereafter by 67%, 50%, 40%, and 30 to 35% of the preceding doses).

In recent years, a number of alternative designs for phase I studies have been investigated. Adaptive or Bayesian designs are increasing in popularity. The primary goal of all these designs is to shorten the duration of phase I trials and to enhance the precision of the phase II dose recommendation. These methods are typically based on the concept of using toxicity as the endpoint of the trial. A mathematical function is created that describes the hypothesized relationship (curve) between the incidence of dose-limiting toxicity (DLT) and dose. This curve is reasonably predicted to assume a sigmoid shape for which the MTD must be estimated first. As information regarding the presence or absence of toxicity accumulates, the original estimate of the MTD is updated to more accurately fit the hypothesized curve to the actual data. Under these types of trial designs, the occurrence of toxicity results in an adjustment of the curve to match the probability that one is now approaching the MTD. Conversely, the absence of toxicity results in adjustments of the curve to match the probability that one is not yet at the MTD. Therefore, the occurrence of no DLT in several sequential patients results in a statistical prediction that the dose can be more rapidly escalated in a safe manner.[47]

Typically, phase I clinical trials, utilizing the standard 3+3 designs as well as the newer Bayesian designs, have been performed in patients with multiple tumor types; however, these trials may focus on a single tumor or a particular group of tumors known to express a specific receptor or mutation. A newer focus in phase I trials is to treat genomic subsets. Thus, eligibility for the trial includes the presence of specific genetic aberrations in the tumors. One example includes mutations in the p110-alpha subunit of PI3K, called *PIK3CA,* responsible for activation of the PI3K/AKT/mammalian target of rapamycin (mTOR) pathway, which can cause neoplastic transformation and promote cancer progression. One report demonstrated that, in a phase I population of patients, *PIK3CA* mutations were detected in 18% of tested patients, and patients with *PIK3CA* mutations treated with PI3K/AKT/mTOR inhibitors demonstrated a higher response rate than patients without mutations.[48]

With agents that are not expected to be overly toxic or when clinical effects are expected before toxic effects are likely to develop, other designs can be used. The phase 0 design is one example in which small numbers of patients are treated with the goal of determining early on whether a given drug will affect its intended target.

Phase I clinical trials involving combination agents have the added emphasis of evaluating the interaction between the two agents. This is particularly important when there might be a pharmacologic interaction resulting in a substantial change in the toxicity profile. These trials

can be complex. Such trial designs were examined by a National Cancer Institute task force, which recommended that proposed drug regimens should be selected on the basis of a biologic or pharmacologic rationale supported by clinical and/or robust and validated preclinical evidence and accompanied by a plan for subsequent development of the combination. The design of the phase I clinical trial should take into consideration the potential pharmacokinetic and pharmacodynamic interactions as well as overlapping toxicity. Depending on the specific hypothesized interaction, the primary endpoint may be dose optimization, pharmacokinetics, and/or pharmacodynamics.[49]

Investigators are discouraged from making definitive decisions regarding the efficacy of a given cancer drug tested in a phase I study. However, observed tumor activity in the phase I setting is usually the impetus for studying the drug in subsequent phase II studies.

PHASE II TRIALS

The primary goal of phase II clinical trials is to better determine the preliminary efficacy and toxicity of an agent. Although traditional phase II trials have used a single-arm design, researchers increasingly use randomized trial designs, which allow for preliminary comparisons of efficacy and toxicity. Typically, a fixed dose and schedule of the therapy are selected and patients have only one tumor type and have similar characteristics, including similar exposure to previous therapies.

The choice of tumor type is based on preclinical and early clinical research, as well as the molecular biology of the mechanism of the agent's action. Many studies involve patients who have untreated metastatic cancer; however, in order to quickly evaluate efficacy and obtain regulatory approval, some studies involve patients who have highly refractory tumors. Phase II clinical research is typically the point at which decisions are made about the subsequent development of a given compound. If minimal or no clinical activity is observed or there is excessive or unmanageable toxicity in phase II studies, development of the drug is usually not continued.

Although the classic statistical design for a phase II single-arm trial relied on drug response (complete or partial), newer targeted therapies are often cytostatic; therefore, time-to-disease-progression endpoints are now more commonly employed. Additionally, randomized phase II trials are sometimes performed to establish proof of efficacy of a biologic agent. The randomized phase II discontinuation design was used to test the drug sorafenib, ultimately contributing to its approval for the treatment of renal cell carcinoma. In this design, after a 12-week run-in period, patients with tumor shrinkage of less than or equal to 25% continued with the drug. These patients were randomly assigned to sorafenib or placebo for an additional 12 weeks, and patients with tumor growth of more than or equal to 25% discontinued treatment.[50,51] The study effectively demonstrated that sorafenib significantly prolonged progression-free survival compared with placebo. Similar to what was done for phase I studies, the Clinical Trials Design Task Force of the National Cancer Institute has developed formal recommendations about aspects of phase II trial design—endpoints, randomization, inclusion of biomarkers, biomarker-based patient enrichment strategies, and statistical design—that are the subject of frequent debate. In general, the recommendations encourage the use of progression-free survival as the primary endpoint and support randomized phase II trials, inclusion of biomarkers, and incorporation of novel designs. However, it is acknowledged that using objective response as an endpoint and single-arm designs remain relevant in certain situations.[52]

PHASE III TRIALS

The ultimate goal of phase III clinical research is either to gain approval of a new agent by a regulatory body or to replace the current standard of care. These trials are typically large, ranging from as few as 300 patients to as many as several thousand. By definition, these trials are randomized clinical studies. The design and size of each trial hinges specifically on the selected endpoints. The gold-standard endpoint is survival, which is recognized by all regulatory agencies. However, survival endpoints may not be optimal for all cancers, especially those in which multiple active agents are available to patients after completion of the clinical trial. For breast and colorectal cancers, the FDA now recognizes disease-free survival, defined as the time to the first event of relapse, development of a second primary cancer, or death. Additionally, response rate, time to disease progression, quality of life, and other nontraditional endpoints have been incorporated into phase III clinical trial designs and have provided support to the approval process of many new agents in oncology.

NOVEL TRIAL DESIGNS

With molecular characterization of tumors becoming routine in clinical practice, the notion of treating tumors according to molecular aberrations rather than histologic classification is becoming more widespread, leading to new study designs. The most common designs are the so-called umbrella and basket trials. In umbrella trials, multiple aberrations in a single tumor type is targeted by different drugs. An example is a current National Cancer Institute (NCI) clinical trials network study in second-line squamous cell cancer of the lung in which aberrations in MET, PI3K, CDK4/6, and others are targeted by different agents.[53] Basket studies involve the treatment of different tumor types that have a specific molecular aberration with specific drugs. In this fashion, therapy is targeting a specific molecular aberration regardless of the tissue of origin. An example is the NCI MATCH trial.[54] While these designs are critical proof-of-concept studies generating important clinical information, the path to regulatory approval of an agent using these designs still remains unclear.

KEY POINTS

- Traditional oncology drug development has comprised phase I pharmacology studies, phase II initial efficacy studies, and phase III randomized comparisons against standard of care.
- With the emergence of molecularly targeted agents, novel study designs such as Bayesian designs, seamless phase I/II designs, basket, and umbrella studies have been introduced.

NEW MEDICINES AND NOVEL MECHANISMS OF ACTION

A growing understanding of the molecular, genetic, and biochemical changes that occur during the processes of carcinogenesis, progression, and metastasis has shifted oncology drug development away from traditional chemotherapeutic agents that target DNA and toward therapeutics that act on specific molecular targets that drive tumor growth and metastasis. Moreover, these same basic science advances in synthetic chemistry, immunology, and

molecular biology have led to novel approaches to inhibiting these targets. In addition to small-molecule kinase inhibitors and antibody therapy (monoclonal, polyclonal, and bispecific antibodies), one area of recent progress is in antibody-drug conjugate (ADC) technology. This approach involves an antibody directed against a surface antigen of the cancer, which is conjugated to a toxin (typically a tubulin such as a maytansine derivative) by a linker. The antibody binds the cell-surface antigen, the complex is internalized by endocytosis, the linker dissociates, and the toxin is released intracellularly, leading to apoptosis. Earlier approaches had led to significant toxicity, particularly hepatotoxicity, as the linker disintegrated significantly in the peripheral circulation. Improvements in linker technology, together with a number of available toxins and identification of tumor antigens with limited normal tissue expression, has advanced this field. Ado-trastuzumab emtansine (TDM-1) links the toxic antitubulin emtansine to trastuzumab; in 2013, it was approved for the treatment of HER2-positive breast cancer that showed progression on treatment with trastuzumab.[55] A number of ADCs are in clinical testing now, with two of the more promising ones being anetumab ravtansine, which targets mesothelin-expressing tumors[56] and rovalpituzumab tesirine, which targets the notch family receptor delta-like ligand 3 (DLL3). The DLL3 antibody is conjugated to a toxic pyrrolobenzodiazepine DNA-damaging agent, tesirine. DLL3 is expressed in about 80% of small cell lung cancers, and phase III trials are ongoing.[57] In terms of novel targets, efforts continue to target signal transduction proteins such as ERK kinase, TRK kinase, cell-cycle regulating proteins (the cyclins, the cyclin-dependent kinases, and inhibitors of cyclin-dependent kinases), epigenetic targets, and tumor metabolic targets (see Chapter 2: Molecular Biology).

Immunotherapy is a third area in which important advances have been made over the past couple of years (see Chapter 4: Principles of Immuno-Oncology and Biologic Therapy). Clinicians have known for many years that using nonspecific enhancers of the immune system, such as interleukin-2 (aldesleukin) and interferon, can generate immune responses that lead to clinical responses for patients with kidney cancer or melanoma. More recently, there has been increased interest in the development of immune-based therapy for more common solid tumors, such as cancers of the breast, bladder, head and neck, lung, and gastrointestinal tract and for hematologic malignancies such as lymphoma. Recent advances in understanding the mechanisms of immune tolerance of the host to tumor-specific antigens have led to the development of immune checkpoint proteins such as monoclonal antibodies against anti-PD-1 and anti-PDL-1. The anti-PD1 inhibitors pembrolizumab, nivolumab, and atezolizumab have been approved by the FDA for multiple solid tumors.

The rapid pace of drug development is evidenced by 22 approvals of novel entities, as well as by expanded indications for previously approved entities by the FDA in 2016. A current list of FDA-approved drugs in oncology can be accessed at https://www.fda.gov/Drugs/InformationOnDrugs/ApprovedDrugs. Two recent FDA approvals warrant mention. The first approval of a plasma-based genomic analysis occurred when the FDA approved the cobas EGFR Mutation Test v2 using plasma specimens as a companion diagnostic test for the detection of exon 19 deletions or exon 21 (L858R) substitution mutations in the *EGFR* gene to identify patients with metastatic non-small cell lung cancer NSCLC eligible for treatment with erlotinib. The approval was based on a multicenter, open-label, randomized, phase III study, to evaluate the efficacy and safety of erlotinib versus gemcitabine plus cisplatin as first-line treatment for patients with stage IIIB/IV NSCLC. The agreement between the cobas EGFR Mutation Test v2 in plasma and the cobas EGFR Mutation Test v1 in tissue was evaluated for detection of *EGFR* mutations in patients with NSCLC who were screened for participation in the study. In 76.7% (95% CI; 70.5, 81.9) of tissue-positive specimens, plasma

was also positive for an *EGFR* mutation. Plasma was negative for *EGFR* mutation in 98.2% (95% CI; 95.4, 99.3) of tissue-negative cases.[58]

In the second approval, the FDA modified the indication for erlotinib for treatment of NSCLC to limit use to patients whose tumors have EGFR exon 19 deletions or exon 21 L858R substitution mutations as detected by an FDA-approved test. This labeling supplement is based on the results of a randomized, double-blind, placebo-controlled trial of erlotinib administered as maintenance therapy in patients with advanced NSCLC who had not experienced disease progression or unacceptable toxicity during four cycles of platinum-based first-line chemotherapy. Patients whose tumors harbored activating *EGFR* mutations (exon 19 deletions or exon 21 L858R mutations) were excluded from this trial. Results demonstrated that survival following treatment with erlotinib was not better than placebo administered as maintenance in patients with metastatic NSCLC tumors not harboring *EGFR*-activating mutations.[59]

KEY POINT

- Substantial gains have been realized in the development of drugs that inhibit novel cancer targets. These targets include, but are not limited to, angiogenesis, signal transduction growth pathways, and immune checkpoints.

PRINCIPLES OF IMMUNO-ONCOLOGY AND BIOLOGIC THERAPY

Rodrigo Ramella Munhoz, MD, and Michael A. Postow, MD

Recent Updates

- A large number of biologic agents that promote antitumor immune and nonimmune responses have been approved for clinical use since the 5th edition was published.
- In collaboration with the National Comprehensive Cancer Network, the American Society of Clinical Oncology issued its first clinical practice guideline on management of immune-related adverse events in patients treated with immune checkpoint inhibitor therapy. (Brahmer JR, *J Clin Oncol* 2018)
- The clinical indications for the use of antibodies blocking the immune checkpoint PD-1 and its ligand PD-L1 continue to expand. In addition to advanced melanoma and non-small cell lung cancer, nivolumab has been approved for the treatment of patients with advanced renal cell carcinoma, relapsed/refractory classic Hodgkin lymphoma, recurrent or metastatic squamous cell carcinoma of the head and neck (SCCHN), urothelial carcinoma following platinum-containing chemotherapy, and mismatch repair–deficient advanced colorectal cancer. Nivolumab is also approved for clinical use in combination with ipilimumab in advanced melanoma. (Ansell SM, *N Engl J Med* 2015; Younes A, *Lancet Oncol* 2016; Ferris RL, *N Engl J Med* 2016; Sharma P, *Lancet Oncol* 2017; Overman MJ, *Lancet Oncol* 2017; Larkin J, *N Engl J Med* 2015; Postow MA, *N Engl J Med* 2015)
- Pembrolizumab is now approved for treatment in the first-line setting of patients with PD-L1–positive non-small cell lung cancer or in combination with chemotherapy irrespective of PD-L1 expression, metastatic SCCHN, classic Hodgkin lymphoma, urothelial carcinoma, and for patients with mismatch repair–deficient solid tumors, expanding prior indications for metastatic melanoma and refractory non-small cell lung cancer. (Reck M, *N Engl J Med* 2016; Langer CJ, *Lancet Oncol* 2016; Seiwert TY, *Lancet Oncol* 2016; Chen R, *J Clin Oncol* 2017; Bellmunt J, *N Engl J Med* 2017; Le DT, *N Engl J Med* 2015;)
- Atezolizumab has been approved for the treatment of patients with advanced urothelial carcinoma and metastatic non-small cell lung cancer. (Rosenberg JE, *Lancet* 2016; Balar AV, *Lancet* 2017; Rittmeyer A, *Lancet* 2017)
- Avelumab became the first systemic agent to be approved for the treatment of advanced Merkel cell carcinoma, and the indication of this agent was subsequently expanded to advanced urothelial carcinoma. (Kaufman HL, *Lancet Oncol* 2016; Apolo AB, *J Clin Oncol* 2017)
- Durvalumab has been approved for the treatment of patients with advanced urothelial carcinoma. (Massard C, *J Clin Oncol* 2016)
- Ipilimumab resulted in significant overall survival improvement when used in the adjuvant setting for patients with stage III melanoma and is approved as adjuvant therapy. (Eggermont AMM, *N Engl J Med* 2016)
- Necitumumab has been approved for use in combination with gemcitabine and cisplatin for patients with advanced squamous non-small cell lung cancer. (Thatcher N, *Lancet Oncol* 2015)
- Olaratumab has been approved for use in combination with doxorubicin for the treatment of patients with advanced soft-tissue sarcomas. (Tap WD, *Lancet* 2016)
- Obinutuzumab in combination with bendamustine, followed by obinutuzumab monotherapy has been approved for the treatment of patients with rituximab-refractory indolent non-Hodgkin lymphoma. (Sehn LH, *Lancet Oncol* 2016)
- Daratumumab, an anti-CD38 monoclonal antibody, has been approved for use as a single agent and in combination with lenalidomide or bortezomib and dexamethasone for the treatment of patients with refractory multiple myeloma. (Palumbo

A, *N Engl J Med* 2016; Dimopoulos MA, *N Engl J Med* 2016)

- Elotuzumab, an immunostimulatory monoclonal antibody targeting SLAMF7, has been approved by the FDA for use in combination with lenalidomide and dexamethasone for the treatment of patients with multiple myeloma in whom prior therapies have failed. (Lonial S, *N Engl J Med* 2015)

OVERVIEW AND GENERAL CONCEPTS OF IMMUNO-ONCOLOGY

Biologic therapy—whether for neoplastic, infectious, immunologic, or other diseases—refers to the use of biologic products or substances that are made by living organisms, such as cytokines, antibodies, and cells. For cancer, these substances are administered primarily to generate or restore host immune responses or to mediate nonimmunologic antitumor activities. Since the introduction of interferon (IFN) more than 25 years ago, progress in biologic therapy for cancer has been rapid. Several cytokines have been approved by the U.S. Food and Drug Administration (FDA). An increasing number of monoclonal antibodies are being used clinically. The introduction of immune checkpoint blockade with monoclonal antibodies has had a major impact in the management of a growing number of malignancies and has paved the way for the development of combined approaches, already in clinical use for the treatment of patients with melanoma. Cellular therapy based on artificially engineered antigen receptors (either chimeric or modified T-cell receptor) produced remarkable results in patients with refractory hematologic malignancies, and in combination with cell-based vaccine approaches already approved for clinical use, are expanding the applicability of cancer immunotherapy, or immuno-oncology. This chapter will focus on the immunology, pharmacology, and toxicology of biologic therapy in clinical use to treat cancer. More detailed review of the clinical application of specific agents is provided in tumor-specific chapters.

The immune system protects against microbial pathogens while simultaneously maintaining tolerance to “self.” The “innate” response forms the first line of defense. Innate immune cells (e.g., macrophages, dendritic cells, and natural killer [NK] cells) express receptors (e.g., toll-like receptors [TLRs]) involved in the recognition of conserved molecular patterns (pathogen-associated molecular patterns [PAMPs]), such as unmethylated CpG DNA motifs, found on exogenous organisms, and cell damage-associated molecular patterns (DAMPs) (e.g., high-mobility group box 1 [HMGB1]) but not on normal, uninflamed human tissues. Stimulation through these receptors triggers a cascade of events that includes the production of cytokines, activation of cellular cytotoxicity, an increase in nitric oxide synthesis, and activation of the complement system. These events promote the elimination or lysis of microbial pathogens and promote recruitment and activation of other immune cells.

Microbial/cellular fragments that result from the destruction produced by the innate immune response are taken up by antigen-presenting cells (e.g., macrophages, dendritic cells, B cells), which then process the fragments and present these antigens to generate the “adaptive” response, largely though the activation and mobilization of T cells and antibody-producing B cells. These cells express highly diverse antigen-specific receptors—the T-cell antigen receptors (TCRs) and the B-cell antigen receptors (BCRs)—generated by random rearrangement of the TCR and immunoglobulin (Ig) gene segments, respectively. The adaptive response allows generation of extremely diverse T- and B-cell repertoires that, compared with the innate response, provide a more specific but also broader and more flexible responses that include the capacity for generating “memory.”

Immune responses are highly regulated. Many types of cells and molecular factors, including

cell-surface molecules, are involved in modulating (either positively or negatively) both the innate and the adaptive response. A key step in the generation of adaptive immunity is the presentation of antigens by antigen-presenting cells to T-helper cells, which promote cellular effectors (e.g., cytolytic T lymphocytes [CTLs]) or humoral effectors (e.g., antibodies) through the production of specific cytokines. Regulatory cells and cytokines also serve to suppress the immune response to maintain tolerance to self and limit immune-mediated damage to normal tissues.

KEY POINTS

- Cells of both the antigen-nonspecific innate and antigen-specific adaptive responses have been implicated in antitumor immunity.
- Specific immunity to tumors requires uptake of tumor antigens by antigen-presenting cells and presentation to T-helper cells, which coordinate the generation of cellular (cytotoxic T cells) and/or humoral (antibody-producing B-cell) responses.
- Immune responses are highly regulated to maintain tolerance to self and limit immune-mediated damage to normal tissues.

IMMUNE CELLS

A wide variety of hematologic and nonhematologic cells are important in innate and adaptive immunity. The following are considered to play prominent roles in antitumor immune responses.

T Cells and Immune Checkpoints

T cells are paramount in the adaptive immune responses as effectors and as regulators. The signaling complex of T cells includes the TCR dimer, the accessory molecules (CD4 or CD8), and the CD3 signal transduction module. Unlike antibodies, which can react to intact proteins, T cells, through the TCR, react only to peptide fragments of antigens that are noncovalently complexed with major histocompatibility complex (MHC) molecules, which are integral membrane glycoproteins. There are two types of MHC molecules. Class I MHC (e.g., human leukocyte antigens A, B, and C) are expressed on all cell types and serve as the antigen-presenting molecule for CD8+ T cells. Class II MHC (e.g., HLA-DR) is recognized by CD4+ T cells and is present primarily on antigen-presenting cells but also can be present on other cells, including tumor cells. Polymorphisms within MHC molecules determine whether a peptide fragment will complex with the MHC molecule and thus whether a T cell from an individual will respond to a specific epitope of an antigen, resulting in the phenomenon referred to as “MHC restriction.” Because of this phenomenon, some peptide cancer vaccines can be applied only to patients with specific HLA types.

T-cell activation requires not only the presentation of an antigen within the context of an MHC molecule and stimulation through the CD3 module but also “costimulatory” signals. Activation is in turn regulated by “coinhibitory” signals, essential in limiting the magnitude of the immune response and autoimmunity, but also exploited as immune evasion mechanisms by tumor cells. The CD28 family of receptors includes the stimulatory receptor CD28 and the inhibitory receptors cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed death 1 (PD-1).

Receptors of the CD28 family interact with the B7 family of ligands, which include B7-1, B7-2, programmed death ligands 1 (PD-L1 also called B7-H1), and 2 (PD-L2 also called B7-DC). These interactions are referred to as “immune checkpoints.” A simplified diagram for the CTLA-4 and PD-1 immune checkpoints is shown in Figure 4-1. Several other receptor–ligand engagements can act as modulators of the immune response, including those mediated by the costimulatory and coinhibitory molecules listed below.

Costimulatory receptors:

- CD28
- CD137
- CD27
- OX40 (or CD134)
- Inducible T-cell costimulator (ICOS)
- Glucocorticoid-induced tumor necrosis factor receptor [TNFR]–related protein (GITR)

Coinhibitory receptors:

- CTLA-4
- PD-1
- B- and T-cell attenuator (BTLA),
- Lymphocyte-activation gene 3 (LAG3)
- T-cell immunoglobulin and mucin-domain containing 3 (TIM3)
- PD-1H (also named VISTA [V-domain Ig suppressor of T cell activation]).

Cytolytic T Lymphocytes

Cytolytic T lymphocytes (CTLs) are primarily CD8+ T cells and thus recognize, through their unique TCR, antigens presented within the context of MHC class I. Two mechanisms are involved in their cytolytic effector activity. The predominant mechanism is granule exocytosis and the release of perforin and granzymes. The second mechanism is mediated by the death activator Fas ligand, which is expressed on the cell surface of CTLs. Both mechanisms cause cells to undergo apoptosis (Fig. 4-2). When appropriately activated, these cells also produce cytokines, such as interferon-gamma, interleukin-2 (IL-2), and tumor necrosis factor α (TNF-α), that also can mediate or enhance antitumor effects. CTL can move to another cell and, by reorienting its granules to another region of contact, destroy it. In this manner, CTL can kill many tumor cells, resulting in a very robust and very specific “serial killing” response that is considered to play a central role in immune-mediated tumor rejection. Tumor-infiltrating CD8+ lymphocytes can be associated with improved clinical outcome.[1]

T-Helper Cells

T-helper cells secrete cytokines that regulate all immune cells. They are essential in generating CTLs, regulating B-cell antibody production, and activating phagocytes. Most T-helper cells express CD4 and thus recognize antigens presented by class II MHC. Depending on the nature of the peptide and the activation status of the antigen-presenting cells, several types of

responses can be promoted, including a cellular immune response mediated by CTLs and by macrophages, referred to as T-helper cell type 1 (Th1) response, or a humoral response mediated by antibody, referred to as Th2 response (which also includes activation of eosinophils). Predominant cytokines produced in a Th1-associated response are interferon-gamma and IL-2. Predominant cytokines produced in a Th2-associated response are IL-4 and IL-5. CD4+ T cells are required in an antitumor response largely to help naive CD8+ T cells, leading to their differentiation and activation into tumor-specific CTLs and the development of antigen (Ag)-specific memory. Cytokines produced by T-helper cells also may mediate antitumor effects by activating macrophages and NK cells. T-helper cytokines (e.g., interferon-gamma) may also directly suppress tumor growth.

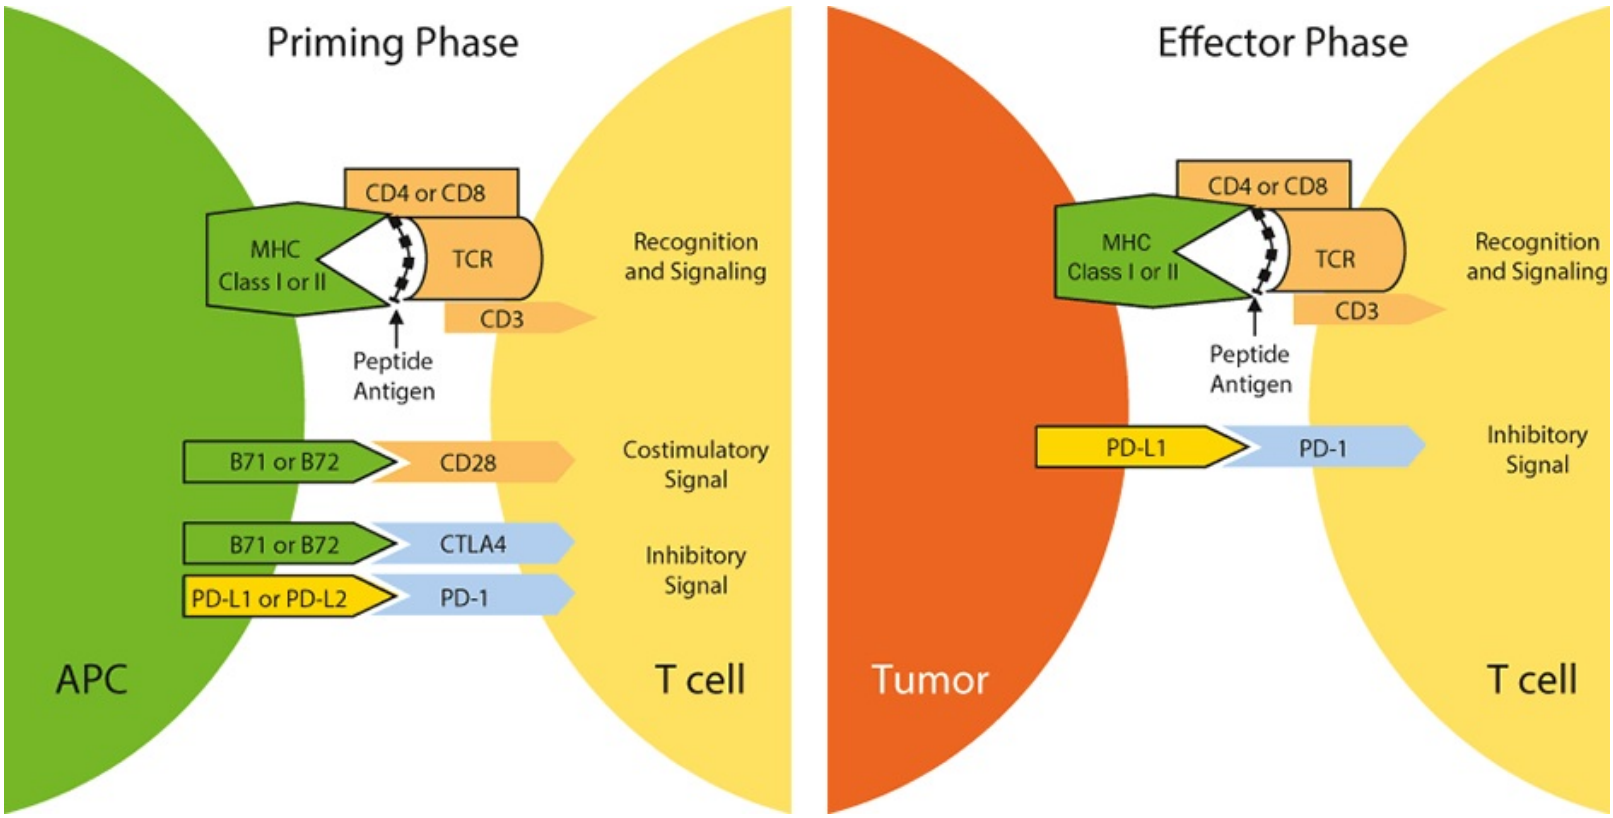

Fig. 4-1 Regulation of T-cell priming and effector function.

During the priming phase of T-cell activation, antigens are presented to the T-cell receptor (TCR) as peptide fragments within major histocompatibility complex (MHC) molecules on antigen-presenting cells (APCs). The primary costimulatory signal is delivered through the CD28 receptor on the T cell after engagement of its ligands, B7-1 or B7-2, on the APC. Fully effective engagement also depends on the interactions among several other molecules, such as adhesion molecules (not shown). Failure of the costimulatory B7/CD28 complex to be engaged results in either a nonactivating T-cell event and/or anergy. Engagement of the cytolytic T-lymphocyte antigen 4 (CTLA-4) receptor (CD152) on the T cell by the same B7-1 or B7-2 ligands results in inhibition of the response. Engagement of the programmed death 1 (PD-1) receptor with one of its two ligands, PD-L1 or PD-L2, on APC also results in inhibition of the response. PD-L1 is also expressed by tumors. During the effector phase, engagement of PD-1 on the activated T cell by PD-L1 on the tumor results in inhibition of T-cell function.

Regulatory T Cells

Regulatory T cells (Tregs) are subsets of T lymphocytes capable of discriminating self-antigens from non–self-antigens. In healthy individuals, Tregs maintain tolerance by suppressing expansion of effector cells directed against self-antigen. Tregs that express CD4, CD25, and forkhead box P3 (FOXP3; a forkhead family transcriptional regulator) play a central role in maintaining immune self-tolerance. The mechanism of suppression of self-reactive lymphocytes is not clear but does appear to involve direct cell-to-cell contact or the production of IL-10 or of

transforming growth factor β (TGF-β). Given that many tumor-associated antigens are normal self-constituents, CD4+CD25+FOXP3 Treg cells engaged in the maintenance of self-tolerance may impede tumor-reactive T cells. Their role in cancer, however, is not established, and the prognostic significance of intratumoral Treg cells may be context-dependent and affected by the tumor type, the other cells in the tumor microenvironment, and soluble molecules that vary with time and treatment. In cancers, such as breast cancer, data show that intratumoral Treg cells confer a poorer prognosis[2]; however, in colorectal cancer, there is a better prognosis.[3]

Natural Killer Cells

Natural killer (NK) cells are a relatively small population (less than 10%) of circulating lymphocytes and are distinct from T cells and B cells. They are part of the innate or immediate non–Ag-specific response to pathogens and transformed cells. Although their cytotoxic mechanisms are similar to those of CTL, NK cells do not require recognition of MHC molecules, and thus killing by NK cells is designated as non-MHC-restricted lysis. In fact, class I MHC molecules send a negative regulatory signal through receptors on the NK cells (killer inhibitory receptors [KIRs]) that inhibit NK cell lytic function. Conversely, loss of class I MHC on tumor cells may result in NK cell killing of cells that could otherwise escape T-cell recognition. Under normal homeostatic conditions, multiple families of NK cell receptors that inhibit their activation exert the predominant effects, while inflammation and infection, as well as malignancy, may lead to activation through a number of other activating receptors that recognize soluble and cell-membrane ligands on tumors and infected cells. Also in contrast to CTLs, NK cells express Fc receptors and thus can mediate antibody-dependent cell-mediated cytotoxicity (ADCC). When activated, NK cells also produce interferon-gamma. Although NK cells do not require activation for lytic activity, the stimulation of NK cells with interferons and IL-2 markedly enhances their antitumor activity. In contrast to CTLs, which can kill multiple cells, there is evidence that NK cells must rearm themselves by exposure to IL-2 before they are effective against new targets. Furthermore, there is, for the most part, no memory component to the NK response.

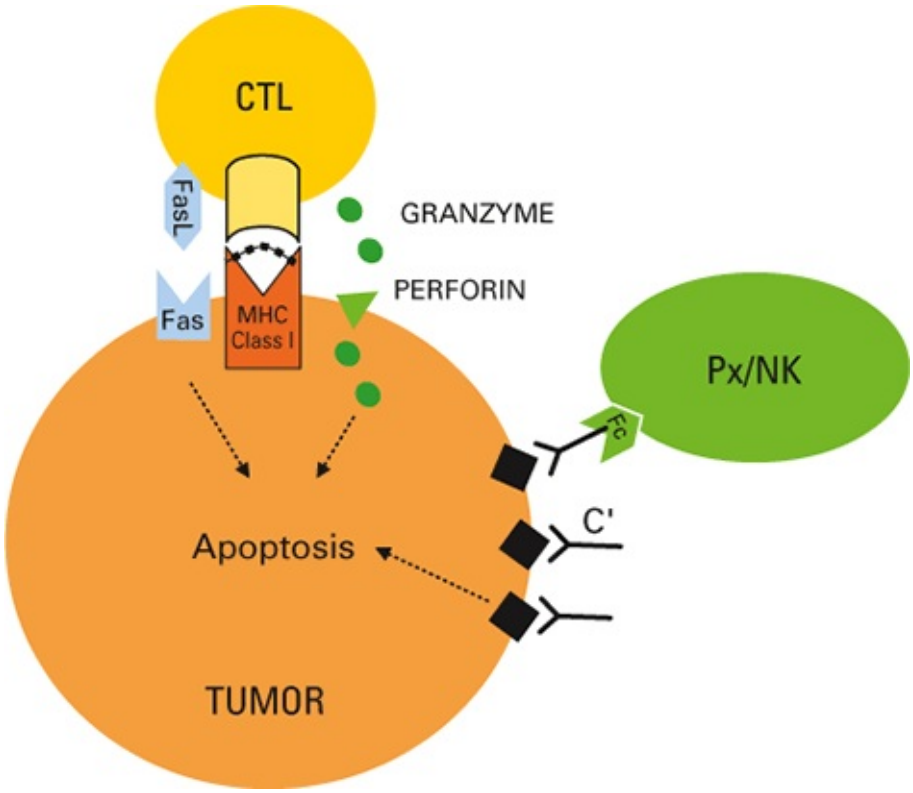

Fig. 4-2 Mechanisms of cell killing by cytolytic T lymphocytes and antibody.

After attaching to the major histocompatibility complex (MHC)–peptide complex, cytolytic T lymphocytes (CTLs) discharge cytoplasmic granules containing perforin and granzymes by exocytosis. Perforin molecules insert themselves into the plasma membrane of target cells, which enables granzymes to enter the cell. Granzymes are serine proteases that, once inside the cell, activate caspases that cause the cells to undergo apoptosis. When CTLs bind to their target, they also upregulate Fas ligand (FasL) on their surface, which binds with the Fas receptor on the surface of the target cell, leading to its death—also by apoptosis. Antibody recognizes antigen in its native conformation. After binding, a complement reactive site on the antibody is activated that sets into motion a cascade of reactions, including the activation of many molecules of the complement system, which in turn activate increasing amounts of enzymes resulting in complement-mediated cytotoxicity (CMC). A product of the complement cascade also strongly activates phagocytosis by macrophages and neutrophils. These phagocytes (Px) and also natural killer (NK) cells bind their Fc receptor (CD16) to the antibody and destroy the antibody-bound cell (antibody-dependent cellular mechanisms). Antibody-recognizing cell-surface molecules that regulate cell signaling/growth can directly elicit apoptosis. Abbreviations: C′, complement.

B Cells

Antibody-producing B cells are involved in adaptive immunity and also serve as antigen-presenting cells. The BCR binds soluble antigens, which are then internalized by receptor-mediated endocytosis and processed into peptide fragments that are then displayed at the cell surface within class II MHC. T-helper cells specific for this structure (i.e., with a complementary TCR) bind the B cell and secrete cytokines that stimulate the B cell to proliferate into cells with identical BCRs and ultimately to differentiate into plasma cells that secrete antibodies (i.e., the soluble version of the BCR). In contrast to T cells, which recognize only processed peptide antigen, antibodies produced by B cells recognize the intact protein antigen in its native conformation. Antibodies also can recognize polysaccharides and nucleic acids. Antigen-binding specificity is encoded by three complementarity-determining regions on the Fab (fragment-antigen binding) region, whereas the monomorphic Fc (fraction-crystallizable) region of the antibody is responsible for binding to serum proteins (e.g., complement) or to cells such as macrophages and NK cells that express Fc receptors that transmit signals leading to ADCC. Complement-mediated cytotoxicity (CMC) may develop in the case of complement-fixing Fc classes of IgG and multimeric antibodies such as IgM, and subsequent activation for the complement protein cascade. Central to CMC is the ability of the antibody to redistribute the target on the cell membrane into large glycolipoprotein microdomains known as “lipid rafts.” Antibodies also can directly mediate antitumor effects by interacting with cell-surface receptors that regulate cell growth (Fig. 4-2). Although cellular immune responses appear to be central in the generation of effective antitumor immunity, a substantial body of data indicates that antibodies are also important. Furthermore, the antitumor effects of antibodies have been validated by the clinical efficacy of monoclonal antibodies specific for tumor-associated molecules.

Dendritic Cells

Dendritic cells are a widely distributed, heterogeneous population of antigen-presenting cells that are derived from bone marrow progenitors and circulate in the blood as immature precursors prior to migration into peripheral tissues. Within different tissues, dendritic cells differentiate and become active in the uptake and processing of antigens via MHC class I and II molecules, which require distinct intracellular processing pathways, termed the “antigen-processing machinery” (APM), generally using class I for endogenous antigens and class II for exogenous antigens, but with substantial overlap. Dendritic cells function at the intersection of the innate and adaptive immune responses. Upon stimulation provided by microbes (via TLRs), cytokines, and/or T-cell signals (e.g., CD40 ligand), dendritic cells undergo further maturation

and migrate to secondary lymphoid tissues, where they present antigen to T cells. The nature of the immune response elicited depends on a variety of factors, including the mode and duration of activation and the cytokine milieu.

Two distinct dendritic cell lineages have been described in humans: myeloid dendritic cells (mDCs) express the receptor for granulocyte–macrophage colony-stimulating factor (GM-CSF) and other myeloid markers. mDCs reside in tissues and are the most efficient antigen-presenting cells, particularly with regard to the primary activation of naive T cells. They stimulate tumor-reactive CTLs through an IL-12–dependent mechanism. Plasmacytoid dendritic cells (pDCs) lack myeloid cell markers and express the receptor for IL-3 (CD123). They reside in peripheral blood, and after encountering a virus, they secrete large amounts of interferon-alpha, a cytokine with immunomodulatory as well as antiviral properties. The role of pDCs in antitumor immunity is under investigation.

Macrophages

Macrophages, which derive from peripheral-blood monocytes, are widely dispersed throughout the body and mediate a variety of functions. Macrophages are specialized phagocytes. Phagocytosis is mediated through surface receptors for complement and other opsonins and through the uptake of particles into phagosomes that then fuse with cytoplasmic lysosomes. Macrophages express Fc receptors for antibodies and can mediate antibody-dependent cellular uptake and cytotoxicity. Similar to dendritic cells, macrophages function at the intersection of the innate and adaptive immune responses and can process antigen via the APM and present peptides within MHC molecules to activate specific T- and B-cell effector mechanisms. Macrophages also are potent secretory cells. They are major producers of the pro-angiogenic vascular endothelial growth factor (VEGF). Distinct activation states of macrophages have been described: M1 macrophages produce high levels of inducible nitric oxide synthase, IL-12, and TNF, whereas M2 macrophages produce arginase, IL-10, TGF-beta, and prostaglandin E_2. M1 macrophages are potent effector cells that kill tumors through nitric oxide and TNF, whereas M2 macrophages limit Th1 immune responses and promote angiogenesis, processes that promote tumor growth. Whereas M2 macrophages are associated with a decrease in survival for patients with cancer, M1 macrophages have been associated with an improved survival.[1,2]

Myeloid-Derived Suppressor Cells

A number of investigations have identified immature myeloid cell populations present in tumors and lymphoid organs, referred to as myeloid-derived suppressor cells (MDSCs), which inhibit T-cell functions and play a role in tumor-associated immune suppression. They have been described in patients with many types of solid tumors.[3-5] Human MDSCs are still poorly defined but have been reported to lack the expression of markers of mature myeloid and lymphoid cells (i.e., lineage-negative) and HLA-DR. MDSCs do express the common myeloid marker CD33. The precise nature of this regulatory cell population and whether they are precursors of granulocytes, macrophages, or dendritic cells appear to depend on the tumor and tumor-derived factors of the host. This highly plastic population suppresses T-cell functions through different molecular pathways, mostly involving arginase metabolism products, inducible nitric oxide synthase, reactive oxygen species, and/or production of soluble inhibitory factors such as TGF-beta, IL-10, prostaglandin E_2, and nitric oxide.

KEY POINTS

- T cells recognize antigens presented to the T-cell antigen receptors as peptide fragments within MHC molecules. T-cell activation requires stimulation not only through the T-cell antigen receptor but also through immune costimulatory receptors.
- Interactions with coinhibitory receptors on T cells, referred to as “immune checkpoints,” suppress unwanted and harmful self-directed immune activities.
- T-helper cells promote Th1–associated CTLs through the production of cytokines, such as interferon-gamma and interleukin-2 (IL-2), and promote Th2-associated antibodies through production of cytokines, such as IL-4 and IL-5.
- CTLs kill tumors by apoptosis through granule exocytosis and Fas-mediated mechanisms.
- B cells produce antibodies that recognize antigens in their native conformation. Antibodies can react against tumors by complement-mediated and ADCC mechanisms.
- Dendritic cells are the most efficient antigen-presenting cells.
- Several lymphoid and myeloid cell populations act to suppress immune responses, including regulatory T cells and MDSCs.

IMMUNE SURVEILLANCE

Several lines of evidence support the existence of cancer immune surveillance—that the innate/adaptive immune system continually recognizes and removes malignant cells that arise throughout an individual’s lifetime. Individuals with suppressed immune systems, such as organ transplant recipients or patients affected with primary or acquired immunodeficiency disorders, are at increased risk for the development of malignancy. The rare spontaneous regression of cancer and the responses to withdrawal of immunosuppression in some cases, as well as waning of the incidence of Kaposi sarcoma in AIDS with the advent of highly active antiretroviral therapies, are further evidence in favor of immune surveillance in cancer control. Brisk infiltration by subpopulations of lymphocytes, especially CD8-T cells, in tumor specimens is an independent positive prognostic factor for some cancers, such as melanoma and ovarian cancer.[1,6,7] Likewise, the natural occurrence of a humoral immune response to a tumor-associated antigen is associated with a favorable clinical outcome in cancers such as breast cancer.[8] Human T cells that accumulate within the mass of a tumor can be shown, in some instances, to proliferate in response to autologous tumor cells in vitro. Most importantly, pharmacologic modulation of the immune response with cytokines and with various types of antibodies has produced objective tumor responses in patients.

Effective surveillance requires that the tumor express determinants, capable of being recognized by the immune system (i.e., tumor antigens), and that are associated with the tumor intrinsic antigenic potential. Numerous tumor-associated antigens (TAAs), including the differentiation antigens carcinoembryonic antigen (CEA), tyrosinase, and prostate-specific antigen (PSA), as well as peptides that result from genes overexpressed in tumors (e.g., *erbB2*), have been defined with antibodies and applied in diagnosis and in monitoring response to therapy. As outlined previously, antigens that are recognized by the T cells differ substantially

from those defined by antibodies. To function as a T-cell rejection antigen, the tumor must express the associated peptide determinant in the context of MHC molecules. Failure of antigen processing or binding to MHC molecules—or inadequate expression of costimulatory or adhesion molecules—may lead to poor immunogenicity. Several targets that can potentially serve as tumor rejection antigens have been identified by a variety of techniques (Table 4-1). Many of these have been targeted in vaccine approaches. Oncofetal, cancer-testis (a group of oncofetal antigens), and differentiation/lineage-specific antigens are expressed by normal adult tissues and, therefore, are not tumor-specific. In contrast to those that are overexpressed and not mutated (e.g., *erbB2*), oncogenes/tumor suppressors that are mutated can be considered tumor-specific and even patient-specific (e.g., *p53*). The tumor immunogenicity and response to treatment with monoclonal antibodies targeting immune checkpoints can be also influenced by peptides and antigenic neoepitopes generated from aberrant gene products and increased number of somatic missense mutations, also defined as tumor mutational load.[9-11] As a demonstration of this principle, significant antitumor effect from PD-1 blockade has been demonstrated in patients with mismatch repair (MMR) deficiency–related tumors, marked by genomic instability and a high mutational burden.[12] Other factors that drive the capacity of mounting an adequate immune response include the expression of proinflammatory chemokines (type I interferons, CCL2, CCL3, CCL4, CCL5, CXCL9, and CXCL10) and mutations involving pathways that are part of the immune activation cascade, including disruptive mutations or, conversely, amplifications of JAK1 or JAK2 (implicated in interferon-dependent signaling), phosphatase and tensin homolog (*PTEN*) loss, and activation of the WNT/beta-catenin pathway.

KEY POINTS

- Several lines of evidence, including clinical responses with pharmacologic modulation of the immune response, support the role of the immune response in cancer regulation, both in immune surveillance against nascent malignancy and in therapy for established malignancy.
- Recognition of tumor cells by the immune system can be influenced by a variety of factors, including the tumor intrinsic antigenic potential (e.g., mutational burden and neoantigen signature, strength of immunogenicity of tumor antigens), preexisting host immune condition and products of genomic aberrations affecting pathways driving the immune response.
- This continuous interaction between tumor cells and immune cells, not always successful in terms of tumor control, is characterized as immune surveillance.

IMMUNE ESCAPE

Animal models have demonstrated the existence of “immunoediting,” in which activation of immune mechanisms initially controls the tumor, but over time leads to the selection of tumor cells that escape the immune pressure, grow progressively and then contribute to the establishment of an immunosuppressive tumor microenvironment.[13] Because most of the tumor antigens identified are nonmutated self-antigens, a high degree of immunologic tolerance exists,

limiting the generation of immune effectors. As noted, Treg cells engaged in the maintenance of self-tolerance may impede tumor-reactive T cells. Tumors are heterogeneous, and the repertoire of tumor antigens on the cells of one tumor may be variable, even within the same patient. Downregulation of MHC class I molecules and other components of the antigen-presentation process can occur. Membrane-associated factors expressed by tumor cells that directly inhibit T-cell function have also been identified, and tumors can exploit inhibitory immune checkpoints as evasion mechanisms. Tumor expression of PD-L1 and PD-L2, ligands of the coinhibitory receptor PD-1, is considered to be a significant mediator of immunosuppression within the tumor microenvironment. However, a large part of the role played by PD-1–expressing T cells may be to secrete interferon-gamma (IFNγ) upon initial T-cell activation, and this in turn upregulates PD-L1 on tumor cells, conferring on the tumor and T cell interaction a dependence on this ligand-receptor association that can be therapeutically targeted by antibodies. The expression of Fas ligand by some tumor cells may help to maintain a state of immune privilege by inducing apoptosis of Fas-sensitive T and NK effector cells—the “Fas counterattack”. There is also evidence that a tumor's expression of antiapoptotic molecules, which prevent perforin or death receptor dependent cytotoxicity, can result in escape despite expression of the target antigen. In addition, tumor-associated factors, such as underglycosylated tumor-associated mucins, have been shown to reduce binding of antibodies to tumor cell surfaces.

Table 4-1 **Potential Immunotherapy Targets**		
Antitumor Antigens	**Example**	**Associated Malignancies**
Oncofetal	CEA	Colorectal, breast, non-small cell lung
	Beta-human chorionic gonadotropin (hCG)	Colorectal, pancreatic, non-small cell lung
Cancer-testis	MAGE	Melanoma, lung, ovary, bladder, liver
	NY-ESO	Melanoma, lung, bladder, liver
Oncogene/ tumor suppressor	*HER2*	Breast, gastric
	p53	Multiple
	RAS	Multiple
	WT1	Multiple
	BCR-ABL	Chronic myeloid leukemia
Differentiation/ lineage-specific	Prostate-specific antigen (PSA)	Prostate
	Prostatic acid phosphatase	Prostate
	gp100	Melanoma
	Tyrosinase	Melanoma
	MART/Melan-A	Melanoma
	Ig (idiotype)	B-cell malignancies
Aberrantly glycosylated molecules	MUC1 (mucin)	Pancreatic, breast
	GM2 (ganglioside)	Melanoma, neuroblastoma
	GD2 (ganglioside)	Melanoma, neuroblastoma
Viral	E6, E7 (HPV)	Cervical cancer
	EBNA (Epstein-Barr virus)	Burkitt lymphoma, nasopharyngeal carcinoma

Tumor cells and the surrounding stroma may release a number of suppressive cytokines and other soluble factors, such as prostaglandin E_2, that are not conducive to antitumor immunity. Cancer-associated factors have been shown to inhibit the production and stimulatory capacity of dendritic cells.[14] The T-helper cell response also may be skewed toward a Th2 phenotype, which inhibits Th1 response and the cellular immunity that is critical in mediating tumor rejection.[15] TGF-beta is produced not only by host cells but also by tumors and can inhibit the differentiation of T cells into CTLs and T-helper cells and promote the generation of Treg cells. By producing cytokines (e.g., GM-CSF), cancers can promote the infiltration of M2-polarized macrophages and MDSCs that can inhibit T-cell function. Downregulation of the CD3 zeta-chain of the TCR complex and impairment of function have been shown for T cells isolated from patients with cancer.[16]

KEY POINTS

- The ability of cancer to evade the immune response is aided by the fact that most tumor antigens are self-proteins, which impede the generation of immunity via tolerogenic mechanisms, such as the elaboration of Treg cells and the central elimination of autoreactive T cells by thymic selection.
- While immune checkpoints are a necessary function to prevent unchecked autoimmunity, tumors can co-opt these mechanisms to escape immune responses.
- Cancer evasion of the immune system results not only from immunosuppressive factors secreted by or expressed on the tumor, but also from the ability of the tumor to modulate antigen expression and to be endowed with or later evolve mechanisms of resistance to immune effectors.
- The recognition of evasion mechanisms involved in tumor immune escape can be exploited therapeutically.

IMMUNE SUBVERSION

Although effective antitumor immunity has been demonstrated in experimental systems and in patients, immune responses are abundantly present in tumor-bearing hosts that provide no apparent protection to the host and may contribute to the oncogenic process. Not only can tumors escape immune response, but they can also exploit or subvert the immune response to promote their growth, invasion, and metastasis. Local tumor growth within the stroma is promoted by angiogenesis. Immune cells, including macrophages, T cells, and neutrophils, fully participate in tumor angiogenesis by secreting cytokines, such as IL-1, IL-8, and VEGF, that directly affect endothelial cell functions including endothelial cell proliferation, migration, and activation. In addition to angiogenic factors, macrophages also produce matrix metalloproteinases that degrade the extracellular matrix involved in tumor cell invasion and metastasis. Accumulating data show that many tumor cells express chemokine receptors and respond to chemokine gradients in vitro. Experiments in vivo also have indicated that certain chemokines can serve as tissue-specific attractant molecules for tumor cells, promoting tumor cell migration/metastasis to particular sites. Several cytokines produced by immune cells have been shown to transmit cell growth signals in tumor cells and directly promote tumor cell growth. TGF-beta, TNF-alpha, and IL-6 are able to promote the growth of some tumors while suppressing the growth of others.

KEY POINTS

- The interaction between tumor cells and immune cells is not unidirectional.
- Tumors can subvert the immune response by stimulating the production of immune cell factors that promote angiogenesis, invasion, and metastases.
- Immune cell cytokines also may function as tumor growth factors.

BIOLOGIC AGENTS

Many cytokines, monoclonal antibodies, and cell therapies for cancer have been developed and are applied clinically, acting through either immune or nonimmune effector pathways.

The immune response can be activated to mediate tumor destruction through one of several mechanisms. These include increasing immune effectors and modifying tumor cells to increase their susceptibility to immune effectors. A highly effective strategy is to block one or more of the negative immunoregulatory host checkpoints involved in evasion mechanisms. The elimination of cells or cytokines that promote immune escape may permit a more effective and persistent antitumor immune response. This approach cannot be effective unless there is a simultaneous positive immune response to the tumor. This may occur naturally, as is observed among select patients (e.g., patients with malignant melanoma with regressed primary lesions). Alternatively, it may have to be induced (e.g., by a cancer vaccine).

There are two general immunotherapy approaches. “Active” immunotherapy attempts to stimulate (in vivo) an intrinsic immune response to the tumor, either nonspecifically with cytokines or specifically with antibody or vaccine approaches. “Passive” or “adoptive” immunotherapy involves the preparation of antibodies and cells outside the body (ex vivo) followed by administration to patients.

Biologic agents can also be used to mediate antitumor effects by nonimmune effector mechanisms. Some biologics are administered not to promote antitumor responses but rather to ameliorate the side effects of therapy and progressing cancer. These include hematopoietic growth factors. They also include cytokines that are produced by nonimmune cells and that do not directly activate antitumor immune effector mechanisms. For example, human recombinant erythropoietin is used to manage anemia.[17] The human recombinant keratinocyte growth factor palifermin is used to decrease the risk of severe mucositis associated with very high-dose chemoradiotherapy such as in hematopoietic stem cell transplantation. Denosumab is a fully human monoclonal antibody that targets receptor activator of nuclear factor kappa B (RANK) ligand, a protein that acts as the primary signal to promote bone removal by osteoclasts. It is used for the prevention of skeletal-related events for patients with bone metastases and myeloma as well as in the management of giant cell tumor of bone.[18,19]

The pharmacokinetics of biologic agents are quite variable. Elimination half-lives for most cytokines are measured in minutes to hours and, for most antibodies, in days to weeks. Infused cells can persist for months. Unlike chemotherapy, which acts directly on the tumor, cancer immunotherapies exert their effects on the immune system and demonstrate kinetics that involve generating an antitumor immune response. The approach to assessing and managing response and toxicity can also differ. Immunotherapy may induce patterns of antitumor response not adequately assessed by Response Evaluation Criteria in Solid Tumors (RECIST) or World Health Organization (WHO) criteria. Patients may have a transient worsening of disease before the tumor regresses. Responses can take appreciably longer to become apparent as compared with those for cytotoxic or targeted therapy. Continued disease regression is frequently observed well after immunotherapy is suspended. Furthermore, some patients who do not meet criteria for objective response can have prolonged periods of stable disease that are clinically relevant. New immune-related response criteria designed to more comprehensively capture all response patterns are under investigation.[20] As the goal of many approaches is to break immune tolerance by the removal of negative immunoregulatory mechanisms, evidence of autoimmunity as a side effect of treatment is predicted and has been associated with clinical benefit in some, but not all, studies.

KEY POINTS

- Biologic agents may elicit an antitumor effect through either immune mechanisms or nonimmune pathways.
- Immunotherapies may stimulate components of an existing tumor-immune interaction ("active immunotherapies"; e.g. cytokines, antibodies targeting immune checkpoints) or harness cells or antibodies engineered ex vivo ("passive immunotherapies"; e.g., adoptive cell therapies).

CYTOKINES

Cytokines are a diverse group of small proteins released by immune and nonimmune cells distributed throughout the body. Cytokines play integral roles in innate and adaptive immunity as effector and regulatory molecules. They also play an integral role in a variety of other biologic processes. Cytokines, which are active physiologically at very low concentrations, may act locally (autocrine or paracrine) or at a distance (endocrine). They are characterized by pleiotropy (one cytokine, multiple effects), redundancy (multiple cytokines, one effect), and synergy (the sum of the response together is greater than the sum of the individual responses). The administration of a cytokine will initiate a cascade of cytokine production and both stimulatory (amplification) and inhibitory/antagonistic effects. Cytokines act on their target cells by binding specific membrane receptors that contain cytokine-specific and signal-transducing subunits. They can be divided into groups based on function (e.g., chemokines are cytokines that are chemoattractants to immune cells) or on cellular source (e.g., lymphokines are cytokines produced by lymphocytes). Study of the structure and function of cytokine receptors, however, has led to improved understanding of cytokine action and a more useful classification (Table 4-2). Cytokines can lead to tumor destruction by one of two general mechanisms. They can function indirectly and enhance the activity of antitumor cellular or humoral immune effector mechanisms, or they can interact directly with tumor cells; cytokines, such as TNF-α, interferon-α, interferon-gamma, IL-4, and IL-6, have been shown to initiate tumor cell apoptosis or cell cycle arrest. Recombinant cytokines in clinical use are shown in Table 4-3.

Table 4-2 **Examples of Cytokines Involved in Immune Regulation**

Group	Function	Receptor	Examples
Hematopoietic	Leukocyte proliferation, differentiation, and activation	▪ Multimers with Trp-Ser-X-Trp-Ser motif ▪ Signals primarily by receptor-associated JAK and STAT	IL-2, IL-3, IL-4, IL-6, IL-7, IL-11, IL-12, G-CSF, GM-CSF
Interferon	Inhibit virus replication	▪ Two polypeptide chains with tandem fibronectin domains ▪ Signals primarily by JAK-STAT	Interferon-alpha, interferon-beta, interferon-gamma
TNF	Inflammation and other biologic processes	Four extracellular domains activate caspases that mediate apoptosis ("death receptor") or pathways that promote cell survival and inflammation	TNF-α
Chemokine	Attract leukocytes to inflammatory sites	Seven transmembrane helices interact with G proteins	MIP-1α, IL-8
IL-1	Inflammation and hematopoiesis	▪ Extracellular Ig domain and cytosolic toll-IL-1 receptor (TIR) domain ▪ TIR activates signaling pathways	IL-1β
Growth factor	Growth and differentiation of nonimmune cells	Multimeric complexes with intrinsic tyrosine or serine/threonine kinase activities	TGF-β, VEGF

Abbreviations: G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukin; JAK, Janus tyrosine kinase; MIP-1α, macrophage inflammatory protein 1α; STAT, signal transducer and activator of transcription; TGF-β, transforming growth factor β; TNF-α, tumor necrosis factor α; VEGF, vascular endothelial growth factor.

INTERFERONS AND INTERLEUKIN-2

Interferons-alpha and beta (referred to as type I interferons), produced by many cell types, and interferon-gamma (referred to as type II interferon), synthesized primarily by lymphocytes, mediate a wide variety of biologic effects, including inducing the transcription of a diversity of genes, and affect nearly all phases of the innate and adaptive immune responses. Interferons, type I in particular, inhibit virus replication in infected cells. All enhance class I MHC and thereby promote CD8+ CTL responses; interferon-gamma is capable of inducing class II MHC. Interferons enhance NK cell cytotoxicity, upregulate Fc receptors, and promote ADCC mechanisms. They regulate the balance between Th1 and Th2 cells, promoting, for the most part, Th1 responses. In addition to affecting humoral immunity by modulating T-helper cells, interferons can have direct effects on B cells, including regulating proliferation and Ig production. Interferon-gamma also plays an important role in macrophage activation.[21] Interferons can directly inhibit the growth of tumor (and normal) cells and produce antiangiogenic effects.

Among the more than 20 different known interferons, only interferon-alpha 2 has been extensively and clinically evaluated for cancer. Two recombinant interferon-alpha 2 preparations have been approved: interferon-alpha 2a and interferon-alpha 2b. The pleiotropic effects of interferons have led to their evaluation in almost all malignancies, alone or in combinations.[22] However, for the most part, the use of interferon in cancers has been supplanted by more active and potentially less toxic drugs. Toxicities, which are highly diverse, include flu-like symptoms, such as fever, chills, and myalgia, neuropsychiatric side effects (fatigue and depression), liver dysfunction and myelotoxicity. Novel applications of interferons are being tested in both solid tumors and hematologic malignancies, and there is growing interest in the

possibility of combining interferon with antibodies against immune checkpoints.

Table 4-3 Recombinant Cytokines in Clinical Use for Cancer

Cytokine	Effects	Cancer Indications
Interferon-α; PEG-interferon alpha	▪ Immune (upregulate MHC, activate NK cells) ▪ Antiangiogenesis ▪ Direct antiproliferative	Melanoma, hairy cell leukemia, chronic myeloid leukemia, follicular lymphoma, Kaposi sarcoma, renal cell carcinoma
Aldesleukin (IL-2)	Activate cytotoxic T lymphocytes and NK cells	Melanoma, renal cell carcinoma
Sargramostim (GM-CSF)	Stimulates the development and function of neutrophils, monocyte–macrophages, and dendritic cells	Shortens chemotherapy-induced neutropenia in elderly patients with acute myeloid leukemia, promotes myeloid reconstitution after HSCT, mobilizes stem cells
Filgrastim (G-CSF) Pegfilgrastim (G-CSF)	Stimulates the development and function of neutrophils	Shortens chemotherapy-induced neutropenia, promotes myeloid reconstitution after HSCT, mobilizes stem cells

Abbreviations: G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; HSCT, hematopoietic stem cell transplantation; MHC, major histocompatibility complex; NK, natural killer; PEG, pegylated.

IL-2 is a T-cell growth factor. Antigen binding to the TCR stimulates the secretion of IL-2 and the expression of high-affinity IL-2 receptors (CD25). The interaction between IL-2 and the IL-2 receptor stimulates the growth, differentiation, and survival of antigen-selected T cells. IL-2 is a major activator of CTL and NK cytotoxicity, and is necessary for the development of memory T cells. It also indirectly regulates B cells and hematopoiesis and the generation and maintenance of Treg cells, which, as noted, has been implicated in abrogating antitumor activity.[23] Furthermore, IL-2 is involved in activation-induced cell death, a process that leads to the elimination of self-reactive T cells.

Recombinant IL-2, aldesleukin, has been applied in a variety of doses, routes, and schedules.[24-26] Aldesleukin was approved as treatment for patients with metastatic renal cell cancer and melanoma on the basis of experience with the high-dose regimens. Objective responses occur in a minority of patients, approximately 15%, at a cost of significant toxicity. However, in approximately 5% of all treated patients, the response is complete and often of prolonged duration.[24] High-dose IL-2 is also used to support the persistence and activity of tumor-infiltrating lymphocyte (TIL) therapies for melanoma and other malignancies. Administration of aldesleukin requires particular expertise, and patients must be treated in an inpatient monitored or intensive care unit setting, as the use high doses is comparable to inducing a controlled state of septic shock with fever, hypotension, decreased renal function, hyperbilirubinemia, rash, and marked malaise.

KEY POINTS

- Cytokines can function indirectly and can enhance the activity of antitumor immune effectors.
- Cytokines, such as the interferons, also have been shown to directly inhibit tumor cell growth.
- IL-2 was approved and is occasionally used for metastatic renal cell cancer and melanoma on the basis of the experience with a high-dose IV bolus of the agent, a

regimen limited by toxicity and very low antitumor activity.

ANTIBODIES

Adoptive therapy with monoclonal antibodies, which can mediate antitumor activities by a variety of mechanisms (Fig. 4-2), has been one of the major advances in cancer immunotherapy. Most of the approved antibodies in oncology are of the human IgG1 subclass, the subclass that is the most effective at engaging Fc receptors on NK cells and macrophages and mediating CMC and ADCC. Antibody constructs designed not to mediate CMC and ADCC have also been developed, as have antibody-based constructs that target more than one epitope. The monoclonal antibodies used in initial clinical trials were mouse-derived and usually generated a vigorous human–antimouse antibody (HAMA) response. Therapeutic monoclonal antibodies come in the following forms:

- chimeric (i.e.,mouse variable chain fused to a human constant chain, termed “ximab,” and are 65 to 90% human);
- humanized (i.e., mouse hypervariable/complementarity-determining regions grafted to human Ig, termed “zumab,” and are 95% human);
- fully human (termed “umab”).

Most antibodies naturally have long serum half-lives. Limitations, however, have been identified. Triggering of tumor antigen-specific cellular immunity by monoclonal antibody, in conjunction with immune escape mechanisms used by tumor cells, may contribute to differential clinical responses to monoclonal antibody-based immunotherapy.[27] The antigenic heterogeneity of most tumors presents challenges, as do the small fraction of injected antibodies that actually bind to tumors, because of the occasional inability of antibodies to penetrate into large tumor masses. Furthermore, binding of antibodies to circulating antigens also can limit delivery to the tumor. Although now rare, immune responses to artificial humanized antibodies can still be problematic, causing hypersensitivity reactions or neutralization of the antibody. Whether they target tumor cell membrane determinants, factors involved in tumor progression such as angiogenesis, or immune checkpoints, monoclonal antibodies are mainstays of cancer therapy (Table 4-4).

IMMUNE CHECKPOINT ANTIBODIES

Monoclonal antibodies against immune checkpoints resulted in an initial paradigm shift in the management of melanoma and non-small cell lung cancer; more recently, approvals have expanded the clinical application of immune checkpoint antibodies to the treatment of patients with squamous cell carcinoma of the head and neck, clear-cell renal cell carcinoma, Hodgkin lymphoma, and urothelial carcinoma, with additional approvals likely.

Increased activation of the immune system and significant (and occasionally, sustained) antitumor effect has been demonstrated in randomized trials investigating the efficacy of monoclonal antibodies targeting CTLA-4, PD-1, and PD-L1. Conceptually, the mechanisms of these immune checkpoints are not redundant: CTLA-4, a CD28 homolog, is induced by exocytosis upon initial activation of naive T cells, primarily in nodal structures. The PD-1–PD-L1 pathway, however, is implicated in tolerance and evasion mechanisms that involve previously activated T cells with cytotoxic capabilities, acting predominantly but not exclusively in the

effector phase within the tumor microenvironment in peripheral tissues. Nevertheless, the complete spectrum of activity of these immune checkpoint inhibitors is not understood. As an example, the efficacy of CTLA-4 blockade has been associated with the elimination—via ADCC mediated by the anti-CTLA4 antibody—of Tregs with immunosuppressive effects.[28]

Table 4-4 Unconjugated Monoclonal Antibodies in Clinical Use for Cancer

Antibody	Type	Target	Indication
Immune Checkpoint			
Ipilimumab	Human	• Blocks CTLA-4	Melanoma
Pembrolizumab	Human	• Blocks PD-1	Melanoma, squamous cell carcinoma of the head and neck, non-small cell lung cancer, Hodgkin lymphoma, urothelial carcinoma, MMR-deficient solid tumors
Nivolumab	Human	• Blocks PD-1	Melanoma, non-small cell lung cancer, renal cell carcinoma, Hodgkin lymphoma, squamous cell carcinoma of the head and neck, urothelial carcinoma, MMR-deficient advanced colorectal cancer
Atezolizumab	Humanized	• Blocks PD-L1	Non-small cell lung cancer, urothelial carcinoma
Avelumab	Human	• Blocks PD-L1	Merkel cell carcinoma, urothelial carcinoma
Durvalumab	Human	• Blocks PD-L1	Urothelial carcinoma
Antitumor Antibodies			
Rituximab	Chimeric	• Binds CD20 • CMC/ADCC • Direct antiproliferative	Follicular lymphoma, diffuse large B-cell lymphoma, chronic lymphocytic leukemia
Ofatumumab	Human	• Binds CD20 • CMC/ADCC • Direct antiproliferative	Chronic lymphocytic leukemia
Obinutuzumab	Humanized	• Binds CD20 • Mediates antibody-dependent cellular mechanisms • Direct antiproliferative	Chronic lymphocytic leukemia, follicular lymphoma
Alemtuzumab	Humanized	• Binds CD52 • CMC/ADCC	Chronic lymphocytic leukemia
Daratumumab	Human	• Binds CD38 • CMC/ADCC	Multiple myeloma
Elotuzumab	Humanized	• Targets SLAMF7 • Immunostimulatory effect	Multiple myeloma
Anti-epidermal Growth Factor Family			
Trastuzumab	Humanized	• Binds HER2 • CMC/ADCC • Direct antiproliferative • Antiangiogenesis	Breast cancer, gastroesophageal cancer, gastric cancer
Pertuzumab	Humanized	• Binds HER2 and blocks ligand-dependent heterodimerization of HER2 with other HER family members, including EGFR, HER3, and HER4 • Direct antiproliferative effects • CMC/ADCC • Antiangiogenesis	Breast cancer
Cetuximab	Chimeric	• Binds EGFR • CMC/ADCC • Direct antiproliferative • Antiangiogenesis	Colorectal cancer, head and neck cancer
Panitumumab	Human	• Binds EGFR • CMC/ADCC • Direct antiproliferative • Antiangiogenesis	Colorectal cancer
Necitumumab	Human	• Binds EGFR • Direct antiproliferative • Antiangiogenesis	Squamous non-small cell lung cancer
Antiplatelet-Derived Growth Factor			
Olaratumab	Human	• Binds PDGFR • Direct antiproliferative	Soft-tissue sarcomas
Angiogenic Factor			
Bevacizumab	Humanized	• Binds VEGF • Antiangiogenesis	Colorectal cancer, nonsquamous non-small cell lung cancer, renal cell carcinoma, glioblastoma, ovarian cancer, cervical cancer
Ramucirumab	Human	• Binds VEGF receptor 2 • Antiangiogenesis	Gastric or gastroesophageal junction adenocarcinoma, colorectal cancer, non-small cell lung cancer

Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; CMC, complement-mediated cytotoxicity; CTLA-4, cytotoxic T-lymphocyte antigen 4; EGFR, epidermal growth factor receptor; MMR, mismatch repair; VEGF, vascular endothelial growth factor; PD-1, programmed death 1; PDGFR, platelet-derived growth factor; PDL-1, programmed death ligand 1.

Despite the unequivocal efficacy, toxicity from immune checkpoint inhibitors can be problematic and results from activation of the immune cells against “self” antigens. These immune-related adverse events (irAEs), include dermatitis, pruritus, colitis/diarrhea, hepatitis, pneumonitis, and endocrinopathies (thyroiditis, hypophysitis, adrenalitis, etc.), among others.[110] Virtually any organ or tissue can be targeted by activated immune cells, and cases of Guillain–Barré syndrome, nephritis, pure red cell aplasia, and myocarditis have been reported. Because

of the potentially serious and life-threatening implications of irAEs, including colonic perforation, Stevens–Johnson syndrome, and myocarditis, active surveillance, and continuous monitoring is advised, and risk evaluation and mitigation strategies and algorithms for the management of adverse side effects have been developed. In general, toxicities are more pronounced with ipilimumab in comparison to monoclonal antibodies targeting PD-1/PD-L1 when used as single agents, particularly colitis/diarrhea, fatigue, rash, and hepatitis. Doses are generally withheld for any moderate irAE or for symptomatic endocrinopathy. The management of symptomatic or severe irAEs usually involves the use of systemic corticosteroids (prednisone, methylprednisolone, or equivalent) and, for patients with irAEs that fail to resolve with steroids, additional immunosuppressive agents (e.g., infliximab [anti-TNF], mycophenolate mofetil [an inhibitor of purine synthesis]). Permanent treatment discontinuation must be considered in situations of a persistent grade 2 or grade 3 irAE and is usually recommended in the setting of a grade 4 irAE. It is important to highlight that the appropriate management of immune-related side effects with immunosuppressive agents, such as corticosteroids, does not appear to impair an established antitumor response, but steroid therapy prior to beginning immune checkpoint blockade is not advised.

The particularities involved in the clinical use of corticosteroids extend beyond the plethora of adverse events. The unique mechanisms of action of immune checkpoint inhibitors makes the assessment of response by conventional criteria difficult, and aberrant patterns of response have been documented. Patients receiving either anti-CTLA-4 or anti-PD-1/PD-L1 agents may experience delayed responses or durable stable disease even after apparent disease progression. Although the immune-related response criteria (irAE) have been proposed, the applicability and, more importantly, interpretation in clinical practice remain challenging. [20] As a general principle, although infrequent, the possibilities of early or delayed pseudoprogression (i.e., initial enlargement of target lesions and/or appearance of new lesions, followed by subsequent response) must be considered, and treatment beyond the first documented progression may be acceptable in select situations, particularly in the setting of clinical stability or symptomatic improvement.

Ipilimumab

Ipilimumab, the first immune checkpoint inhibitor approved by the FDA, blocks the effects of the negative T-cell regulator CTLA-4 (Fig. 4-1), which then, in turn, augments T-cell responses to tumor cells. It was the first drug shown to improve overall survival in metastatic melanoma in randomized clinical trials in both pretreated (as monotherapy) and treatment-naive (in combination with dacarbazine) patients.[29,30] Objective response rates have been low, on the order of 10 to 15%; nevertheless, long-lasting responses have been demonstrated: in a combined analysis of more than 1800 patients treated with ipilimumab in phase 2 and phase 3 trials, long-term overall survival rates of approximately 20% were demonstrated, with an apparent plateau in the survival curves beyond 3 years.[31] Ipilimumab is FDA-approved for the treatment of melanoma, not only in the metastatic setting but also in the adjuvant setting, where it has been shown to improve relapse-free and overall survival.[32]

Ipilimumab is administered intravenously over 90 minutes every 3 weeks for 4 doses, with additional maintenance doses every 12 weeks for up to 3 years when used in the adjuvant setting. Nevertheless, the optimal dose recommended for patients with advanced disease remains debatable, in view of a randomized trial that demonstrated an improvement in overall survival with a higher dose (10 mg/kg) in comparison to the standard, FDA-approved dose (3

mg/kg).[33] The higher dose was accompanied by an increase in treatment-related adverse events, including grade 3 to 5 adverse events (34.3% vs. 18.5%), and its acceptability for treating metastatic disease remains uncertain.

Ipilimumab has also shown preliminary activity for patients with non-small cell lung, renal cell, and castrate-resistant prostate cancers, but has not been approved for these indications. In addition, the combination of ipilimumab and nivolumab is approved to treat patients with melanoma and is discussed in more detail in the following section.[34,35] Combinations with other immune modulators are also being tested, as are combinations with targeted, cytotoxic, and radiation therapies, to potentially improve the efficacy of therapy.[36]

Pembrolizumab

Pembrolizumab is an IgG4 kappa isotype monoclonal antibody against PD-1 which blocks this major immune checkpoint. Pembrolizumab is approved for the treatment of metastatic melanoma, squamous cell carcinoma of the head and neck, and refractory non-small cell lung cancer. It is also indicated for the treatment in the first-line setting of patients with metastatic non-small cell lung cancer whose tumors express PD-L1 on at least 50% of tumor cells and no sensitizing mutation of the *EGFR* gene or translocation of the anaplastic lymphoma kinase (*ALK*) gene.

Pembrolizumab produced a response rate of 33% among patients with advanced melanoma in a large phase I trial that randomly assigned 655 patients with various prior therapies to a variety of doses and schedules.[37] In a randomized trial, pembrolizumab resulted in improved response rates and 6-month progression-free survival when compared to chemotherapy in ipilimumab-refractory cases[38]; pembrolizumab, administered on two different schedules, also demonstrated significant improvement in 2-year overall survival rates and progression-free survival rates at 6 months when compared to ipilimumab, with a more favorable toxicity profile.[39]

Analyses performed in tumor samples of patients treated in the phase I trial of pembrolizumab studied PD-L1 expression in the tumor as a predictive marker for responsiveness in patients with melanoma.[40] Although these studies suggested that PD-L1 positivity correlated with increased responsiveness, absence of PD-L1 expression did not preclude a clinical response. Pembrolizumab should therefore be considered for patients with melanoma regardless of their PD-L1 status.

In non-small cell lung cancer, the superiority in terms of overall survival of pembrolizumab over docetaxel in previously treated patients with PD-L1–positive tumors was demonstrated in a randomized, phase 3 trial.[41] In addition, pembrolizumab was associated with significantly longer progression-free survival and overall survival and fewer adverse events (grade 3, 4, or 5 treatment-related adverse events, 26.5% vs. 53.3%) in comparison to platinum-based chemotherapy in treatment-naive patients with advanced non-small cell lung cancer and PD-L1 expression on at least 50% of tumor cells.[42] Also in the first-line setting for patients with nonsquamous, non-small cell lung cancer and with no *EGFR* or *ALK* genomic tumor aberrations, pembrolizumab used in combination with carboplatin and pemetrexed resulted in an objective response rate of 55%, compared to 29% with chemotherapy alone, and improved progression-free survival in a randomized, phase 2 study, with a similar incidence of grade 3 or worse treatment-related adverse events.[43]

Although phase III trials are ongoing, pembrolizumab was also approved for patients with recurrent or metastatic head and neck squamous cell carcinoma who have had progression

after platinum-based chemotherapy based on results of a phase Ib trial.[44] Among 60 patients with PD-L1–positive tumors (expression of at least 1% of tumor cells or stroma), objective responses occurred in 8 of 45 evaluable cases (18%); the median duration of response was not reached.[44]

Pronounced activity leading to FDA approval was also documented in classic Hodgkin lymphoma,[45] urothelial carcinoma refractory to platinum-based chemotherapy,[46] and solid tumors with microsatellite instability–high (MSI-H) or mismatch-repair deficiency (dMMR). Of note, the biomarker-directed use of pembrolizumab for this latter subgroup of patients is supported by the results of at least five single-arm clinical trials that showed an objective response rate of 39.6% among almost 150 patients with MSI-H or dMMR, including those accrued in the pilot trial by Le and colleagues published in 2015.[47]

Pembrolizumab is administered intravenously over 30 minutes every 3 weeks until disease progression or unacceptable toxicity occurs. Its half-life is approximately 26 days. Treatment toxicity has been minimal. The most common toxicities are fatigue, pruritus, rash, diarrhea, and arthralgia. Approximately 10 to 25% of patients experienced grade 3 or 4 toxicity, with significant variability among different indications and trials. Pembrolizumab is being studied in phase III trials as adjuvant therapy after complete resection of high-risk melanoma and in other cancers.

Nivolumab

Nivolumab is a fully human IgG4 PD-1 immune checkpoint inhibitor antibody that selectively blocks the interaction of the PD-1 receptor with its two known programmed death ligands, PD-L1 and PD-L2. In a phase I study, nivolumab was associated with promising antitumor activity and a favorable safety profile for patients with several solid tumors, including advanced melanoma.[48] Nivolumab is approved to treat metastatic melanoma, alone and in combination with ipilimumab. As a single agent, nivolumab is approved in non-small cell lung cancer, renal cell carcinoma, classic Hodgkin lymphoma, and squamous cell carcinoma of the head and neck.

Randomized trials involving patients with ipilimumab-refractory melanoma demonstrated a higher rate of objective responses from nivolumab when compared to chemotherapy.[49] Nivolumab also improved overall survival when compared to dacarbazine among untreated patients with melanoma who did not have a *BRAF* mutation.[50] Nivolumab has been approved for use in combination with ipilimumab, as discussed in other sections. This combination is associated with greater toxicity than either ipilimumab or nivolumab alone.

Nivolumab was approved for patients with advanced squamous cell non-small cell lung cancer whose disease has progressed on or after platinum-based chemotherapy, irrespectively of PD-L1 expression, based on a randomized trial that demonstrated improved overall survival and a nearly doubled 12-month overall survival rate (42% vs. 24%) compared to docetaxel.[51] Nivolumab also has been shown to improve survival over docetaxel in advanced nonsquamous non-small cell lung cancer.[52] In both trials, the use of nivolumab was associated with a favorable toxicity profile when compared to standard chemotherapy.

In November 2015, the FDA approved nivolumab to treat patients with advanced/metastatic renal cell carcinoma. The safety and efficacy of nivolumab were demonstrated in a randomized, phase 3 study that compared nivolumab to everolimus in 821 patients with advanced clear cell renal cell carcinoma whose disease progressed on prior antiangiogenic therapy.[53] Both overall survival and objective response rate (25% vs. 5%; odds ratio, 5.98; 95% CI; 3.68, 9.72; $p < 0.001$) were improved.

Nivolumab has also been approved for recurrent or metastatic SCCHN based on overall survival improvements demonstrated in a randomized, phase 3 trial.[54] In addition to prolonged overall survival and a higher 1-year survival rate (36% vs. 16.6%), nivolumab resulted in a lower incidence of treatment-related grade 3 or 4 adverse events (13.1% vs. 35.1%) when compared to standard-therapy (methotrexate, docetaxel, or cetuximab) in patients whose disease had progressed within 6 months after platinum-based chemotherapy.[54]

Nivolumab was the first immune checkpoint inhibitor to be incorporated into the management of hematologic malignancies. The approval for the treatment of patients with classic Hodgkin lymphoma that has relapsed or progressed after autologous hematopoietic stem cell transplantation and brentuximab vedotin was based on single-arm, multicenter trials that demonstrated response rates of 66 to 87%.[55,56]

Subsequently, the indications of nivolumab have been expanded to other solid tumors. In metastatic urothelial carcinoma following platinum-based therapy, objective responses occurred in 52 of 265 patients (objective response rate, 19.6%), including 23 of 81 patients (28.4%) with a PD-L1 expression of at least 5% and a median duration of response not yet reached.[57] The most recent approval was for patients with metastatic colorectal cancer and DNA mismatch repair–deficient tumors or tumors harboring microsatellite instability. In a phase 2 study that accrued 74 pretreated individuals with the previously described characteristics, nivolumab resulted in an objective response rate of 31.1%, with 51 of 74 (64%) achieving disease control for 12 weeks or longer.[58]

Nivolumab is administered intravenously over 60 minutes every 2 weeks until disease progression or unacceptable toxicity occurs; the FDA modified the dosage regimens for the currently approved indications to a flat dose of 240 mg IV, and a new regimen of 480 mg administered every 4 weeks is under evaluation. Nivolumab's half-life is approximately 27 days. The spectrum of toxicity of nivolumab is comparable to that of pembrolizumab. Again, irAEs are less frequent than with ipilimumab; the most serious of these include pneumonitis, colitis, hepatitis, nephritis and renal dysfunction, and thyroid dysfunction.

Nivolumab is being studied in phase III trials as adjuvant therapy after complete resection of high-risk melanoma. It is anticipated that additional approvals will be forthcoming for several cancers.

Atezolizumab

Atezolizumab is a humanized monoclonal antibody that blocks the PD-L1 protein on tumor cells, disrupting the PD-1–PD-L1 checkpoint pathway. Atezolizumab is currently approved for the treatment of patients with non-small cell lung cancer that has progressed after platinum-based chemotherapy (and targeted therapy against *EGFR* or *ALK* genomic aberrations, in patients with tumors harboring these target mutations), as well as for advanced bladder cancer.

This anti-PD-L1 agent was initially approved for the treatment of patients with urothelial carcinoma previously treated with a platinum-containing regimen. In a single-arm, phase 2 trial, atezolizumab produced objective responses in 15% of the cases in a preliminary analysis, reaching 26% with longer follow-up.[59] Of note, grade 3 or 4 treatment-related adverse events occurred in 16% of the patients, with fatigue being the most common. Atezolizumab was also investigated as first-line treatment for patients with advanced urothelial carcinoma that is ineligible for platinum-based therapies, resulting in durable response rates, good tolerability, and a median overall survival of 15.9 months.[60]

Following a breakthrough therapy designation by the FDA based on preliminary results, a

randomized, phase III trial confirmed the superiority of atezolizumab when compared to docetaxel in patients with previously treated non-small cell lung cancer.[61] Among patients with both squamous and nonsquamous lung cancer, atezolizumab resulted in prolonged overall survival and fewer grade 3 or 4 adverse events regardless of PD-L1 expression or histology.

Avelumab

Avelumab is a fully human anti–PD-L1 IgG1 antibody. In 2017, avelumab was granted accelerated approval by the FDA and became the first systemic therapy approved for the treatment of patients with advanced Merkel cell carcinoma (MCC). This agent was evaluated in an open-label, single-arm, phase 2 study that included 88 patients with advanced MCC refractory to cytotoxic chemotherapy.[62] Among 28 patients with objective responses, resulting in an objective response rate of 31.8%, there were 8 complete responses. The proportion of responses with a duration of at least 6 months was 92%, with a median duration of response not reached. Of note, only five grade 3 treatment-related adverse events were reported (5%) and there were no grade 4 adverse events or treatment-related deaths.[62] Avelumab has also been approved for the treatment of patients with advanced urothelial carcinoma who progressed on a platinum-based therapy.[63]

The recommended dose of avelumab is 10 mg/kg administered intravenously over 60 minutes every 2 weeks, and patients should be premedicated with acetaminophen and an antihistamine for the first four infusions and subsequently as needed because of the risk of infusion-related reactions, which can manifest in up to 25% of the patients.

Durvalumab

The fully human, anti–PD-L1 human monoclonal antibody durvalumab received accelerated FDA approval for the treatment of patients chemotherapy-refractory disease with advanced urothelial carcinoma. In the preliminary publication of the phase I/II multicenter, open label trial that subsequently supported the approval, 61 patients with advanced bladder cancer were treated with durvalumab; the incidence of grade 3 treatment-related adverse events was 4.9%, and there were no grade 4 or 5 toxicities. The objective response rate was 31% in the entire evaluable study population, and 46.4% among those with PD-L1 expression of at least 25% in tumor cells or tumor-infiltrating immune cells by immunohistochemistry.[64] The recommended dose of durvalumab is 10 mg/kg administered intravenously over 60 minutes every 2 weeks, without premedication.

Combinations of Immune Checkpoint Inhibitors

The combination of ipilimumab and nivolumab is also approved for clinical use in patients with advanced melanoma. In two randomized trials, the combination demonstrated superior response rates and progression-free survival in comparison to ipilimumab.[34,35] Exploratory analysis also demonstrated that patients whose tumors expressed low PD-L1 levels benefited from the combination over nivolumab alone, but because of the limited size, unplanned retrospective subset analysis, and technical limitations of current methods for PD-L1 testing, the use of this marker to select therapy is not advised. The combination also had a significant increase in the incidence of immune-mediated adverse events requiring experience and very close communication between the treating physician, the patient, and other members of the health care team to offer this highly active regimen to patients with advanced melanoma. Long-

term results and data regarding overall survival, as well as the identification of predictors that will allow patients to be selected for single or combined therapy, are awaited, and clinical trials are ongoing for immunomodulators that will enhance antitumor activity with less immune-related toxicity. The same combination with different doses and intervals of therapy is being investigated in patients with non-small cell lung cancer, breast cancer, head and neck carcinoma, and other solid tumors and hematologic malignancies.

Despite the advances achieved with the use of immune-checkpoint blockade, disease progression develops in a significant proportion of patients as a result of mechanisms involved in primary and secondary resistance. Although these mechanisms are yet to be properly characterized, their understanding may pave the way for a rational development of combinations and treatment sequencing in the near future.

KEY POINTS

- Immunologic checkpoint blockade with antibodies against CTLA-4 and PD-1 is an effective method for reversing cancer immunosuppression and promoting immune responses against several cancer types.
- Checkpoint inhibition is associated with a unique spectrum of side effects called irAEs, which include dermatologic, gastrointestinal, hepatic, endocrine, and other less common inflammatory events.
- The patterns and kinetics of response to immune checkpoint inhibitors can differ from those observed with conventional cytotoxic chemotherapy or targeted therapy.
- The clinical applications of anti–PD-1 and anti–PD-L1 agents continue to expand.
- The combination of immune checkpoint inhibitors may result in improved response rates and disease control at a cost of greater toxicities; nevertheless, long-term effects and the impact on survival are still unknown.

MONOCLONAL ANTIBODIES THAT DIRECTLY TARGET THE TUMOR

Rituximab

The first monoclonal antibody to receive FDA approval for therapeutic use was rituximab, a human/mouse chimeric IgG1 directed to CD20, a transmembrane protein expressed on malignant and normal B cells. CD20 is expressed on more than 90% of cells in B-cell non-Hodgkin lymphoma and to a lesser degree on chronic lymphocytic leukemia (CLL) cells. CD20 function is not established. The intracellular portion of CD20 contains phosphorylation sites for signaling kinases. It may affect the cell cycle through calcium-channel regulation. The cytotoxic effects of rituximab appear to involve CMC, ADCC, and induction of apoptosis.

Rituximab is approved for the treatment of CD20-positive non-Hodgkin lymphoma (low-grade or follicular B-cell and diffuse large B-cell) and CLL. Dosing of rituximab is dependent on the clinical setting. Rituximab is usually administered IV for 4 or 8 doses weekly. Manageable infusion-related reactions occur for the majority of patients, thus premedication with acetaminophen and diphenhydramine is recommended. Mild to moderate flulike symptoms are also common. Severe infusion reactions, such as bronchospasm and hypotension, occur in 10%

of patients and are usually reversible with appropriate interventions. Transient hypotension may occur; therefore, withholding antihypertensives 12 hours before infusion should be considered. To address infusion reactions, the initial infusion is administered slowly. If hypersensitivity or infusion-related events do not occur, the infusion rate is increased incrementally. Subsequent infusions also are administered more slowly initially, with incremental rate increases. The incidence of hypersensitivity reactions decreases markedly with subsequent infusions. Rituximab can elicit a tumor lysis syndrome. It also induces B-cell lymphopenia, which lasts for approximately 6 months. Full recovery occurs in 9 to 12 months. CD20 is not expressed on hematopoietic stem cells. Rituximab therapy has been associated with reactivation of hepatitis B and with progressive multifocal leukoencephalopathy due to opportunistic viruses, including the JC papovavirus.[65,66] Screening patients for hepatitis B prior to therapy is recommended. Antiviral therapy and comanagement with infectious disease specialists are recommended for patients with serologic evidence of virus.[67] When used in combination with a variety of chemotherapeutic regimens, rituximab does not add to the toxicity of chemotherapy, with the exception of a slightly higher rate of neutropenia. This does not, however, translate into a higher infection rate.[68] Laboratory assays are being developed to identify patients who are likely to have a response to rituximab, including assays of Fc receptor polymorphisms and tumor apoptotic regulators.[69]

Ofatumumab

Ofatumumab is a human IgG1 monoclonal antibody also directed against the CD20 protein currently approved for the treatment of patients with recurrent or progressive CLL. Ofatumumab targets an epitope different from that for rituximab and most other CD20-directed antibodies. Ofatumumab binds to both the small and large loops of the CD20 molecule on B cells. Its location is in closer proximity to the membrane, which in theory allows for more effective complement deposition and subsequent B-cell killing. Preclinical data suggest improved CMC and ADCC compared with rituximab. Direct effects on B-cell proliferation have also been demonstrated.

Ofatumumab is administered as an IV infusion weekly for the first 8 doses, then every 4 weeks for the remaining 4 doses. The first dose of ofatumumab is reduced (300 mg) to lessen the risk of serious infusion reactions; all subsequent doses are 2000 mg. Ofatumumab can be used in combination with fludarabine and cyclophosphamide for relapsed CLL. Infusion reactions can be problematic, and premedication with a PO or IV antihistamine, PO acetaminophen, and an IV corticosteroid prior to each dose is recommended. In addition to infusion reactions, which occurred in 44% of patients with the first infusion and 29% with the second infusion, adverse reactions have included infections, neutropenia, and pyrexia. The most serious side effect of ofatumumab is an increased chance of infections. Progressive multifocal leukoencephalopathy is a rare but also serious side effect. As with rituximab, screening of patients for hepatitis B and comanagement with infectious disease specialists for patients who test positive are recommended.

Obinutuzumab

Obinutuzumab is a humanized, type II CD20 monoclonal antibody that has been glycoengineered to reduce core fucosylation, conferring enhanced affinity for the human FcγRIIIa receptor on effector cells and, hence, enhanced ADCC. As a type II monoclonal antibody, obinutuzumab has lower capacity to relocalize CD20 into lipid rafts upon binding

compared with the type I antibodies rituximab and ofatumumab and is less potent in inducing CMC. It is, however, more potent in mediating cell adhesion and direct cell death. Obinutuzumab and rituximab bind adjacent and partially overlapping epitopes on CD20 but acquire different orientation upon binding, which most likely contributes to different biologic characteristics of type I and II antibodies. In preclinical studies, obinutuzumab showed superior induction of direct cell death and enhanced ADCC with less CMC compared to rituximab.

Obinutuzumab has been approved for the treatment of patients with rituximab-refractory follicular lymphoma and in combination with chlorambucil for CLL. Premedication with glucocorticoid, acetaminophen, and antihistamine is recommended. The FDA-approved regimen for treatment of CLL is obinutuzumab as outlined above in combination with chlorambucil on days 1 and 15 of each cycle; in patients with refractory non-Hodgkin lymphoma, obinutuzumab is used in combination with bendamustine, followed by obinutuzumab monotherapy.[70] The most common adverse reactions with obinutuzumab in combination with chlorambucil were infusion-related reactions, neutropenia, thrombocytopenia, anemia, pyrexia, cough, and musculoskeletal disorders. As with other CD20 targeted antibodies, hepatitis B virus reactivation and progressive multifocal leukoencephalopathy are also risks that require surveillance and treatment, including screening for hepatitis B as for the other B-cell–directed antibody therapies.

Alemtuzumab

Alemtuzumab is a humanized IgG1 directed against CD52, a nonmodulating glycoprotein expressed on the surface of normal and malignant B cells, including the malignant B cells of CLL. It is also expressed on T cells, NK cells, monocytes, macrophages, and tissues of the male reproductive system. CD52 function is unknown. The cytotoxic effects of alemtuzumab are presumed to involve ADCC and CMC mechanisms.

Alemtuzumab is approved for the treatment of CLL, cutaneous T-cell lymphoma, and T-cell lymphoma. Alemtuzumab administration can be limited by infusion-related toxicities such as hypotension, rigors, fever, dyspnea, bronchospasm, chills, and/or rash. Premedication with diphenhydramine and acetaminophen before infusion is recommended, as is hydrocortisone if infusion-related events occur. Alemtuzumab induces profound B- and T-cell lymphopenia, and a variety of opportunistic infections have been reported.[71] Severe and prolonged myelosuppression also can occur. Infection prophylaxis, trimethoprim–sulfamethoxazole for pneumocystis prophylaxis, and famciclovir (or its equivalent) for herpetic infections are necessary and must be continued for 2 months after completion of therapy or until CD4 cell counts are greater than 200, whichever occurs later. Alemtuzumab is also being tested as part of the conditioning regimens for allogeneic hematopoietic stem cell transplantation (HSCT) to support engraftment.

Daratumumab

Daratumumab is a human IgG1k monoclonal antibody that targets CD38, a protein that is overexpressed in multiple myeloma cells. Daratumumab binds to CD38, resulting in complement-dependent and antibody-dependent cell-mediated cytotoxic effects.

Daratumumab was initially approved as single agent for the treatment of patients with multiple myeloma who have received at least three prior lines of therapy; in November 2016, the FDA expanded the indication of daratumumab in combination with lenalidomide or bortezomib and dexamethasone for the treatment of patients with refractory multiple myeloma

and at least one prior therapy.[72-74]

As a single agent, daratumumab is administered intravenously at 16 mg/kg weekly for 8 weeks, and then less frequently. Most common toxicities include infusion reactions, fatigue, nausea, pyrexia, and respiratory symptoms. Pre- and postinfusion medications (acetaminophen, steroids, and antihistamines) are advised to prevent infusion reactions. Daratumumab is associated with anemia, lymphopenia, neutropenia, and thrombocytopenia. Prophylaxis for herpes zoster reactivation is also recommended.

Elotuzumab

Elotuzumab is an immunostimulatory humanized IgG1k monoclonal antibody targeting the signaling lymphocytic activation molecule F7 (SLAMF7), a cell-surface glycoprotein involved in inhibitory signaling of NK cells. SLAMF7 is expressed on multiple myeloma (MM) cells, NK cells, plasma cells, and subsets of cells of hematopoietic lineage. Binding of elotuzumab to the extracellular domain SLAMF7 results in antitumor activity against MM cells through antibody-dependent cellular cytotoxicity and lysis of tumor cells through the activation of NK cells. Elotuzumab is currently approved by the FDA for use in combination with lenalidomide and dexamethasone for the treatment of patients with multiple myeloma in whom prior therapies have failed.[75]

The recommended dose of elotuzumab is 10 mg/kg intravenously every week for the first two cycles and every 2 weeks thereafter, in combination with lenalidomide and dexamethasone. The most frequent adverse events include lymphopenia, neutropenia, fatigue, pyrexia, peripheral neuropathy, respiratory symptoms, upper respiratory tract infection, and pneumonia. Infusion reactions and hepatotoxicity may also occur.

Trastuzumab

Trastuzumab is a humanized IgG1 directed against the extracellular domain of HER2, also known as ErbB2, a member of the epidermal growth factor (EGF) family of receptor tyrosine kinases. HER2 may be overexpressed by breast, gastroesophageal, and many other cancers. Overexpression is implicated in the malignant transformation process, is an independent adverse prognostic factor in breast cancer, and may predict response to both chemotherapy and hormonal agents, depending on other characteristics of the tumor cells. Trastuzumab exerts antitumor effects by several mechanisms that are not yet completely understood. Immune effector mechanisms, namely ADCC and CMC, are considered to be central. Trastuzumab has direct antiproliferative effects, which include cell-cycle arrest and/or induction of apoptosis; it markedly accelerates HER2 endocytosis and degradation. Trastuzumab also can mediate antiangiogenic effects, including the inhibition of VEGF production.

Trastuzumab is approved for use in breast, gastric, and gastroesophageal junction cancers. It is administered IV, with an initial loading dose followed by weekly administration. Other regimens, such as dosing every 3 weeks, also have been effectively applied. Trastuzumab is generally well tolerated. Infusion reactions do occur, but premedication is usually not required. Cardiac dysfunction may be problematic. It was observed in almost 30% of patients who received an anthracycline and cyclophosphamide; thus, concurrent therapy with anthracyclines is not recommended. Cardiac dysfunction also has been observed in approximately 15% of patients receiving trastuzumab plus paclitaxel and in approximately 5% of patients receiving trastuzumab alone. Patients should undergo monitoring for decreased left ventricular function before trastuzumab treatment and frequently during and after treatment.

Ado-trastuzumab emtansine (TDM-1), a HER-2-targeted antibody-drug conjugate of trastuzumab and mertansine, a microtubule inhibitor, is also approved for the treatment of patients with HER2-positive, advanced breast cancer as single agent.

Pertuzumab

Pertuzumab targets the extracellular dimerization domain (subdomain II) of HER2 and thereby blocks ligand-dependent heterodimerization of HER2 with other HER family members, including EGF receptor (EGFR), HER3, and HER4. Pertuzumab was the first drug approved in the breast cancer neoadjuvant treatment setting. Approval was based on the pathologic complete response rate, defined as the absence of invasive cancer in the breast and lymph nodes, observed in a phase II study involving women with early HER2-positive breast cancer who were randomly assigned to receive to one of four neoadjuvant treatment regimens.[76]

Pertuzumab is administered IV; an initial loading dose is administered, followed by infusions every 3 weeks. Its half-life is approximately 3 weeks. There are specific dosing recommendations for drugs, such as trastuzumab and docetaxel, when administered with pertuzumab. The most common adverse reactions observed among patients who received pertuzumab in combination with trastuzumab and docetaxel were diarrhea, alopecia, neutropenia, nausea, fatigue, rash, and peripheral neuropathy. Cardiac dysfunction can occur; however, pertuzumab in combination with trastuzumab and docetaxel was not associated with increases in the incidence of symptomatic left ventricular systolic dysfunction or decreases in left ventricular ejection fraction compared with placebo in combination with trastuzumab and docetaxel. Other significant adverse reactions reported with pertuzumab included infusion-associated reactions, hypersensitivity reactions, and anaphylaxis.

Cetuximab

Cetuximab is a human/mouse chimeric IgG1 to the extracellular domain of the EGFR, also known as ErbB1. It is approved for treatment of colorectal cancer and squamous cell carcinoma of the head and neck. Cetuximab competitively inhibits the binding of EGF and other ligands, such as TGF-alpha. It blocks activation of receptor-associated kinases, resulting in inhibition of cell growth, apoptosis, and decreased VEGF and matrix metalloproteinase production. EGFR is expressed in many normal epithelial tissues, such as skin. Many different human carcinomas overexpress EGFR, including colorectal and head and neck cancers. EGFR protein overexpression, which can be accompanied by gene amplification, or copy number gains, is associated with a negative prognosis across different cancers. In animal studies, cetuximab inhibited tumor cells that overexpress EGFR as well as increased the activity of chemotherapy and radiation. The presence of mutations in the *KRAS* oncogene, which encodes a signal transducer that mediates response to stimulation of cell-surface receptors, including EGFR, has been associated with lack of response to cetuximab.[77] *KRAS, NRAS,* and *BRAF* testing is recommended for all patients with metastatic colorectal cancer who are candidates for anti-EGFR antibody therapy, and it is recommended that patients with *KRAS, NRAS,* or *BRAF* mutations should not receive anti-EGFR antibody therapy.[78]

Cetuximab is administered IV; an initial loading dose is administered, followed by weekly infusions. The plasma half-life is approximately 5 days. Every-other-week infusions have also been used. In general, cetuximab has been well tolerated. Infusion reactions do occur and can be severe, particularly with the initial infusions, and premedication with diphenhydramine is recommended. The most common side effect has been an acnelike skin rash, which develops in

up to 75% of patients and which probably represents the biologic effects of the blocking EGFR present in the skin. The rash develops rapidly following cetuximab initiation, peaks between weeks 2 and 4, and thereafter tends to steadily abate in severity with continuation. The development of a rash has been associated with greater therapeutic effectiveness.[79] Life-threatening toxicities, such as interstitial lung disease, have been observed rarely.

Panitumumab

Panitumumab is a recombinant, human IgG2 monoclonal antibody that also binds specifically to EGFR with identical target specificity to that of cetuximab. IgG2 is less efficient than IgG1 in mediating ADCC. In contrast to cetuximab, panitumumab is fully human. The theoretical advantage conferred by this agent, compared with its chimeric counterpart, is that there is less potential for an antigenic response against the therapeutic antibody, since panitumumab is fully human. The antitumor effects are considered to be identical to those of cetuximab. Efficacy has been confined to patients whose tumors do not express *KRAS* mutations.[80] Panitumumab is administered IV, without a loading dose, every 14 days. As was predicted, the development of human antihuman antibodies has not been detected with treatment. Approximately 1% of patients exposed to panitumumab, however, experienced severe infusion reactions, whereas approximately 3% of patients treated with cetuximab experienced severe infusion reactions. Other toxicities appear to be similar. Skin rash with variable presentation is common. An association between the development of rash and response has also been suggested. Rare but serious adverse events, such as pulmonary fibrosis, have been observed. Anecdotal reports have suggested that patients whose disease is considered intolerant to cetuximab may be safely treated with panitumumab, but their disease is not considered non–cross-resistant, so antitumor activity cannot be rescued with a switch in antibodies. Panitumumab was approved on the basis of a phase III trial in which patients with metastatic colorectal cancer were randomly assigned to receive either panitumumab with best supportive care or best supportive care alone.[81] No patients who had been previously treated with cetuximab were included, and in a randomized comparison trial, panitumumab and cetuximab demonstrated similar antitumor activity and toxicity.

Necitumumab

Necitumumab is a recombinant, fully human IgG1 monoclonal antibody directed against the extracellular region of EGFR that blocks the binding of EGFR to its ligands, also leading to ADCC. In preclinical models, necitumumab resulted in EGFR binding activity similar to that of cetuximab, both IgG1 class antibodies, and higher than that of panitumumab, an IgG2 class antibody with less pronounced ADCC activity. The FDA granted approval to necitumumab in combination with gemcitabine and cisplatin for first-line treatment of patients with metastatic squamous non-small cell lung cancer. In a randomized, phase III trial, the addition of necitumumab to chemotherapy resulted in longer overall survival.[82]

Necitumumab 800 mg (absolute dose) is administered intravenously over 60 minutes on days 1 and 8 of 21-day cycles. The most common adverse events include skin rash and hypomagnesemia. Cardiopulmonary arrest and/or sudden death (3%) have been reported in patients receiving necitumumab. Close monitoring of serum electrolytes is recommended.

Olaratumab

Olaratumab is a recombinant human monoclonal antibody against platelet-derived growth factor receptor alpha (PDGFRα), a receptor tyrosine kinase expressed on mesenchymal cells involved in cell growth, chemotaxis, and differentiation. Olaratumab is indicated for use in combination with doxorubicin in patients with advanced soft-tissue sarcomas not amenable to curative treatment, and it was the first therapy approved by the FDA for the treatment of soft-tissue sarcomas in the first-line setting in more than four decades. Approval was based on results of an open-label, phase Ib and a randomized phase II trial that included patients with diverse soft-tissue sarcomas not previously treated with an anthracycline.[83] In comparison to doxorubicin alone, the addition of olaratumab to doxorubicin resulted in prolongation of both progression-free survival and overall survival. A phase III trial of olaratumab in combination with doxorubicin has been completed and results are awaited.

Olaratumab is administered intravenously at 15 mg/kg on days 1 and 8 of each 21-day cycle in combination with doxorubicin on day 1 for up to eight cycles, and then as single agent until disease progression or unacceptable toxicity occurs. Most common adverse events include nausea, vomiting, diarrhea, fatigue, lymphopenia, neutropenia, mucositis, neuropathy, decreased appetite, and abdominal pain. Infusion reactions can occur, and premedication with diphenhydramine and dexamethasone is recommended.

KEY POINTS

- The effectiveness of monoclonal antibodies has been established for both hematologic malignancies and solid tumors.
- Targets have included tumor cell membrane determinants and factors involved in tumor progression.
- Monoclonal antibodies can mediate antitumor activity via immune mechanisms (e.g., antibody-dependent and complement-mediated cellular mechanisms) and by nonimmunologic mechanisms (e.g., direct induction of apoptosis).
- Although active as single agents in some cases, monoclonal antibodies are most often administered with chemotherapy or radiation therapy.
- Because of infusion reactions, premedication is required for treatment with many monoclonal antibodies, particularly those that are used to treat hematologic diseases.
- Unique and often severe organ toxicity related to the molecule being targeted can be seen.

ANTIANGIOGENIC ANTIBODIES

Bevacizumab

Bevacizumab is humanized IgG1 directed against vascular endothelial growth factor (VEGF). Often overexpressed by tumor cells as well as by tumor-associated macrophages, VEGF has proven to be a pivotal stimulator of endothelial cell development and angiogenesis. Bevacizumab binds the VEGF isoform and prevents the interaction with its receptors (Flt-1 and KDR) on endothelial cells. Bevacizumab has been shown to inhibit new blood vessel formation in in vitro models and to reduce tumor vascularity and progression in in vivo animal tumor

models. Bevacizumab has been shown to have a direct and rapid antivascular effect in the tumors of patients with colorectal cancer.[84] Most of bevacizumab's indications (colorectal cancer, lung cancer, ovarian cancer, cervical cancer) are in combination with chemotherapy. Bevacizumab is also approved in combination with interferon-alphaa for the treatment of patients with metastatic renal cell carcinoma and as a single agent or in combination with irinotecan for the treatment of patients with glioblastoma, although it is rarely used now for either indication because of its toxicity and low antitumor activity.[85]

Bevacizumab is administered intravenously every 14 days. The plasma half-life is approximately 20 days (free plus bound to circulating VEGF). Clinical toxicities include hemorrhagic complications, which are more common among patients with squamous cell histology non-small cell lung cancer than with adenocarcinoma. Other important toxicities also include hypertension, proteinuria, gastrointestinal perforations, thrombohemorrhagic events, and wound healing complications that make it advisable to avoid bevacizumab for several weeks prior to any major surgical procedure and to delay its administration until the surgical incisions are fully healed. Administration also should be suspended several weeks prior to elective surgery. Hypertensive crisis, nephrotic syndrome, and congestive heart failure have been observed. Bevacizumab must be suspended for patients with gastrointestinal perforation, wound dehiscence, serious bleeding, nephrotic syndrome, or hypertensive crisis. The risk of continuation or temporary suspension for patients with moderate to severe proteinuria is unknown. Infusion reactions are relatively uncommon. Other rare complications, including a reversible posterior leukoencephalopathy syndrome, have been observed among patients treated with bevacizumab.[86]

Ramucirumab

Ramucirumab is a monoclonal antibody that binds to VEGF receptor 2 (VEGFR-2) and blocks the activation and downstream signaling mediated by the receptor. It is the first biologic treatment given as a single drug that has survival benefits for patients with advanced gastric or gastroesophageal junction adenocarcinoma that progressed after first-line chemotherapy.[87] Ramucirumab is also approved for use in combination with paclitaxel for advanced gastroesophageal junction adenocarcinoma following prior fluoropyrimidine- or platinum-containing chemotherapy, in combination with folinic acid, fluorouracil, and irinotecan (FOLFIRI) for patients with advanced colorectal cancer whose disease progressed while on prior bevacizumab- and oxaliplatin-containing regimens (second-line setting) and in combination with docetaxel for patients with metastatic non-small cell lung cancer with disease progression following platinum-based chemotherapy.

Ramucirumab is administered by IV infusion every 2 weeks. Premedication with antihistamines is recommended to decrease the risk of infusion-related reactions. Patients who suffer a grade 1 (mild) or 2 (moderate) infusion-related reaction should also be premedicated with acetaminophen and dexamethasone or its equivalent before each infusion, and the infusion rate should be slowed by 50%. The most common adverse reactions of ramucirumab are hypertension and diarrhea. Other important risks include hemorrhage, arterial thrombotic events, infusion-related reactions, gastrointestinal perforation, impaired wound healing, clinical deterioration among patients with cirrhosis, and reversible posterior leukoencephalopathy.

BISPECIFIC ANTIBODY THERAPY

A bispecific monoclonal antibody is an artificial protein that is composed of fragments of two

different monoclonal antibodies and consequently binds to two different types of antigen. Bispecific monoclonal antibodies have been developed to simultaneously bind to a cytotoxic cell and to a tumor cell in order to destroy the tumor cell.

Blinatumomab

Blinatumomab belongs to a class of constructed antibodies known as bispecific T-cell engagers (BiTEs). It consists of genetically engineered, murine tandem single-chain variable fragments (scFvs), which are not actually a fragment of an antibody but instead a fusion protein of the variable regions of the heavy- (V_H) and light- (V_L) chains of Igs, connected with a short linker. scFvs lack the antibody Fc domains and thus do not mediate CMC or ADCC. One scFv binds T-cell–specific CD3 and the other B-cell–specific CD19. By targeting CTL against the CD-19–expressing B cells, the T cells become activated within minutes and induce perforin-mediated death to the targeted B cells. In contrast to CD20, CD19 is expressed on the earliest B-precursor lymphocytes that undergo malignant transformation in acute lymphocytic leukemia. Blinatumomab is approved by the FDA for the treatment of Philadelphia chromosome–negative relapsed/refractory B-lineage acute lymphocytic leukemia in adult patients, specifically for eradication of minimal residual disease.[88]

Blinatumomab has a short serum half-life of 1 to 2 hours. As a consequence of the short elimination half-life, blinatumomab is administered as a 4-week continuous IV infusion. Shorter infusion times had also been explored but seemed to result in higher incidences of adverse effects, including neurologic symptoms, such as seizures, and a cytokine-release syndrome—a symptom complex that can be life-threatening and includes fever, nausea, chills, hypotension, tachycardia, headache, rash, and dyspnea that results from the release of cytokines from cells targeted by the antibody as well as immune cells that are recruited.[89] Although blinatumomab was derived from murine sources, HAMA is rare; HAMAs develop in less than 1% of patients during therapy. Absence of the Fc region along with B-cell depletion resulting from therapy are assumed to be the critical components for this low immunogenicity.

KEY POINTS

- The efficacy of antiangiogenic agents, particularly of monoclonal antibodies against VEGF and VEGFR, has been demonstrated in different solid tumors.
- Bowel perforation, hemorrhagic complications, and thromboembolic events may develop in patients receiving antiangiogenic drugs, and treatment suspension is advised in those undergoing surgical procedures.
- Bispecific monoclonal antibodies, such as blinatumomab, have been developed to simultaneously bind to a cytotoxic cell and to a tumor cell in order to destroy the tumor cell.

IMMUNOTOXINS AND RADIOIMMUNOCONJUGATES

Biologic agents have been used to deliver toxins or radiation to malignant cells, as opposed to activating host antitumor mechanisms. Denileukin diftitox is a recombinant immunotoxin consisting of IL-2 fused to the enzymatically active domains of diphtheria toxin. It is internalized

into IL-2–receptor-bearing cells (CD25) by endocytosis. Diphtheria toxin activation is controlled by its intracellular cleavage from the bispecific molecule and then inhibits protein synthesis, leading to apoptosis. Denileukin diftitox is indicated for the treatment of patients with persistent or recurrent CD25+ cutaneous T-cell lymphoma.[90] Cytokine release may occur, the result of the killing of T cells, and can result in capillary leak syndrome. Vision loss has also been observed.

Brentuximab vedotin is an antibody-drug conjugate approved to treat anaplastic large cell lymphoma and Hodgkin lymphoma. The compound consists of the chimeric monoclonal antibody brentuximab, which targets the cell-membrane protein CD30, linked to 3 to 5 units of the antimitotic agent monomethyl auristatin E (MMAE, designated “vedotin”). The antibody portion of the drug attaches to CD30 on the surface of malignant cells, delivering MMAE, which is responsible for the antitumor activity. Brentuximab vedotin is usually well tolerated, with manageable side effects including peripheral sensory neuropathy.[91]

Ado-trastuzumab emtansine, which consists of trastuzumab linked to the cytotoxic agent mertansine, an antitubulin, has demonstrated activity for patients with breast cancer that has not responded to prior treatment with trastuzumab.[92] Although ado-trastuzumab is well tolerated in clinical trials, thrombocytopenia has been reported, and liver and cardiac toxicity can develop. The drug is approved for treatment of advanced breast cancer.

Two mouse monoclonal antibodies to CD20 conjugated to radioisotopes, ^{131}iodine-tositumomab and ^{90}yttrium-ibritumomab, have demonstrated clinical effectiveness for patients with lymphoma. Both are indicated for the treatment of relapsed or refractory, low-grade or follicular B-cell non-Hodgkin lymphoma, with or without transformation, including rituximab-refractory disease. Toxicity is typically quite mild. The main side effect is reversible myelosuppression, and exposure is limited to a single dose because of the radiation exposure as well as to the high incidence of HAMA development.[93,94]

KEY POINTS

- Biologic agents can be engineered to deliver toxins and radiation to malignant cells in the form of immunotoxins and radioimmunoconjugates.
- Examples of effective immunotoxins include brentuximab vedotin, approved for the treatment of patients with anaplastic large cell lymphoma and Hodgkin lymphoma, and ado-trastuzumab, a molecule that incorporates trastuzumab and a cytotoxic agent, used in the treatment of breast cancer.

CELLULAR THERAPY

A distinct immunotherapy approach, termed “adoptive cell therapy,” is to infuse immune cells expanded, engineered or generated ex vivo. A variety of immune effector cells have been explored for adoptive cellular therapy and tested in clinical trials. Early efforts examined the infusion of LAK cells, which had little activity and required the coadministration of high-dose IL-2 to maintain their activity. Initial studies of patients with advanced melanoma and renal cell carcinoma demonstrated antitumor activity. Comparable results, however, were subsequently seen with IL-2 alone. Methods of generating antitumor CTLs by culturing peripheral blood, lymph node, or TILs with cytokines and tumor antigens ex vivo also have been evaluated clinically. Response rates of 50% or more among patients with metastatic melanoma

accompanied by long progression-free survival have been observed with the infusion of TIL in nonrandomized studies.[95] The infusion of T cells that have been genetically modified either with a reprogrammed, recombinant chimeric antigen receptor (CAR) or with an engineered TCR have demonstrated encouraging results in clinical trials. CARs redirect T-cell specificity toward antibody-recognized antigens expressed on the surface of cancer cells and are composed of an extracellular antigen-recognition domain, a transmembrane domain, and an intracellular T-cell signal domain. Of note, CARs are able to recognize a variety of antigens without restriction of their MHC determinants, since the target cell antigen is not processed and presented but is there in its entirety on the malignant cell surface, and costimulatory signals can be incorporated into the intracellular domain in order to enhance cellular responses. CAR-redirected T cells specific for the B-cell differentiation antigen CD19 have demonstrated significant activity in the treatment of B-cell malignancies.[96,97] Similarly, CAR-T cells targeting the B-cell maturation antigen (BCMA) appear promising in the treatment of relapsed refractory myeloma. TCR-modified T cells have demonstrated activity in the treatment of selected solid tumors but are structurally dependent on HLA type and antigen expression on MHC molecules of the target cell.[98,99] The toxicities of adoptive T-cell therapies can be severe; they include cytokine release syndrome, hypotension, pyrexia, and neurologic adverse events. Dendritic cells also have been generated ex vivo and are under investigation in vaccine approaches (including Sipuleucel-T, detailed below), as have monocytes/macrophages as potent antigen-presenting cells.

DONOR LYMPHOCYTE INFUSION

Cells infused in allogeneic HSCT represent an effective adoptive cellular therapy in clinical use. An allogeneic graft-versus-leukemia (GVL) effect, which is a restricted form of graft-versus-host disease (GVHD), has been suggested by the increased relapse rate for recipients of T-cell–depleted allografts, higher relapse rates after either syngeneic or autologous transplantation, and the lower frequency of relapse for patients with more severe GVHD. Given these clinical observations, donor leukocyte infusion (DLI) was tested among patients whose malignancies relapsed after allogeneic transplantation. Numerous reports have documented success of DLI for patients with chronic myeloid leukemia; the majority of these patients achieved durable complete molecular remission.[100] Acute myeloid leukemia has only modest response rates, and acute lymphoblastic leukemia rarely responds. DLI also can eradicate Epstein–Barr virus–associated posttransplantation lymphoproliferative disease following allogeneic transplantation. More recent studies have identified potential target antigens among patients responding to DLI. The major drawback of DLI is GVHD, which is a major source of transplantation-related mortality, and methods of promoting GVL over GVHD are under investigation. New investigational approaches aimed at improving the efficacy of DLI under investigation include priming of donor lymphocytes to recipient tumor antigens ex vivo and infusions of alloreactive NK cells. The effects of lymphocyte infusions in the setting of myeloablative and nonmyeloablative treatment are also under investigation in solid tumors.[101]

SIPULEUCEL-T

Sipuleucel-T is an autologous cellular immunotherapy designed to stimulate an immune response to prostate cancer. It is approved for the treatment of asymptomatic or minimally symptomatic metastatic castrate-resistant (hormone-refractory) prostate cancer. Sipuleucel-T is manufactured from peripheral-blood mononuclear cells (PBMCs) isolated during leukapheresis. PBMCs are cultured ex vivo with PA2024, a fusion protein consisting of prostatic

acid phosphatase (PAP) and GM-CSF for 2 days and then reinfused into the patient. The approach is designed for the GM-CSF portion of the fusion molecule to activate blood monocytes and dendritic cells to present PAP as a tumor antigen.[102,103] The final cell product, however, includes a variety of leukocytes, including T and B cells. Median overall survival was improved for patients treated with sipuleucel-T compared with those receiving similarly prepared autologous dendritic cells not exposed to the antigen–GM-CSF fusion protein.[102] Adverse events more commonly reported in the sipuleucel-T group were chills, pyrexia, headache, flulike illness, myalgia, hypertension, hyperhidrosis, and groin pain. These events were generally mild or moderate in severity and usually resolved within 1 to 2 days. Investigations are ongoing to enhance the benefits of Sipuleucel-T by the addition of other immunomodulators, and the technology also is being explored in the treatment of other malignancies.

KEY POINTS

- Many cells of the immune system generated and/or modified ex vivo can be administered to an individual to effect an antitumor immune response.
- The use of reprogrammed CAR- and TCR-endowed lymphocytes has produced promising results in both hematologic and solid malignancies; nevertheless, the applicability of these approaches remains restricted to specialized centers and toxicities can be limiting.
- An autologous cell-based vaccine and donor leukocyte infusion after allogeneic hematopoietic cell transplantation are examples of cellular therapies in clinical use and under active investigation.

SUPPORTIVE CARE BIOLOGIC AGENTS—HEMATOPOIETIC GROWTH FACTORS

Many cytokines affect hematopoiesis either directly or indirectly. Cytokines that serve as hematopoietic growth factors are now in common use for the prophylaxis of febrile neutropenia for patients receiving cytotoxic treatments, and in the setting of HSCT, where they are used to mobilize hematopoietic progenitor cells for transplantation.

GM-CSF

GM-CSF stimulates the development of neutrophils and monocytes/macrophages and promotes the proliferation and development of early erythroid, megakaryocytic, and eosinophilic progenitor cells. It is produced by endothelial cells and fibroblasts as well as by T cells and monocytes/macrophages. GM-CSF produces a variety of effects on cells of the neutrophil and monocyte/macrophage lineages, including augmentation of monocyte/macrophage MHC class II expression and enhancement of granulocyte and macrophage cellular cytotoxicity and ADCC mechanisms. GM-CSF also serves as the principal mediator of the proliferation and differentiation of mDC. It enhances dendritic cell antigen uptake, MHC, and costimulatory molecule expression, as well as the ability of dendritic cells to stimulate T cells.

Recombinant GM-CSF (sargramostim) can be used in the prophylaxis of neutropenia. Because of the sensitivity of rapidly dividing myeloid cells, sargramostim is typically initiated 1

to 3 days after completion of chemotherapy and administered daily through postnadir recovery. Sargramostim is generally well tolerated; however, side effects include pain and inflammation at the injection site, bone pain, myalgia, arthralgia, and low-grade fever. Nausea, fluid retention, dyspnea, pericarditis, pleuritis, pulmonary emboli, splenomegaly, and hypersensitivity reactions have been reported but are rare.

The ability of GM-CSF to function as an immunoadjuvant and to stimulate DC and tumor-specific T-cell responses has led to its evaluation in a number of clinical trials as anticancer therapy. Various cancer vaccine approaches that incorporate GM-CSF have been tested clinically, including combination with immune checkpoint inhibition with favorable effects on both survival and toxicity in melanoma that are undergoing further investigation.[104] There also is evidence that administering sargramostim as monotherapy has antitumor activity for patients with prostate cancer or melanoma, in whom increases in DC have been observed.[105-107] The ability of sargramostim to promote phagocyte-mediated ADCC is also being tested in clinical trials in which it is being administered with monoclonal antibodies.[108]

Granulocyte Colony-Stimulating Factor (G-CSF)

G-CSF is produced by macrophages, lymphocytes, fibroblasts, and endothelial cells. It induces the production and release of neutrophilic granulocytes in the bone marrow and enhances their functional capacity in the periphery. Moreover, G-CSF possesses essential neutrophil-activating functions, such as the oxidative burst, degranulation, phagocytosis, and chemotaxis. G-CSF markedly stimulates neutrophil ADCC mechanisms. As a regulator of neutrophil activity, G-CSF plays a role in innate immune responses. There is growing evidence that G-CSF also exerts immunoregulatory effects in adaptive immunity. G-CSF mediates anti-inflammatory reactions accompanied by Th2 differentiation and promotes tolerogenic antigen-presenting cell–T-cell interactions.

Recombinant G-CSF (filgrastim) may be used to decrease the risk of febrile neutropenia associated with cytotoxic chemotherapy treatment. It is usually administered SC daily for up to 2 weeks, until postnadir neutrophil recovery is at normal or near-normal neutrophil levels. Because filgrastim stimulates myeloid cells to divide and because dividing cells are sensitive to cytotoxic chemotherapy, filgrastim should be administered no earlier than 24 hours after the administration of cytotoxic chemotherapy and no earlier than 24 hours before the administration of chemotherapy to lessen the risk of aggravating leukopenia. Recently, two biosimilars to filgrastim, filgrastim sndz, and tbo-filgrastim, have been approved for the same indications as those for filgrastim.[109] A pegylated form of recombinant G-CSF, pegfilgrastim, has a variable plasma half-life of 15 to 80 hours, which allows administration once per chemotherapy treatment cycle rather than daily. Pegfilgrastim should not be administered in the period between 14 days before and 24 hours after the administration of cytotoxic chemotherapy. The safety data appear to be similar between filgrastim and pegfilgrastim. The most commonly observed adverse effects are mild to moderate bone pain after repeated administration and local skin reactions at the site of injection. Fever, diarrhea, edema, dyspnea, skin rash, splenomegaly (with rupture), and hypersensitivity reactions also may occur but are very rare. The G-CSF receptor, through which filgrastim and pegfilgrastim act, has been found on tumor cell lines. The possibility that pegfilgrastim acts as a growth factor for any tumor type, including myeloid malignancies and myelodysplasia, diseases for which pegfilgrastim is not approved, cannot be excluded. The immunomodulatory effects of G-CSF, such as the ability to promote ADCC mechanisms and to promote T-cell tolerance in pathologic conditions associated with a

Th1–Th2 imbalance, are under investigation.

KEY POINTS

- Hematopoietic factors, recombinant G-CSF, and GM-CSF are commonly used for the prophylaxis of febrile neutropenia and in hematopoietic stem cell transplantation.
- The ability of G-CSF and GM-CSF to modulate antitumor immune responses is under investigation, with particular interest in combinations with immune checkpoint inhibitors.

CLINICAL TRIALS AND BIOSTATISTICS

Brent R. Logan, PhD

Recent Updates

- Increasingly, clinical trials are being conducted in a biomarker driven fashion. (Redig AJ, *J Clin Oncol* 2015)
- Adaptive designs are being used more frequently to improve trial efficiency. (Bhatt DL, *N Engl J Med* 2016)

OVERVIEW

Both practicing oncologists and cancer researchers are aware of the heterogeneity that appears in almost every dimension of cancer and its treatment: among types of cancer, among patients with cancer, and in the response of disease to treatment. Although this challenge can be met in part by gaining a better understanding of the underlying factors that affect the disease and its response to treatment, the complexity of the underlying biology makes it almost certain that randomness and unpredictability will continue to be a significant component of cancer research and treatment.

Statistics is the branch of mathematics that deals with the collection and analysis of data in the face of uncertainty and random variation. “Biostatistics” is a term commonly used to refer to statistical methods and applications related to medical research, although the distinction is not necessary and not used here. The term “biometry” more commonly refers to nonmedical biologic applications. Not surprisingly, statistics plays a significant role in medicine as a whole and in oncology in particular, and statistical concepts and ideas will be encountered repeatedly in the medical literature relevant to the oncologist. This chapter is intended to cover topics that an oncologist will encounter and for which he or she will need a basic understanding in order to read and interpret current articles in medical journals. The intention of this chapter is not to detail the how of statistics (i.e. no formulas or equations) but rather to elucidate the what and why of biostatistics in oncology.

Of course, it is impossible to summarize in any depth or breadth an entire scientific discipline in a single chapter, even when focused on its application to clinical oncology; therefore, there is a focus on topics that are either commonly encountered or frequently misunderstood. In addition to reviewing basic statistical concepts and analytic methods common in clinical research, the chapter includes a section on clinical trial design. Although perhaps not a purely statistical topic, clinical trials are an essential part of clinical research, and they are the means by which one attempts to control systematic sources of variation. Properly designed clinical trials help one to isolate the random components of variation, which can then be quantified

using appropriate statistical analysis. Taken together, proper design and analysis allow one to make an objective evaluation of treatment options, reflecting both the strengths and uncertainties of the evidence at hand.

BASIC CONCEPTS

Basic statistical concepts are reviewed in this section,[1,2] with a focus on terms and issues that commonly arise in the analysis of medical data, especially those that are most commonly misunderstood and starting with the notion of sample and population, for which basic descriptive statistics are relevant. Then the chapter moves to topics in inferential statistics, where one attempts to relate characteristics of the sample to characteristics of the population. This is the crux of using statistics in medical research, and includes the concepts of hypothesis testing, p values, and confidence intervals. Finally, the chapter covers a somewhat different point of view relating to these concepts, that of Bayesian statistics.

SAMPLE AND POPULATION

Two terms that occur early in a discussion of statistics are “sample” and “population.” In general terms, the data that are generated in medical studies (e.g., in a clinical trial) represent an observed sample from an idealized larger population, such as all patients with a particular diagnosis and stage of disease. The sample data are described and subjected to statistical analysis in hopes of making inferences about the larger population from which they came. In practice, the sample is rarely drawn randomly from the population, but it is assumed that the behavior of the sample, and statistics calculated from it, are governed by parameters that characterize this hypothetical larger population.

A “statistic,” as compared with the discipline called “statistics,” is a quantity summarized from a set of data—for example, the mean or median. These are commonly referred to as “descriptive statistics.” They may describe quantitative variables, such as age or tumor size; ordinal variables, such as stage of disease; or categorical variables, such as sex or race.

Table 5-1 defines some common descriptive statistics. Most of these terms refer also to characteristics of a population, but are considered here as statistics calculated from a sample of data. In some cases, a simple description of the sample characteristics is all that is intended; however, a common use of sample statistics, either explicitly or implicitly, is to estimate their counterparts in a population. For example, the mean is a statistic computed from a sample. At least conceptually, the mean of the population from which the sample arose could be determined by enumerating and averaging all the values in the population. Instead, the sample mean (a statistic whose value varies from sample to sample) is used to estimate the population mean (a parameter with a fixed value). Such usage is a part of inferential statistics.

HYPOTHESIS TESTING

The two basic components of inferential statistics are estimation, which was previously noted and hypothesis testing.[3] Whereas estimation attempts to ascertain the value of a population parameter, hypothesis testing attempts to decide only whether the parameter has a particular value (or range of values). Many aspects of clinical trial design are framed in terms of hypothesis testing. This framework is sometimes somewhat artificial, but it is often used to plan the size of clinical trials and is the origin of many commonly encountered statistical terms.

Table 5-1 **Basic Descriptive Statistics**	
Statistic	**Definition and Description**
Mean	The average value of the sample.
Median	The value dividing the ordered values of the sample in half; equivalent to the 50th percentile. For an odd sample size, the median is the middle value; for an even sample size, the median is the average of the two middle values.
Percentile	The value below or equal to which a specified percentage of ordered observations fall. Tertiles, quartiles, and quintiles are values dividing an ordered sample into thirds, fourths, and fifths, respectively.
Mode	The most frequent value in the sample. Not often used.
Standard deviation	A measure of the variation of a sample distribution, based on the average squared distance from the sample mean. Most of a sample from a normal distribution is contained within two standard deviations above and below the mean.
Standard error	A measure of variation of the sample mean, or other estimated parameter describing a distribution. Unlike the standard deviation, the standard error gets smaller with larger sample sizes.
Range	The difference between the maximum and minimum value. In practice, the maximum and minimum are usually given, not the difference.

The statistical hypothesis test involves three basic steps: (a) formulation of the null hypothesis, (b) collection and analysis of data, and (c) a decision to reject or not reject the null hypothesis. The term “not reject” is deliberately used here, rather than the term “accept,” for reasons that are elaborated as follows. The null hypothesis is a semantic concept that is not at all the same as a scientific hypothesis. For example, in a trial of a new therapy, there is likely a scientific belief or hypothesis that the new therapy will be more effective than a standard therapy currently in use. However, the null hypothesis in such a setting would be just the opposite: The new therapy has the same effectiveness as the standard therapy. In the clinical trial setting, the desired scientific outcome is usually to reject the null hypothesis.

If one formulates the problem such that the only outcomes are to reject or not reject the null hypothesis, then there are two possible errors that can be made. One is that the null hypothesis is true and is incorrectly rejected (false-positive); the other is that the null hypothesis is false and is incorrectly not rejected (false-negative). The first of these is called a “type I error,” and the rate of type I error is usually designated α and referred to as the significance level; the second is called a “type II error,” and the rate of type II error is usually designated β. The rate

of type II error requires specification of exactly how the null hypothesis is false, which is referred to as the “alternative hypothesis.” It is more commonly specified by the probability of correctly rejecting the null hypothesis when a particular alternative to the null hypothesis is true; this is called “power” and is designated $1 - \beta$.

Hypothesis tests are carried out by calculating a test statistic from one or more samples. In years past, one then referred to a table of critical values for the test statistic, calculated from the theoretical distribution of the test statistic under the null hypothesis for a given sample size and type I error rate. If the test statistic was larger than the critical value (or smaller, depending on the type of statistic and test), then one rejected the null hypothesis. Although this can still be done, the computation of a test statistic now almost always involves the automatic computation of an associated p value, whose use, and misuse, is discussed in the next section.

Table 5-2 describes some common statistical tests. These all relate to simple comparisons of a quantitative or categorical characteristic, between groups or within a group. The table includes examples of both parametric and nonparametric tests. Parametric tests are derived using a specific assumption about the distribution of the data (e.g., normal, binomial, or exponential), whereas nonparametric tests make fewer such assumptions. Although the latter feature is desirable, a nonparametric test will generally have somewhat less statistical power than a parametric test that is correctly matched to a specific distribution. Fortunately, these considerations usually become less important with increasing sample size, and the choice of a parametric or nonparametric test is not critical. More complex statistical methods that relate to other types of endpoints, or that consider multiple variables simultaneously, are described later in this chapter.

INTERPRETING P VALUES AND CONFIDENCE INTERVALS

One of the most widespread concepts related to the statistical analysis of medical data, and possibly the most often misunderstood, is the p value. The p value is calculated after data have been collected, and it measures the strength of the evidence against the null hypothesis. For a given statistical model and assumptions, the p value is the probability, if the null hypothesis were true, that a result as different from (or more different than) the one observed could be produced by chance alone. If the p value is small, then one can reasonably infer that chance is not a good explanation for the observed data under the null hypothesis and that, therefore, it is a consequence of some systematic effect. Whether the systematic effect has been designed into the study, as in a randomized trial, or is a result of bias or selection factors is a different question.

What constitutes a small p value? In the world of clinical research, a p value of less than 0.05 is commonly used to indicate statistical significance. This number is arbitrary but is as good as any other if one wants only to establish a minimum threshold of evidence for something that is being measured on a continuous scale. In the formal hypothesis testing paradigm, it is equivalent to rejecting the null hypothesis when the type I error rate is set at 5%. The major error in interpretation of the p value involves outcomes for which the p value is large. The fact that a result is not statistically significant means only that chance is at least a reasonable explanation for the observed data. It does not mean that it is the only explanation and that the null hypothesis is true. The 0.05 level of significance (or any other level) does not discriminate truth from falsehood, and the p value is most certainly not the probability that the null hypothesis is true.

Table 5-2 **Basic Statistical Tests**

Setting	Test	Definition and Description
Comparing means	Two-sample t	Used to compare means between two groups for a quantitative variable. Generally robust to small sample size and nonnormal distributions, but sensitive to outlying values, which inflate estimates of variability.
	Paired t	Used to compare paired quantitative data; for example, a quantitative characteristic measured before and after treatment in each patient. Same sensitivity to outlying values as the two-sample t-test.
Comparing medians or distributions	Wilcoxon rank sum (Mann–Whitney)	A nonparametric alternative to the two-sample t-test. Less sensitive to outlying values than the two-sample t-test, although somewhat more conservative.
	Wilcoxon signed rank	A nonparametric version of the paired t-test. Less sensitive to outlying values than the paired t-test, although somewhat more conservative.
Comparing proportions	Chi-square	Used to compare proportions between two or more groups. Fairly robust to small sample sizes, unless there is an imbalance between groups. The "continuity correction" sometimes applied to the chi-square test is conservative and generally unnecessary.
	Fisher exact	Used to compare proportions with small sample size. A conservative test compared to the chi-squared.
	McNemar	Used to compare paired proportions; for example, a binary characteristic assessed before and after treatment in each patient. It is based only on the discordant pairs (where outcome is different) and is not used to assess concordance.

What, then, does a large p value mean? In the absence of any other information, and assuming that the data arise from a properly designed study, the safest and most accurate interpretation is that "there is insufficient evidence that the null hypothesis is false." Whether a nonsignificant p value provides useful information will depend on considerations such as how well powered the study is to detect important clinical effects, as described further in the next section. The reality is that the p value, whether small or large, actually carries very little information. It conveys no information about the direction or magnitude of an effect, no information about the uncertainty in the estimated effect, and no information about the clinical significance of the effect. Even a small p value is no guarantee that an effect has clinical significance. In studies with a very large sample size, even a modest departure from the null hypothesis can be associated with a high degree of statistical significance, but the departure from the null hypothesis may have little practical meaning.

The quantity that contains this missing information is the confidence interval.[4] The confidence interval represents a range within which the true population value likely lies. An interval with a 95% confidence level will be expected to contain the true value of an effect 95% of the time, and miss it 5% of the time. Of course, for any particular confidence interval it is unknown whether it does or does not contain the true value. In contrast, the p value provides information only about a single value. Figure 5-1 shows a variety of scenarios for the outcome of a statistical analysis and illustrates how confidence intervals relate to the concepts of statistical and clinical significance.

When a p value is not less than 0.05, the associated null value will be contained within the 95% confidence interval. The fallacy that this is, therefore, the true value is readily apparent, since the null value is only one among a range of possible values that could reasonably have produced the observed data.

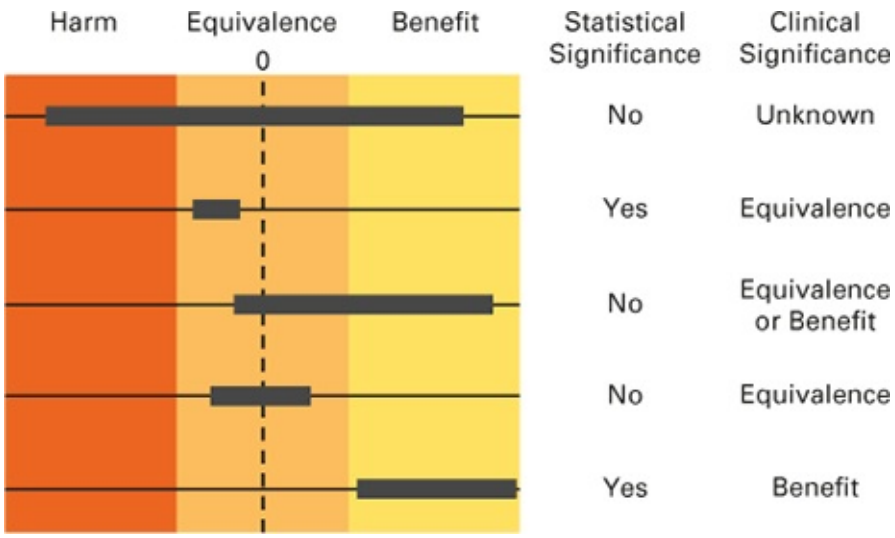

Fig. 5-1 Interpreting confidence intervals with respect to statistical and clinical significance.

Heavy black lines illustrate 95% confidence intervals that could arise from a comparative clinical trial of an experimental therapy compared with standard therapy. The vertical dashed line indicates exact equality between arms, and the light orange area indicates a difference close to equality that is considered clinically insignificant. The yellow area indicates a difference between arms that would be considered a clinically significant benefit for the experimental arm; the dark orange indicates clinically significant harm for the experimental arm. The determination of statistical significance (at the $\alpha = 0.05$ level) is based only on whether the confidence interval includes 0. The full range of the confidence interval must be examined to determine what conclusions are reasonable with respect to the clinical significance of the study.

SAMPLE SIZE AND POWER CALCULATIONS

The calculation of sample size for a clinical trial depends on a variety of factors, including the endpoint to be evaluated and the particular method of statistical analysis; however, all such calculations depend on the same basic considerations: the acceptable rates of type I and type II error (or power); a null hypothesis and the particular alternative to the null hypothesis for which power is calculated; and the variability of the outcome. In some cases, the latter is determined by the null hypothesis and a specified alternative, in other cases, it can vary independently. These factors influence the calculation of sample size or power in a reasonably intuitive way, summarized in Table 5-3.

The most common value specified for the α level is the ubiquitous 5%, especially in comparative clinical trials, and a common value for power is 80% or 90%, but of course these can vary depending on the situation. The factor with the greatest influence in the design of a clinical trial is the particular alternative to the null selected for use in the calculations. This is frequently referred to as the effect size that one is (scientifically) hypothesizing or would be of interest. Depending on the outcome of interest in the study, the effect size may be, for example, a difference in proportions, a difference in means, or a hazard ratio (HR). In most cases, with all else being equal, a halving of the effect size used in the calculation results in roughly a fourfold increase in the sample size requirement. Conversely, doubling the effect size results in roughly a 75% lower sample size. Thus, it is critically important to make realistic assumptions about the effect size for which a clinical trial is designed.

As previously noted, the hypothesis testing framework is useful for formulating the calculation of power and sample size, but is an artificial and oversimplified view of the clinical trial as a whole. In the real world, interpreting a clinical trial and acting on its results is a far more complex undertaking than simply rejecting or not rejecting a statistical null hypothesis.

BAYESIAN STATISTICS

Most of the familiar statistical concepts and applications encountered in medical research are based on what is called the “frequentist view” of statistics and probability. In the frequentist perspective, probability is a quantity that, in principle, reflects the underlying long-term frequency with which an event will occur under repeated observation. This frequency is governed by unknown but fixed parameters that define a probability distribution. For example, the mean and standard deviation of a normal distribution determine how frequently, on average, a value from that distribution will exceed a certain value. The statistical procedures derived from this perspective are all based on relating observed data to the fixed parameters of the probability model that generates the data.

Table 5-3 **Factors Influencing Sample Size in a Comparative Study**

Quantity	Effect
Type I error rate	Decreasing error rate increases sample size
Type II error rate	Decreasing error rate increases sample size
Effect size*	Smaller effect size increases sample size
Variability	Smaller variability decreases sample size

*Difference between null and alternative hypothesis values.

Bayesian statistics also seek to relate observed data to the probability model that generates the data. The term “Bayesian” derives from a basic theorem known as “Bayes rule,” which was formulated by the Reverend Thomas Bayes in the mid-18th century. Although partly just a matter of mathematics, the Bayesian formulation allows the incorporation of a more subjective notion of probability—the notion of probability as a measure of the strength of one's belief in a single outcome—for example, the probability that your team will win the Super Bowl this season or that the moon is made of green cheese. It further allows the application of this view of probability to unknown parameters governing a probability distribution—for example, the probability that the rate of response to a treatment exceeds a fixed value. This is not a meaningful concept in a frequentist framework, because the response rate is viewed as a fixed number.

The Bayesian approach to statistical inference involves three basic steps: (a) specification of a prior distribution for the unknown parameter, based on existing knowledge; (b) collection of data; and (c) use of the data to update the prior distribution, resulting in a posterior distribution. A simple example involves a card game such as poker. In a fair game, it is presumed that any particular hand of cards is equally likely to be dealt to any particular player (the prior distribution). After the cards are dealt, one observes one’s own hand and perhaps parts of the hands of other players (the data). This information can be used to recalculate the probability that other players hold particular hands, which are no longer equally likely (the posterior distribution).

Although the mathematical basis of Bayesian statistics is not in question, the first of the steps previously noted is one that has the potential to generate controversy in applying Bayesian methods to medical research. This is because the prior distribution is allowed to incorporate subjective judgments about the quantity under investigation. Many statisticians argue that prior beliefs about an unknown quantity represent a form of bias that should be avoided in scientific research; others argue that ignoring prior knowledge is in itself a bias. It is

possible to employ a Bayesian framework in a way that minimizes the use of information contained in prior beliefs, thereby letting the data speak for themselves. This is done by choosing a prior distribution that is said to be uninformative with respect to the quantity under study (also sometimes called a "flat prior"). Interestingly, and reassuringly, statistical procedures conducted within the latter framework are often very similar, or even identical, to those conducted within a frequentist framework, and they produce very similar results. They simply use different mathematical machinery and terminology.

Some clinical trial designs make use of Bayesian concepts, and these are described briefly in the next section, on clinical trial design. Although less common, some forms of data analysis may also employ Bayesian methods. In situations in which Bayesian methods have been employed in the design or analysis of a research study, one should always be able to ascertain the nature of the prior distribution. If a subjective or informative prior distribution has been used, its rationale and appropriateness should be carefully considered, and it should be recognized that the choice of a prior distribution can influence the interpretation and conclusions of the study.

KEY POINTS

- Statistical significance and clinical significance are different concepts.
- Large p values, by themselves, are not evidence for a lack of effect; they should generally be regarded as uninformative.
- Confidence intervals provide information about both statistical and clinical significance.
- Sample size requirements for comparative trials are extremely sensitive to the assumed effect size (difference in outcome between arms); for example, halving the effect size results in a fourfold increase in the total number of patients required for a trial.
- Frequentist and Bayesian methods provide alternative frameworks for viewing the parameter of interest in a statistical model.

CLINICAL TRIAL DESIGN

Clinical trials are a fundamental part of the process of medical science leading to the development of treatments for cancer, as well as its prevention and detection.[5-8] In oncology, clinical trials have historically been classified according to the general phases of drug development. Although this classification by no means accounts for all of the clinical trials relevant to oncology, it is a useful starting point for describing the key elements of trial design, which necessarily vary according to the objectives of the trial.

Phase I trials focus on toxicity, with a goal of determining a dose and treatment regimen that would have acceptable toxicity if the drug were effective. Phase II trials are designed to provide a preliminary indication of whether that therapy is effective. The result is considered preliminary because the study is uncontrolled, uses a surrogate endpoint (such as tumor response instead of survival), or is not large enough to rule out chance effects. The phase III trial is typically a controlled, randomized trial large enough to distinguish chance effects from true treatment effects. It is also not uncommon to see trials that are classified in other ways: e.g., as phase I/II, phase Ib, or phase II/III. There is no single governing body for trial nomenclature, and trial

sponsors are free to attach whatever labels they wish to a particular study. Sometimes this is driven by regulatory or insurance considerations: for example, the Food and Drug Administration offers definitions of trial phases for studies that it regulates, and insurers may decline coverage for patients participating in certain phases of trials.

PHASE I

The initial phase of human experimentation in the development of chemotherapeutic agents involves finding a dose that produces an acceptable level of toxicity. What is acceptable obviously depends on the disease in question: in diseases like cancer, with significant morbidity and mortality, the acceptable level of toxicity may be quite high. Indeed, with cytotoxic drugs, the toxicity of the drug may be, to some extent, a measure of its potential efficacy. With newer cytostatic or targeted agents, however, the presumed correlation of toxicity and efficacy may not hold, and the design of appropriate phase I trials for such agents can be challenging.

Traditionally, the objective of a phase I trial is to determine the maximum dose of an agent, either alone or in combination with other agents, that will produce an acceptable level of toxicity when administered on a specific schedule and by a specific route. This dose is usually referred to as the maximum tolerated dose (MTD) or the recommended phase II dose. For example, a simple definition of acceptable toxicity might be “toxicity of grade 4 or worse in not more than one out of six patients,” where grade 4 toxicity is defined according to standard criteria. The toxicity that defines the MTD is said to be dose-limiting toxicity (DLT). Once an MTD is established, one presumes that this dose will be used in further evaluations of efficacy in phase II trials; however, this logical progression is complicated by the fact that patient populations in phase I and II trials are likely to be dissimilar.

Phase I Endpoints and Patient Population

Since agents or regimens being tested in phase I trials have unproven efficacy, ethical considerations necessarily limit the patient population that can be enrolled in these trials. Typically, these are patients for whom multiple lines of therapy have failed and for whom no standard treatment options remain. The patient population is generally heterogeneous with respect to disease diagnosis, but may be restricted to specific cancers, depending on the type of agent being tested and its mechanism of action. For example, it would have been inappropriate to test a highly targeted agent like imatinib mesylate in a phase I trial in cancers that do not have the specific mutation targeted by this drug.

The most important endpoint to specify in a phase I trial is the definition of DLT. Although certain definitions are relatively common, the definition can vary considerably and may be tailored to reflect toxicities expected on the basis of the mechanism of action of the agent. The most common standard for rating the severity of toxicities is the National Cancer Institute’s Common Toxicity Criteria, which provides specific criteria for grading a wide range of toxicities on a numeric scale: 0 (none), 1 (mild), 2 (moderate), 3 (severe), 4 (life-threatening), 5 (fatal). Most definitions of DLT exclude grade 1 or 2 toxicities, and possibly some grade 3 toxicities if these are expected and manageable—for example, neutropenia or nausea/vomiting. Thus, a composite definition of DLT might be “grade 3 nonhematologic toxicity or grade 4 hematologic toxicity.” One must also specify the time frame during which toxicities will be evaluated for purposes of the trial. This is typically a relatively short time, such as 4 weeks or one treatment cycle, and, thus, captures only acute toxicities. Toxicities that occur after the specified observation period are not reflected in the outcome of the phase I trial, but may influence how

the agent is used in later phase II trials.

Phase I Design Options

Almost all phase I trials prespecify the starting dose of the agent being tested and a sequence of doses to be tested subsequently. The initial dose level is generally derived either from animal experiments, if the agent in question is completely novel, or by conservative consideration of previous human experience, if the agent in question has been used before but with a different schedule and route of administration or with other concomitant drugs. A common starting point based on the former is from one-tenth to one-third of the mouse LD_{10}, the lethal dose for 10% of mice, adjusted for size of the animal on a per-kilogram basis or by some other method. Subsequent dose levels are determined by increasing the preceding dose by decreasing fractions—for example, 100%, 67%, 50%, 40%, and 33%—thereafter. Such sequences are often referred to as modified Fibonacci. With some agents, particularly biologic agents, the dose levels may be determined by log (i.e., 10-fold) or half-log increases of the preceding dose.

Designs for phase I trials are constrained by the practical need to use relatively small numbers of patients and the ethical need to approach the MTD conservatively. By far the most common design option for phase I trials is the 3+3 design. This design, or minor variations on it, has been in use since the 1950s. Briefly, beginning at the first dose level, cohorts of three patients are entered. If all three patients receive the agent at the specified dose without DLT, then the next cohort of three patients is entered at the next higher dose level. If two of three patients experience DLT, then the toxicity associated with that dose is considered unacceptable, and the dose level below it (if any was tested) is considered the MTD. If one of three patients experiences DLT, then an additional cohort of three patients is entered at the same dose level. If no further DLT is seen, then escalation to the next dose level is permitted for the next cohort; otherwise, the toxicity is considered unacceptable, and the dose level below it is considered the MTD.

If the starting dose is too low, and/or the spacing of doses is too small relative to the steepness of the dose–response curve, then large numbers of patients may be enrolled at doses without toxicity (and likely with no therapeutic benefit). To address this problem, an accelerated titration design may use only single patients at the initial dose levels. Escalation continues until a grade 2 toxicity is seen, and then a standard 3+3 design is implemented at the next lower dose level. Because dose escalation is permitted on the basis of the experience of only one patient, such designs are usually restricted to situations in which there is some human experience with the agent, and the toxicity profile is known to be manageable.

Another design option, based on a Bayesian approach, is referred to as the continual reassessment method. Although there are many variations in the details, the basic concept is to define the probability of DLT that is acceptable (e.g., 20% or 33%), assume a simple mathematical model for a dose–response curve, and then, after each patient (or cohort of patients) has been treated, update the mathematical estimate of the dose–response curve and treat the next patient (or cohort) at the dose level at which the estimated probability of DLT would be closest to the target. Although it is well recognized in the statistical literature that model-based designs can outperform the 3+3 design in many aspects, this design is still frequently used in practice because of its simplicity and transparency.

The modified toxicity probability interval design was proposed as a design that is simple to implement yet has superior performance compared with the 3+3 design.[9] In it, toxicity

probability intervals are defined that refer to underdosing, proper dosing, and overdosing. Bayesian-model–based inference is used to determine the likelihood that a dose toxicity rate will be in each of these intervals. Dose-escalation decisions are easily made based on the three dosing intervals; they can be described using simple tables for ease of application. The modified toxicity probability interval design tends to treat fewer patients at doses greater than the MTD and is more likely to identify the true MTD than the 3+3 design.

For some treatments, toxicity is not expected to be substantial throughout the anticipated therapeutic range of doses, and the objective of dose finding is to determine the range of biologically active doses. In this setting, further escalation of the dose to an MTD is not needed to maximize the benefit of the treatment.

PHASE II

Trials falling under the umbrella of phase II can be highly variable in design. These can range from small, single-arm trials involving a dozen patients to double-blind, placebo-controlled trials involving 200 patients. Trials like the latter typically fall into the phase II category only because they use an endpoint or sample size that falls short of that required to get regulatory approval for a drug. Nevertheless, there are some typical features that characterize a phase II trial: the endpoints are related primarily to efficacy, rather than to toxicity; the sample size is moderately small, often 25 to 50 patients; the efficacy endpoint is short term and/or not definitive, such as tumor response; and the study relies on historical experience as context for judging whether the result is promising enough to carry forward to a phase III trial. This is the type of trial that will be considered phase II for purposes of this discussion.

Phase II Endpoints and Patient Population

The general objective of a phase II trial is to evaluate the potential effectiveness of a drug or regimen in a specific patient population. The patient population is usually somewhat narrowly defined (e.g., patients with stage III estrogen-receptor–negative breast cancer). Typically, patients enrolled in phase II trials have experienced treatment failure with at least one or two standard therapies; however, in diseases with no effective therapy, or when adding a new agent to the standard of care, a phase II trial may be tenable in the first-line setting. Finally, there are cases in which the treatment being evaluated in a phase II study is not novel, but is being applied to a new patient population (e.g., a different type of cancer, or a subtype of cancer defined by a genetic or another biologic marker).

As noted, the primary endpoint of a phase II trial is efficacy. The specific endpoint driving the trial design reflects a balance between the ability to assess it during a relatively short time frame (weeks or months) and its validity as a measure of true long-term benefit. For this reason, 5-year survival is almost never an endpoint for a phase II trial, although 6-month or 1-year survival might be. With cytotoxic agents, partial or complete tumor response is a common and accepted phase II endpoint; with cytostatic agents, stable disease or lack of progression might be included as a successful short-term response.

A number of schemes for defining tumor response have been established. For solid tumors, the Response Evaluation Criteria in Solid Tumors (RECIST) is standard. Most response definitions for solid tumors are based on the size and presence of measurable lesions. Other criteria must be used for hematologic malignancies. Whatever criteria are used, the trial design must specify how and when response will be assessed. The assessment criteria used to judge the outcome of the trial must be homogeneous within the trial and also reasonably comparable

to other trials or to whatever data are used as historical context.

In addition to tumor response and survival, there has been growing interest in the use of tumor biomarkers or other biochemical measures to assess the effectiveness of therapy (e.g., prostate-specific antigen in prostate cancer, CA125 in ovarian cancer, and carcinoembryonic antigen in colon cancer). A biomarker is a single trait or signature of traits that separates different populations, including genetic sequencing or mutation of cancer. The interest in biomarkers correlates especially with the use of so-called targeted therapy, which may have very specific mechanisms of action that are measured by a variety of assays, possibly from blood or tumor samples that can be obtained quickly and easily; although, the assays themselves may be neither inexpensive nor quick. Unfortunately, the appropriate use of biomarkers as surrogate endpoints requires specific criteria that may be difficult to validate. Notably, it is not sufficient to establish a correlation between the biomarker and outcome. A full discussion of these issues is beyond the scope of this chapter, but in general, one should be cautious in evaluating claims of effectiveness that are based on biomarkers or other surrogate endpoints.

Phase II Design Options

First, consider the most common phase II paradigm: a simple single-arm trial using historical outcomes as a point of reference for the design and interpretation of the trial. Such a trial is often designed from a hypothesis-testing point of view. For example, suppose that tumor response is the endpoint of choice, and that standard regimens have a response rate of approximately p_0, or otherwise that a regimen with a response rate of p_0 would be considered not worthy of further study. Conversely, suppose that p_1 is a response rate that would represent meaningful improvement compared with standard regimens or otherwise that a regimen with a response rate of p_1 would be considered of interest for further study.

The hypothesis-testing paradigm assumes that at the end of the trial, one will either (a) conclude that the true response rate for the regimen is greater than p_0 or (b) not conclude this. The design parameters must also include a specification of the false-positive (type I or α) error rate and false-negative (type II or β) error rate. The false-positive error rate is the probability of falsely concluding that the true response rate for the regimen is greater than p_0, when in fact it is equal to p_0. The false-negative error rate is the probability of falsely not concluding that the true response rate for the regimen is greater than p_0, when in fact it is greater than p_0. Often the false-negative rate is evaluated at p_1, the target of interest; these error rates typically range from 5 to 20%. The possibility of relatively high error rates is accepted, because low error rates require a larger sample size for the trial; however, the major factor driving the sample size is the difference between p_0 and p_1: the larger the difference, the smaller the sample size required for a specified set of error rates. This fact often leads to unrealistic design assumptions—i.e., setting p_0 unrealistically low or p_1 implausibly high.

Table 5-4 shows some possible trial designs under a variety of assumptions about p_0 and p_1 and allowable error rates. The value r is the minimum number of responses required in n patients required to conclude (with a specified type I error rate no greater than α) that the true response rate for the regimen is greater than p_0. A common misconception is that observing r responses allows one to conclude that the true response rate is at least p_1. That this is not the case is obvious from the fact that the observed minimum response rate required (i.e., r/n) is

less than p_1.

Table 5-4 Examples of Single-Stage Phase II Designs

Design Criteria				Resulting Design	
p_0	p_1	α	β	n	r
0.10	0.25	0.05	0.10	55	10
0.10	0.25	0.05	0.20	40	8
0.10	0.25	0.10	0.10	40	7
0.10	0.25	0.10	0.20	31	6
0.10	0.25	0.05	0.10	33	7
0.10	0.25	0.05	0.20	25	6
0.10	0.25	0.10	0.10	25	5
0.10	0.25	0.10	0.20	18	4
0.50	0.70	0.05	0.10	53	33
0.50	0.70	0.05	0.20	37	24
0.50	0.70	0.10	0.10	39	24
0.50	0.70	0.10	0.20	28	18

Abbreviations: p_0, response rate under null hypothesis; p_1, response rate under alternative hypothesis; α, type I (false-positive) error rate if $p = p_0$; β, type II (false-negative) error rate if $p = p_1$; n, smallest sample size that satisfies design criteria; r, minimum number of responses required to reject null hypothesis and conclude that $p > p_0$.

In some cases, the endpoint of interest in a phase II trial may not be tumor response but a time-to-event endpoint, such as overall survival or progression-free survival. For many cancer diagnoses, unfortunately, the median time to death or progression is measured in months or weeks. Thus, for example, if historical data suggest that the median progression-free interval with standard regimens is 3 months, this can be recast into the paradigm by noting that this is equivalent to specifying that the percentage of patients alive and progression-free at 3 months, p_0, is 50%. With some simple assumptions about the distribution of progression times, a hypothetical improvement to the median progression-free interval can be converted to a value of p_1 at 3 months.

The hypothesis-testing framework is useful for formulating a design and deciding on a sample size. In reality, however, it is rare for the hypothesis test to be formally carried out at the end of the trial. Instead, one calculates an estimate and confidence interval for the response rate associated with the agent and places this in context with a host of other factors before deciding whether further trials are warranted. The estimated response rate is relatively imprecise (Table 5-5) and actually provides only a rough indication of the response rate.

A common alternative to the simple single-stage design is a one that enrolls patients in two stages. The motivation for this alternative is simple. For example, consider the first scenario in Table 5-4, requiring 55 patients and 10 observed responses in order to reach a successful conclusion. Suppose that in a particular trial, after 25 patients have been treated, only two

responses have been observed. Thus, in order to reach the target of 10 responses, 8 must be observed in the final 30 patients, a seemingly unlikely scenario given what has been observed in the initial patients. Two-stage designs formalize the intuitive notion that the trial should be terminated early if the results are poorer than hoped for and that there is little chance of a successful outcome to the trial. This is done by dividing the enrollment into two stages and specifying the minimum number of responses that must be observed in the first stage before enrolling the second stage. Many two-stage designs may satisfy a given set of design parameters. One common criterion for selecting a two-stage design is to use the optimal Simon design, which minimizes the average number of patients that would be enrolled if the true response rate was no better than the historical reference p_0. Table 5-6 shows the optimal Simon two-stage design for the same situations as in Table 5-4. Note that the maximum sample size for these designs is often only slightly larger than for a single-stage design, with error rates satisfying the same specifications. For example, the design for the first scenario uses (at most) 57 patients compared with the 55 patients required with a single-stage design.

Table 5-5 Confidence Intervals for True Response Rates

Observed Rate = 0.10			Observed Rate = 0.50		
n	***r***	**95% CI**	***N***	***r***	**95% CI**
10	1	0.3, 44.5	10	5	18.7, 81.3
20	2	1.2, 31.7	20	10	27.2, 72.8
30	3	2.1, 31.7	30	15	31.3, 68.7
40	4	2.8, 23.7	40	20	33.8, 66.2
50	5	3.3, 21.8	50	25	35.5, 64.5
60	6	4.9, 17.6	60	30	39.8, 60.2

Abbreviations: CI, confidence interval for true response rate (Clopper-Pearson exact interval); *n*, sample size; *r*, observed number of responses.

The term “optimal” relates to a mathematical criterion, which sometimes leads to a design with an imbalance in the sizes of the stages that seems impractical; for example, by assigning 70% of the enrollment to the first stage. In such cases, there are almost always alternatives that are mathematically not quite optimal, but are more appealing in terms of the split between stages while still satisfying the other design parameters.

All of the designs considered thus far are single-arm, nonrandomized; however, some phase II trials use random assignment to allocate patients to more than one arm. Phase II trials may also randomly assign patients to a control or placebo group; this is discussed further in the next section. The reasons motivating randomized phase II designs with multiple therapeutic arms are many and sometimes somewhat controversial. Some studies assert that there is no intent to compare the arms: they are to be regarded as independent trials of different agents or regimens that happen to target the same patient population, and random assignment is simply a mechanism to ensure that the arms enroll patients with roughly similar characteristics.

Table 5-6 **Examples of Two-Stage Phase II Designs (Optimal Simon Design)**

Design Criteria				Resulting Design			
				First Stage		Overall	
p_0	p_1	α	β	n_1	r_1	N	r
0.10	0.25	0.05	0.10	28	4	57	10
0.10	0.25	0.05	0.20	18	3	43	8
0.10	0.25	0.10	0.10	21	3	50	8
0.10	0.25	0.10	0.20	13	2	34	6
0.10	0.25	0.05	0.10	18	3	35	7
0.10	0.25	0.05	0.20	10	2	29	6
0.10	0.25	0.10	0.10	12	2	35	6
0.10	0.25	0.10	0.20	7	1	18	4
0.50	0.70	0.05	0.10	23	13	57	35
0.50	0.70	0.05	0.20	15	9	43	27
0.50	0.70	0.10	0.10	21	12	45	27
0.50	0.70	0.10	0.20	12	7	32	20

Abbreviations: p_0, response rate under null hypothesis; p_1, response rate under alternative hypothesis; α, type I (false-positive) error rate if $p = p_0$; β, type II (false-negative) error rate if $p = p_1$; n_1, sample size for first stage; n, total sample size after both stages; r, total number of responses required to reject null hypothesis and conclude $p > p_0$; r_1, minimum number of responses required in first stage to enroll second stage.

The more classic randomized phase II trial is one in which two or more variations of the same experimental agent, or two or more closely related experimental agents, are compared in order to "pick the winner" for subsequent study or for comparison against standard therapy in a phase III trial. For example, two plausible doses of an agent or a gene vaccine may be carried in three possible vectors. In this case, the stated desire is to compare the arms and pick the best one, but since both arms are experimental there is no need to control the false-positive (type I) error rate. That is, if the true response rate for two experimental arms is equivalent, there is no error in picking one over the other. This is in contrast to the prototypical phase III paradigm, in which concluding that the experimental arm is different from standard, when in fact they are equivalent, is considered an error.

In a pick-the-winner design, the arm that has the highest observed response rate at the end of the trial is selected for further study. The sole design consideration is that if the response rates in the two arms differ by a specified amount *A,* then the false-negative (type II) error rate should be no higher than β. Thus, Δ is a difference in response rates that is considered clinically important. If two arms differ by this amount or more, then the sample size should be large enough that the observed response rate in the better arm will be higher than that in the other arm, with probability 1 – β. Table 5-7 provides some examples of design parameters for a randomized phase II trial and the sample size required for each. One advantage of the pick-the-

winner design is that the objective of picking the winner requires fairly modest sample sizes, which is often feasible in the phase II setting. However, because of these limited sample sizes, these studies are not powered to do formal statistical hypothesis testing between the arms, and these comparative statistical analyses should not be conducted.

Increasingly phase II trials are conducted in a biomarker driven fashion.[10,11] Biomarkers may be prognostic, whereby they affect the risk of the outcome in the absence of treatment, or predictive, whereby they change the outcome in response to a particular targeted treatment. Biomarkers that are prognostic may be used to identify high-risk patients, so that enriching the patient population for those with the biomarker can make it easier to detect a signal due to the higher event rate. If the biomarker is predictive for a particular therapy, then a biomarker subgroup would be expected to have a stronger efficacy signal. Basket trials may be used to enroll patients with similar tumor molecular characteristics across multiple tumor locations, in order to treat them with the same biomarker targeted treatment. Umbrella trials are often used to conduct multiple trials under one protocol, where patients first have their biomarker profile assessed and then are assigned to a particular randomization and biomarker targeted treatment scheme depending on their biomarker profile.

Table 5-7 Minimum Sample Size (per Arm) for Pick-the-Winner Randomized Phase II Designs

	Two Arms (p_0, p_1)		Three Arms (p_0, p_0, p_1)	
Difference ($p_1 - p_0$)	$1 - \beta = 0.80$	$1 - \beta = 0.90$	$1 - \beta = 0.80$	$1 - \beta = 0.90$
0.10	45	92	78	134
0.15	22	43	37	61
0.20	13	25	22	35

Abbreviations: $1 - \beta$, probability that arm with highest true response rate has highest observed response rate; p_0, lower response rate; p_1, higher response rate.

A final phase II design strategy that should be mentioned is an approach known as “adaptive randomization.” The trial starts out by randomly assigning patients in equal proportions to each arm. As outcome data on these patients accumulate, the randomization scheme is altered so that it favors arms in which the strength of the evidence that the response rate is greater than p_0 is greatest. Conversely, it disfavors arms in which the strength of evidence is lowest, and ultimately may drop arms altogether if the strength of evidence falls too low. Adaptive randomization has been used in biomarker-based designs, such as the I-SPY2 trial,[12] so that patients with certain biomarker profiles who respond more favorably to certain treatments will be randomly assigned more frequently to those agents. Such designs are associated often with Bayesian methods, although this is not an essential feature of the approach.

Although adaptive randomization seems like a highly rational way to select among competing experimental regimens, in practice it is often difficult to mount such a trial. The different agents likely have different sponsors and advocates, each of which naturally has a principal interest in their own agent and is reluctant to cede control of its evaluation to an external process. Others have some ethical discomfort with the notion of unequal allocation based on evidence of

efficacy, feeling that this violates the principle of clinical equipoise (that one truly is unable to say which treatment is better for the patient population to be enrolled).

Biases in Phase II Trials

Among all the phases of therapeutic development, phase II is the most fraught with the potential for bias. The major source of bias is the absence of contemporaneous randomized comparison groups. Historical outcomes vary widely, for many reasons, and past experience may reflect many factors besides the agents being tested. These can include the eligibility criteria defining the patient population; the definition, timing, and methods used to assess outcome; standards of supportive care that vary by institution and over time; the use of surrogate endpoints; and, of course, simple random variation. Even in the absence of any systematic bias—an ideal unlikely to be achieved—the random outcomes observed in relatively small numbers of patients lead to many false conclusions. The most observable of these are false-positive results—agents that look promising in phase II trials often fail to be proven effective in phase III trials. Less observable, but just as unfortunate, are agents that are in truth effective but fail to show positive results in phase II trials. Randomized control arms are sometimes used in phase II trial settings to remove potential sources of bias resulting from historical control comparisons[13]; however, they introduce additional variability in the treatment-effect estimate. As a result, they typically require larger sample sizes and may use a higher type I error rate in order to maintain sufficient power to identify promising agents in the phase II setting.

PHASE III

The randomized clinical trial is the gold standard of clinical research, and this is the trial that is most often referred to as a “phase III trial.” The classic goal for the phase III trial is to compare an experimental therapy with a standard therapy. A common analogy applied to this setting is that of a legal trial. In a clinical trial, one formulates a null hypothesis that the experimental treatment is equally as effective as the standard (the defendant is innocent), although, of course, there must be some scientific basis to believe otherwise (the prosecution has evidence). In order to establish effectiveness (guilt), a trial is conducted that will lead to the rejection of the null hypothesis in a convincing way (beyond a reasonable doubt). As in a legal trial, failure to reject the null hypothesis (finding of not guilty) is not the same as establishing equivalence of the therapies (innocence).

Of course, randomized clinical trials do not always fit the classic paradigm of an experimental therapy compared with standard therapy, but the principles underlying the design and analysis will most likely be equally applicable.

Basic Principles

The primary goal of a phase III trial is to provide a comparison of treatments that is free of the many biases that occur when trying to compare phase II trials conducted at different times, at different institutions, among different patient populations, etc. The accepted standard for ensuring freedom from bias is randomization. Randomization is not the only way to create comparable treatment groups, nor does randomization guarantee that the results of a particular trial are correct, but it does allow one to control and quantify the possibility of error.

The most common randomization strategy is equal allocation among all treatment arms.

From the standpoint of statistical power, this is the most efficient allocation, and also the one most compatible with the notion of clinical equipoise. A common variation of simple randomization is stratified randomization, which seeks to ensure even greater balance between arms by randomly assigning patients within strata defined by factors that strongly predict outcome. Additionally, the randomization may be blocked, which generally refers to a form of stratification designed to keep the number of patients allocated to each arm balanced over time. Stratification and blocking are most useful in small trials, in which random imbalances large enough to skew the composition of the treatment arms are not impossible. When the trials become larger (several hundred patients), these devices are largely superfluous, as it becomes highly unlikely that the arms will become meaningfully imbalanced by chance.

Departures from equal allocation sometimes occur—for example, a 2:1 allocation between the experimental and control arms. Most commonly, this is justified using the argument that this allocation makes the trial more attractive to potential patients and their physicians, particularly when there is no way to get access to an experimental agent except through participation in the trial. It also allows one to generate more experience with the new agent. However, this argument seems to presume that the experimental therapy is likely to be more effective than standard therapy, which contradicts the principle of equipoise.

Other common, but by no means necessary, components of a phase III design include the use of a placebo, and the implementation of blinded (to the patient) or double-blinded (to both patient and physician) treatment assignments. Although randomization can help ensure that the treatment arms are balanced with respect to patient characteristics at the start of the trial, it cannot remove bias that occurs after the trial starts, when differences arise between arms with respect to the conduct of the trial or the evaluation of trial data. This bias can be entirely unintentional and unconscious, but it reflects behavior by either patients or physicians that compromises the benefits of randomization. The susceptibility of trials to bias can vary considerably depending on the endpoint in question. For example, placebo effects and ascertainment bias are probably unlikely to affect a trial in which mortality is the primary endpoint. On the other hand, assessment of tumor response without blinding to treatment assignment could be subject to subtle bias, and studies with self-reported quality-of-life endpoints are obviously prone to placebo effects.

The use of placebo as the control arm in therapeutic oncology trials is extremely rare, since usually some form of therapy is available, even if it is ineffective. A placebo control is much more likely to be used in adjuvant trials or in trials of combination therapy in which a new agent is being added to an existing combination. Though one may question the extent to which placebo effects play a role in such settings, if a placebo is feasible it adds credibility to a trial even if the likelihood of placebo effects is small. In some cases, of course, the nature of the treatments differs so much that neither a placebo nor blinding is feasible.

The most acceptable primary analysis of a phase III trial is the intention-to-treat analysis. This analysis includes all patients enrolled in an arm of a randomized trial, no matter what happens thereafter—for example, if they are unable to receive the full course of treatment, they cross over to another treatment, etc. Since any of these contingencies can be related to the treatment itself and to the effectiveness of the treatment, an unbiased analysis must incorporate that information. For example, if a new drug is potentially effective but many patients will not take it because of its side effects, then as a practical matter it may not be as effective as a drug with fewer side effects.

Nevertheless, alternative analyses may be undertaken that deviate from the intention-to-treat principle. These may involve analyzing a subset of patients (e.g., those who received a

minimum amount of therapy) or defining the treatment groups according to the treatment actually received instead of the treatment to which they were randomly assigned. These alternative analyses can be informative, but must be interpreted cautiously and are problematic when the results differ markedly from the intention-to-treat analysis.

Other subset analyses may be undertaken to evaluate whether the treatment difference, if any, varies according to other factors, such as disease stage, age, or the presence of a biomarker. Even if specified in advance, the results of such subset analyses must be interpreted cautiously. Phase III studies are almost never large enough to have reliable power in subsets of patients; conversely, examining many subsets of patients in a trial with an overall negative result can lead to spurious findings that are caused by only random fluctuation.

Interim Analysis

Randomized phase III trials can be large, expensive, and of several years' duration. For this reason, most phase III trials have a provision for interim analysis at one or more points in time, with the possibility of terminating the trial early. The indications for early termination can be varied and are generally specified in advance. These may include strong evidence that the experimental therapy is better than the control therapy, strong evidence that it is worse, or a determination that the trial will not be conclusive (futility). Interim analyses are also ethically important, as information may be sufficient early to alter trial conduct.

A number of statistical approaches to interim analysis codify the timing and nature of the analyses and the threshold required to terminate the trial early. In the case that the trial is to be stopped early because of evidence that the experimental therapy is superior, the overall false-positive rate (type I error rate) for the trial needs to be quantified and controlled because multiple analyses of the data without adjustment can lead to inflation of the type I error rate. Because small sample sizes are subject to a large amount of random variation, the threshold for stopping a trial early generally involves a high degree of statistical significance, meaning type I error rates that are much lower than a standard 0.05 level of significance (e.g., as low as 0.001 or 0.0001). Also, if some of the type I error rate is "spent" during interim analyses, then the significance level for the final analysis will be lower than nominal. The threshold significance levels at each of the interim analyses and final analysis comprise the stopping boundaries.

In some cases, the data at an interim analysis contain little suggestion that there is a difference in outcome between arms, or indicate that the difference is much smaller than hypothesized when designing the trial. Based on the accumulated data and assumptions about the true treatment effect, it is possible to generate estimates of the probability that the trial will prove successful at demonstrating the superiority of the experimental arm. If this probability is too low, the trial may be terminated early so as to minimize unnecessary time and expense. This is referred to as "stopping for futility." On the other hand, as previously noted, the inability to demonstrate a difference is not the same as demonstrating equivalence. A trial that is terminated early for futility may be inconclusive. Therefore, in some cases, it may be desirable to complete a trial that cannot demonstrate a treatment benefit, if completing the trial might allow one to make firm conclusions regarding the lack of benefit.

Although the interim analysis plan for a phase III trial should be prespecified and an integral part of the trial design, the decision to stop a trial early involves complex and important issues that cannot be summarized in a simple statistical test. Typically, the results of an interim analysis will be reviewed by a data and safety monitoring board. The role of this board is to independently review the results of an interim analysis, consider the results in context with a

host of other factors (which may be scientific, ethical, legal, or financial), and make a recommendation as to whether to continue the trial or not.

Endpoints

Phase III clinical trials focus on identifying whether the treatment being investigated provides a direct clinical benefit to patients. In the oncology setting, an improvement in survival is often the gold standard for demonstrating such a benefit. However, other endpoints are also used to demonstrate clinical benefit, while providing efficiencies in trial design.[14] “Progression-free survival” (PFS), defined as the time until disease progression or death, or “disease-free survival” (DFS), defined as the time until disease relapse or death, provide a faster determination of the endpoint that can speed up trial completion. DFS typically uses only the patients who have a complete response, whereas PFS can be defined for all patients. “Time to progression” (TTP) is defined as the time until disease progression, but is complicated by how to handle patients who die from causes other than progression (see the section on Competing Risks and Cumulative Incidence for more detail). Event-free survival may include additional “events,” besides death and progression, but these are often defined in a study-specific way. All of these endpoints may introduce many complications in interpretation. Superiority on TTP, PFS, or DFS can occur despite a therapy causing more toxic deaths, and superiority on PFS or DFS can occur because of a more favorable safety profile, without any therapeutic effect on the cancer. Often PFS or DFS may not be established surrogate endpoints for overall survival, meaning that it is not known whether an improvement in these endpoints actually correlates with an improvement in overall survival. This makes it unclear whether an improvement in PFS or DFS really represents a direct clinical benefit to patients, especially in the presence of treatment toxicities. Endpoints may be subject to assessment bias, so additional trial design considerations are important, including patient/physician blinding, independent endpoint review committees, and regular disease evaluations. Patient-reported outcomes (PROs) use questionnaires to measure how a patient feels and functions; therefore, PROs can also be important for assessing direct clinical benefit of a treatment being evaluated in a clinical trial. These instruments need to undergo rigorous development and testing to ensure that they are measuring what is expected and that they are reliable. Several distinct aspects of PROs are important for understanding the benefits and toxicities of treatment, including the burden of disease symptoms, physical functioning and the ability to conduct activities of daily life, and symptomatic adverse events. Blinding in the trial design is important for these outcomes in order to avoid assessment bias, and completeness of data collection is crucial in order to minimize the impact of missing PRO data and the biases that this may introduce.

Adaptive Designs

"Adaptive trial designs" are defined as those that include a provision for changing the future course of the trial using accumulated data. Several features of adaptation in exploratory or early-phase clinical trials have already been described, including continual reassessment methods in phase I trials, and adaptive randomization in phase II trials. Here adaptations used in the confirmatory clinical trial setting are described.[15] The implications of adaptations are different depending on whether the changes are made blinded or unblinded to the available data on treatment differences; for example, increasing the sample size because of a lower-than-expected overall event rate has minimal impact on the final analysis because it does not actually utilize the treatment differences. In contrast, unblinded adaptation is subject to greater scrutiny,

and requires careful attention to statistical methodology and operational procedures in order to ensure that the results are free from bias. Several types of adaptations in late-stage clinical trials have been considered. Seamless phase II/III clinical trials combine the phase II trial (which may involve dose selection from among multiple doses) and the phase III trial (which uses the final selected dose for inference). This can be operationally efficient since it eliminates time between phase II and III, and it can be statistically efficient, since the data from the two stages are combined for inference. Sample size reestimation designs allow for an increase in sample size based on interim assessments of the treatment effect, particularly when the interim treatment effect is in a promising zone in which the study may be underpowered. An adaptive population-enrichment design allows for restricting enrollment to a biomarker-based subgroup at an interim analysis, if it appears that the biomarker-positive patients may benefit from treatment and the biomarker-negative patients do not.

Equivalence and Noninferiority Designs

Although most phase III trials are undertaken with an underlying goal of demonstrating a difference between treatment arms, there are circumstances in which the goal is merely to demonstrate that one therapy is equivalent, or at least not inferior, to another. For example, a therapy that is less toxic, less inconvenient, or less expensive than another would be preferred if it was nearly equally effective.

It is impossible to design a trial to demonstrate that two therapies are exactly equivalent, and highly unlikely in truth that they are. Instead, one specifies the smallest difference that would be of practical clinical significance—for example, a 5% difference in 1-year survival—and then designs a trial that has high power to reject the null hypothesis (low type II error rate) if such a difference truly existed. A successful trial from the standpoint of equivalence would then fail to reject the null hypothesis. Note that the concepts of a false-positive or a false-negative conclusion are in a way reversed from the usual design perspective, and the typical rates of type I and type II error employed in such designs might need to be reconsidered. Equivalence studies are notoriously large because the difference in outcome said to define equivalence is typically smaller than the difference hypothesized for a superiority trial, which dramatically affects the sample size. For example, as seen in Table 5-8, a trial with an equivalency threshold set at a 5% difference requires a sample size four times as large as a superiority trial powered to detect a 10% difference.

Table 5-8 **Required Sample Size (Per Arm) for Equivalence and Noninferiority Trials with a Binomial Endpoint ($p_0 = 0.50$, $\alpha = 0.05$, and $1 - \beta = 0.90$)**

Allowable Difference ($p_0 - p_1$)	Equivalence Design	Noninferiority Design
0.25	77	69
0.20	124	108
0.15	227	191
0.10	519	429
0.05	2,095	1,713

An alternative to an equivalency design that can require a somewhat smaller sample size is the noninferiority design. In this case, one specifies an acceptable upper limit to inferiority of the new therapy compared with the old—that is, how much worse it could be and still be considered acceptable. The trial is designed by formulating a null hypothesis that the new therapy has that level of inferiority, or worse, and then is powered to reject that null hypothesis for a specified alternative assumption (which might be equivalence, a lesser degree of inferiority, or even superiority). This usually results in a smaller sample size than an equivalence design, partly because it involves a one-sided hypothesis test, but often as a result of claiming a wider limit of acceptability for noninferiority than for equivalence.

KEY POINTS

- Phase I trials focus on identifying safe doses or combinations of therapies using small sample sizes to minimize exposure to therapies with unknown toxicity profiles.
- Phase II trials are difficult to interpret because so many factors can vary from trial to trial.
- The typical sample sizes used in phase II trials provide imprecise estimates of outcome.
- Promising results from phase II trials are often not confirmed in phase III trials.
- Biomarker-driven trials may improve efficiency by directly targeting patients who are most likely to respond to treatment.
- Phase III trials require careful consideration of study design parameters, including randomization, blinding, and choice of endpoint, to minimize bias in the assessment of the treatment benefit.

CORRELATIVE STUDIES

Many studies in oncology are focused on evaluating the association between measurable attributes of a patient or the patient's disease at a particular point in time and subsequent events or outcomes. These attributes may be measured before the start of treatment, possibly with a view toward predicting the therapy most likely to be effective, or after treatment has been initiated, with the intent of predicting whether the treatment is working. Although almost any clinical study is involved with evaluating association in the broad sense, the term "correlative study" most often refers to studies in which the attribute being associated is not clinically apparent but must be assessed through some kind of test procedure—imaging, immunohistochemistry, gene expression, or any of a wide range of other procedures. Also bear in mind that a correlative study may or may not involve the analysis of "correlation," which is a statistical term for a specific kind of association.

Correlative studies can be conducted during any of the phases of therapeutic development and, in fact, are often explicitly incorporated as ancillary objectives in a therapeutic trial. They can also be conducted completely independently of therapeutic trials. The potential range of correlative studies is so broad that it is impossible to summarize succinctly the statistical methods or designs for such studies; this chapter first shows some examples of a basic measure of correlation and illustrates some general pitfalls in the evaluation of correlation. This

chapter also discusses two important issues that can occur under the umbrella of correlative studies: the relationship between correlation and causation and the issue of multiple comparisons.

Examples of Correlation

As previously noted, “correlation” is a generic term that might describe almost any trial or analysis of association, but it may be helpful to consider a very basic notion of correlation that occurs when both factors being studied are measurable on a continuous scale, exemplified by the *x*–*y* scatterplot and the sample correlation coefficient.[16] The scatterplot is simply a visual representation of how one factor varies as a function of another. The Pearson correlation coefficient, *r,* is a measure of the linear correlation between the two variables: a value of +1 means perfect correlation, a value of 0 means no correlation, and a value of –1 means perfect inverse correlation. The associated value r^2 ranges from 0 to 1 and is interpreted as the fraction of the variation in one variable that is explained by variation in another. For r^2, variation is measured by the sum of squared deviations from the mean, but there are many other measures of variation. The degree of correlation is a function of three factors: (a) the magnitude of the association (i.e., whether the change in one variable is associated with a large or small change in the other); (b) the consistency of the relationship (i.e., whether the changes are consistent or highly variable); and (c) the linearity of the relationship. The first two factors pertain generally to any measure of correlation; the third is a consideration for Pearson’s correlation coefficient *r.*

Figure 5-2 provides several examples of an *x*–*y* scatterplot, along with a fitted line and the value of *r*. The top panels illustrate how both the scatter and steepness of the association affect the degree of correlation. Moving from panel A to panel B, the data are just as variable, but there is an increase in the rate of change in *y* as a function of the change in *x* (slope), resulting in higher correlation. In panel C, the slope stays the same as in panel B, but the variability increases, decreasing correlation. The bottom panels illustrate common pitfalls that occur in correlation studies. In panel D, the apparent correlation between *x* and *y* is based on a single point that is far away from the majority of data. It is debatable whether this represents a real biologic phenomenon. Conversely, in panel E, an outlying observation obscures an apparent correlation in the majority of observations. Finally, in panel F, there is a clear relationship between *x* and *y,* but it is not a linear relationship and, therefore, is not reflected in *r*.

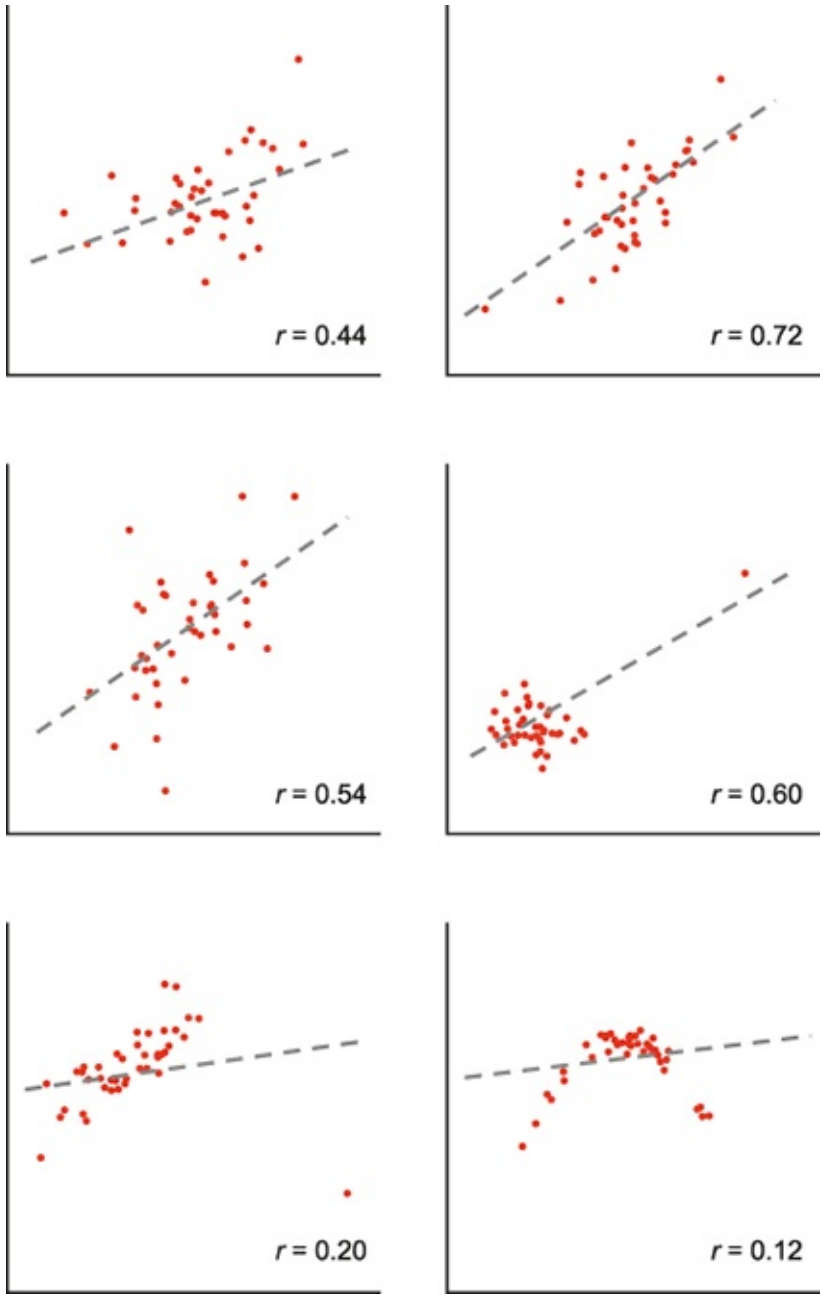

Fig. 5-2 Examples of linear correlation.

The six panels illustrate possible correlations between two variables, *x* and *y.* The dashed line indicates the least-squares line fit to the data, and *r* is the Pearson correlation coefficient.

Correlation and Causation

One setting in which correlative studies have become common is the development of so-called targeted therapies. These therapies are designed around specific attributes of tumors, which nominally can be quantified by measuring some biologic parameter. It may be possible to establish a clear correlation between this biomarker and prognosis; it may also be possible to establish that a targeted therapy has an effect on the biomarker in a direction that would imply a more favorable prognosis. Taking these two correlations together, it might appear that this is a clear indication that the therapy would be effective for that cancer, but this is not necessarily the case. Figure 5-3 indicates how this seeming contradiction can occur when the biomarker is correlated with the disease process but is not part of the causal pathway related to the ultimate outcomes of interest.

A familiar analogy would be the association of elevated blood pressure and cholesterol with various forms of cardiovascular disease. Although there are many drugs that lower blood

pressure and cholesterol, there is no guarantee that these drugs will be effective in lowering the risk for the correlated cardiovascular disease. In order for this to be true, the elevation of blood pressure or cholesterol must be part of the causal pathway to the cardiovascular event, not just a marker or symptom of the severity of the disease process. The same must hold true in order for the effect of a targeted therapy on a cancer biomarker to be considered an indicator of efficacy; that is, the biomarker must reflect at least part of the direct causal pathway by which growth or spread of the tumor has an effect on the survival of the patient.

Multiple Comparisons

Advances in technology have made it possible to assess hundreds, thousands, or even millions of potential markers within reasonable limits of expense and time. This is particularly true in the field of genomics, in which single chips have the ability to simultaneously quantify the expression of 20,000 genes or to genotype more than a million single-nucleotide polymorphisms. Although some sophisticated statistical methodology may underlie the quantification of gene expression or assigning a genotype, the basic methodology for evaluating a correlation with outcome could be based on a simple t-test or chi-square test that is repeated thousands or hundreds of thousands of times.

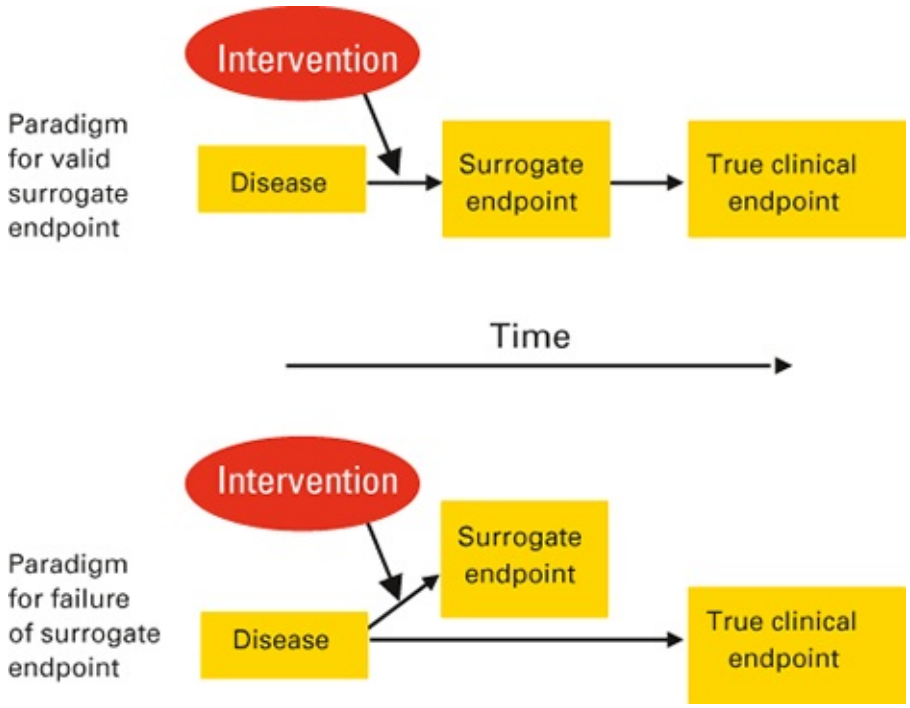

Fig. 5-3 Criteria for surrogate endpoints.

A schematic illustrating how a surrogate endpoint, or biomarker, may or may not be valid as a substitute for the true clinical endpoint. At the top, the surrogate endpoint is in the causal pathway of the disease process. An intervention that affects the surrogate endpoint should also affect the true clinical endpoint. At the bottom, the surrogate endpoint results from an independent causal pathway. It will be correlated with the clinical endpoint, but an intervention affecting the surrogate endpoint will have no effect on clinical outcome.

From the hypothesis-testing point of view, if each of these tests of association has a positive (type I) error rate set at conventional levels, such as 5%, then the number of false-positive correlations found will be enormous. For example, consider a gene expression study of 20,000 genes that is to be correlated with tumor response in hopes of determining one or more markers that signal a high likelihood of treatment failure. Even if the 20,000 genes have been

selected to represent a range of plausible causal pathways, only a small fraction of them are likely to be truly correlated with outcome. As an order-of-magnitude calculation, the number of false-positives that will result from 20,000 hypothesis tests conducted with a 5% type I error rate is 1000, which is far too many to represent practical progress.

Although it is obvious in this setting that some measure must be taken to decrease the number of false-positive correlations, it is not always clear what specific target to set. For example, if one insists that the rate of *any* false-positive correlation must be 5%, then a simple, though conservative, method is to apply the Bonferroni correction, which divides the nominal single-test error rate by the number of tests. In the example at hand, this would mean conducting each test with a type I error rate of 0.0000025. Although there are methods to make this conservative adjustment more accurate, it is not clear that this is even a reasonable goal. For example, it seems unduly conservative to demand that the rate of even a single false-positive result across 20,000 tests be only 5%. Unless the size of the study is increased, a reduction in the false-positive error rate by four orders of magnitude will increase the false-negative error rate, perhaps to the point at which correlations of a plausible magnitude cannot be detected.

Another method of controlling false-positives considers the error rate among the tests that have been declared positive, not among all tests. This is called the false discovery rate (FDR). With this approach, if there were 100 positive tests, an FDR of 5% would mean that, on average, 5 would be false-positives. Most researchers would consider such a result highly successful. In fact, 10 positive tests with an FDR of 20 to 30% could be considered an excellent result and would greatly reduce the scale of the subsequent studies required to replicate and validate the findings. The FDR method is generally less conservative than a strict Bonferroni adjustment, though as previously noted, there are ways to calibrate the Bonferroni approach (e.g., through permutation) to make it more comparable to the FDR approach.

Although examples have been described previously in which the need to account for multiple tests is obvious, the problem of false-positives remains even when dealing with 5 to 10 markers. Explicit accounting of the multiple tests is often omitted in such situations, but this does not obviate the need for independent replication and validation of any apparent correlation.

KEY POINTS

- Common measures of correlation assess the linear correlation between variables. Lack of linear correlation does not necessarily mean that the variables are not related.
- Measures of correlation may be sensitive to a few outlying observations.
- Correlation, by itself, does not imply causation. Even though a biomarker may be correlated with both treatment and outcome, this is not sufficient to establish that the biomarker is a useful surrogate endpoint.

STATISTICAL ANALYSIS METHODS

This section discusses some of the more important and advanced statistical methods that are common in oncology studies. Of course, each of these is itself the subject of entire books, and,

thus, only the most basic features of these methods can be covered here. The greater part of this section is devoted to the analysis of survival or time-to-event data, which are ubiquitous in the evaluation of clinical research. Some other advanced methods that may be encountered are also covered.

A common feature of the analytic methods discussed here is that they can be extended to incorporate the simultaneous effects of multiple variables on outcome, referred to as "regression analysis." Regression analysis involving multiple variables is frequently referred to as multivariate (or sometimes multivariable) analysis, in contrast to univariate analysis, which considers only one variable at a time. Adjustment for multiple variables is particularly important in comparative studies using retrospective or other nonrandomized data or in developing predictive models to evaluate multiple, possibly correlated factors.

SURVIVAL ANALYSIS

Because of the potentially long temporal course of the disease, a large part of the evaluation of cancer and its treatment involves extended periods of follow-up, often spanning many years. Measures of therapeutic efficacy or prognostic value are frequently defined by the percentage of patients alive at a particular time or alive and free of recurrence at a particular time. Conversely, one might be interested in the median time to death, recurrence, or some other defining event. Often it is not possible to follow all patients until the defining event occurs, or even until they have reached a specified length of follow-up.

The analysis of data related to the duration of time until an event is generically referred to as "time-to-event analysis" or "survival analysis."[17] The methods employed in such analysis must take into account the fact that some patients will not be followed until the time of the event, but provide partial information about the length of that time—that is, the length of time from the start of follow-up until the time of analysis. The discontinuation of follow-up prior to a defining event is called "censoring." The fraction of event times that are censored may range from near zero, in settings where almost all patients die or have recurrent disease, to greater than 90%, in settings with excellent survival.

The most common display of censored survival data is the survival curve. This is an estimate of the underlying survival function, $S(t)$, that defines the probability of surviving past time t or more generally that the time to a defining event exceeds t. Although this is the way that data are visualized, the statistical analysis of such data is more often based on a related quantity called the "hazard function," $\lambda(t)$, which is the underlying rate at which events occur among the population of patients at risk. This is feasible because there is a well-defined and fundamental mathematical relationship between the survival function and hazard function; intuitively, if the rate of events increases, then the probability of surviving without that event decreases.

The most common methods associated with displaying and analyzing time-to-event data are described later. There are two key assumptions underlying all of these methods. One is that the censoring of event times, if it occurs, is not related to the subsequent occurrence of the event—that is, that the reason for censoring is uninformative with respect to what happens afterward. Another fundamental principle of survival analysis, since survival is a predictive quantity, is that only past information can be used in modeling and analyzing future events. An example in which the latter principle is violated would be the division of patients into two groups, depending on whether or not they had a tumor response, and evaluating time to death from the time of initiation of therapy. Therefore, the groups are defined using future information, and unbiased predictions of survival after the start of therapy cannot use this information.

Kaplan–Meier Curves

The universal standard for providing estimates of survival curves is the Kaplan–Meier estimator (sometimes also called the “product-limit estimator”). This is typically plotted as a step function, with a step occurring at every unique death time. The calculation involved in the Kaplan–Meier estimator is actually quite simple—the height of each step is the height of the curve at the previous step multiplied by the fraction of patients at risk at the particular death time who survive beyond that time. The number of patients at risk at a particular point in time is the number of patients who have not died or been censored before that time. For example, suppose that the time until death or censoring is measured to the nearest week. If the estimated survival probability just before 14 weeks is 0.6, there are 10 patients who have not died or been censored before 14 weeks, and one patient dies at 14 weeks, then the height of the curve drops at that time from 0.6 to 0.54 [0.6 × (9/10)]. In plots of Kaplan–Meier curves, it is common to indicate points of censor with tick marks or to provide a table indicating the numbers of patients at risk at convenient benchmarks.

Because the Kaplan–Meier estimate is the product of fractions with progressively smaller denominators, the precision of the estimate decreases over time. This is readily apparent if confidence intervals are provided, as the confidence intervals will grow increasingly wide over time. In almost all cases, the confidence intervals provided with a Kaplan–Meier curve are based on pointwise estimates of the variability of the survival estimate; it is usually not correct to infer that the bands contain the entirety of the true survival curve with the stated level of confidence. The step following the last observed time of death is often extended out as far as the last censoring time, although, technically, the estimate is undefined after the last death. As previously noted, the steps in the right-hand tail of the estimated curve grow larger as the number of patients at risk decreases. If the last patient under observation dies, then the estimated survival probability drops to zero at that time point.

Figure 5-4 illustrates a Kaplan–Meier curve in a relatively small sample of 33 patients, 15 of whom died. Tick marks indicate the points at which surviving patients are last known to be alive. The gray lines indicate pointwise 95% confidence intervals for the survival probability. The green line indicates how median survival is estimated from a Kaplan–Meier curve: this is the time at which the estimated survival probability first drops below 50%.

Although in the previous discussion only deaths have been referred to, the Kaplan–Meier method readily encompasses the concept of event-free survival. For example, the estimate of disease-free survival counts both deaths and relapses as events, and the curve steps down whenever either event occurs, using the same calculation. The term “overall survival” is usually meant to refer to a survival curve that counts only deaths as events. The term “actuarial survival” is a misnomer—it refers back to a different method of estimating the survival curve (the actuarial or life-table method) that was used prior to the introduction of the Kaplan–Meier method but is now obsolete in the medical context. The Kaplan–Meier method should not be used when the intent is to estimate the probability of being free of a particular kind of event, for example a particular cause of death. This is a “competing risks” problem and requires the use of methods described as follows.

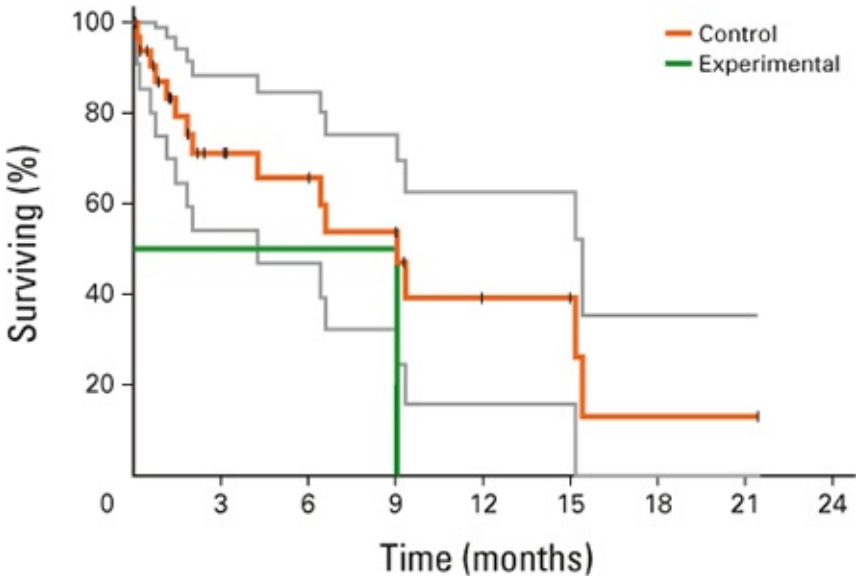

Fig. 5-4 A survival curve and related quantities.

The orange line is an example of a Kaplan–Meier curve for a group of 33 patients. At any point in time, the curve estimates the probability of surviving at least as long as that time. Gray lines indicate the 95% confidence intervals for the survival probability calculated at each point in time. Tick marks indicate times at which surviving patients are last known to be alive. The green line indicates how median survival would be calculated: in this curve, the survival probability drops to less than 50% at 9 months.

Comparing Kaplan–Meier Curves

The comparison of survival curves can be approached in several ways: (a) by comparing the estimated survival probability at a fixed point in time; (b) by comparing the time at which the estimated survival probability is a fixed value, usually the median; or (c) by comparing the survival curves across the entire period of follow-up. In general, the first two approaches should be avoided unless there is a very strong justification for focusing on a particular survival time or percentile. This is because the comparison clearly can vary depending on the point chosen.

The most common way to compare survival curves across time is with the log-rank statistic, as illustrated in Fig. 5-5, which compares disease-free survival in a hypothetical clinical trial of an experimental compared with a control treatment. Perhaps somewhat surprisingly, this statistic is not based directly on the calculated survival estimates; rather, it is based on a comparison of the number of events observed in one group to the number of events that would have been expected in that group if the deaths occurred solely in proportion to the numbers of patients at risk. If this difference is too extreme (as reflected in a p value), then it provides evidence that the underlying event rates in the groups are different. The standard log-rank test is most sensitive to situations in which the event rates in the groups differ by the same ratio across time. There are weighted versions of this test that are appropriate if the differences are expected to occur primarily during the early or later periods of follow-up; however, the intent to use a weighted log-rank test should be specified prior to observing where the differences in event rates occur.

The comparison of survival curves is a special case of HR analysis, performed through Cox regression, which is discussed later. In fact, the log-rank test is also a test of the equality of hazard rates in the two groups. The result of the HR analysis is also provided in Fig. 5-5, illustrating the notion that better survival is associated with a lower event rate for mortality.

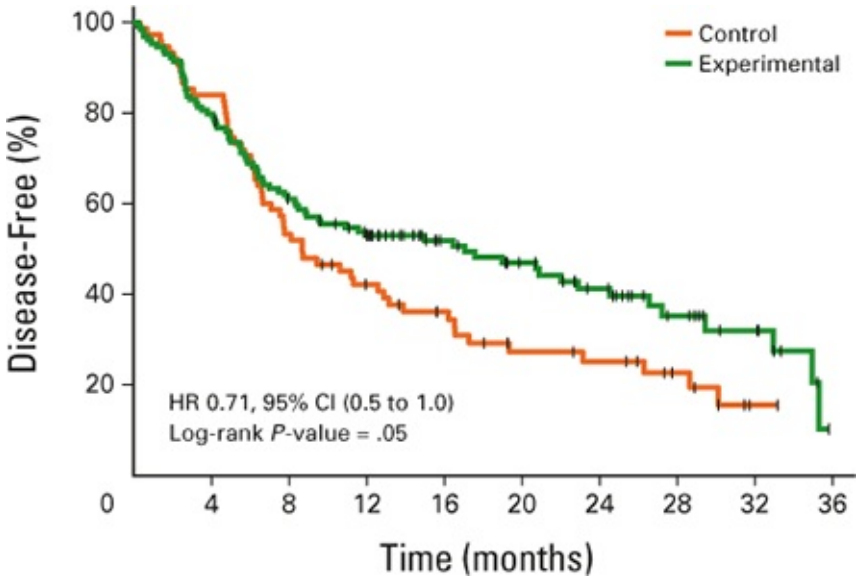

Fig. 5-5 Comparing survival curves.

The two curves represent a hypothetical comparison of disease-free survival for two treatments. The curves drop when a patient experiences relapse or dies without relapse (treatment-related mortality).

Competing Risks and Cumulative Incidence

As noted previously, when there are multiple types of events that define event-free survival, or multiple causes of death, then probabilities associated with a specific type of event or a specific cause of death should not be estimated by Kaplan–Meier methods. For example, suppose that one is interested in comparing breast cancer mortality as opposed to all-cause mortality (the complement of overall survival) between two treatment groups. The relevance of this comparison might be debated, since cause-of-death classification can be fairly subjective. A common but incorrect approach to this problem is to censor patients at the time of a non–breast-cancer death, and to plot the complement of the resulting Kaplan–Meier curve as a representation of cumulative breast cancer mortality over time. The problem with this approach is that patients who die of other causes are not even hypothetically at risk for future death from breast cancer—the implicit assumption that they are, which is appropriate for the standard types of censoring, results in an overestimation of the probability of breast cancer death.

The correct calculation of cumulative incidence in the competing risks setting must take into account the probability of remaining at risk (or event-free). When this is done, the sum of the cumulative incidence probabilities for each of the types of events is exactly the complement of the event-free survival probability. For example, at any point in time, (a) the overall survival probability, (b) the probability of breast cancer death, and (c) the probability of non−breast-cancer death will sum to 100%.

Although Kaplan–Meier methods are generally inappropriate for generating estimates of cumulative incidence in the presence of competing risks, the comparison of cumulative incidence curves is properly handled using the same previously discussed log-rank statistic, with events other than the type of interest being censored at the time of their occurrence. This seeming contradiction relates to the fact that in neither case is the log-rank statistic based directly on the estimates of the event probabilities themselves. Rather, it is based on the relative numbers of events that occur in each patient group, given the numbers of patients remaining at risk in each group over time. Thus, it is appropriate, for this purpose, to censor patients who experience competing events at the time of the event, since they are no longer at risk for the event of interest.

Figure 5-6 illustrates competing risks analysis derived from the same data shown in Fig. 5-5. Disease-free survival reflects two competing risks: relapse and death without relapse, which perhaps reflects toxic complications of treatment. Panel A shows the cumulative incidence of relapse and Panel B the cumulative incidence of treatment-related mortality. The sum of these two incidences, plus the event-free survival probability from Fig. 5-5, will equal 100% at any point in time. The curves and the log-rank analysis clearly suggest that the improvement in disease-free survival associated with the experimental arm is based largely on a reduction in treatment-related mortality, with little apparent effect on relapse.

At the risk of making the issue seem overly complicated, it should be noted that in the competing risks setting, the results of statistical analysis may not always appear concordant with the visual interpretation of cumulative incidence curves. This is because incidence is a composite result of (a) the rate at which events occur among those at risk (the hazard rate), and (b) the size of the population at risk. For example, consider a setting in which toxic regimens with potentially fatal complications are employed in a setting with high rates of relapse. The events of relapse and nonrelapse death constitute competing risks. Suppose that one regimen is much more effective than the other in preventing relapse but has the same underlying toxicity, based on a HR analysis showing equivalent hazard rates for nonrelapse death in the two groups. In this case, the cumulative incidence of nonrelapse death will appear higher in the group receiving the more effective therapy. This is because the effectiveness of the therapy in preventing relapse places more patients at risk for nonrelapse death.

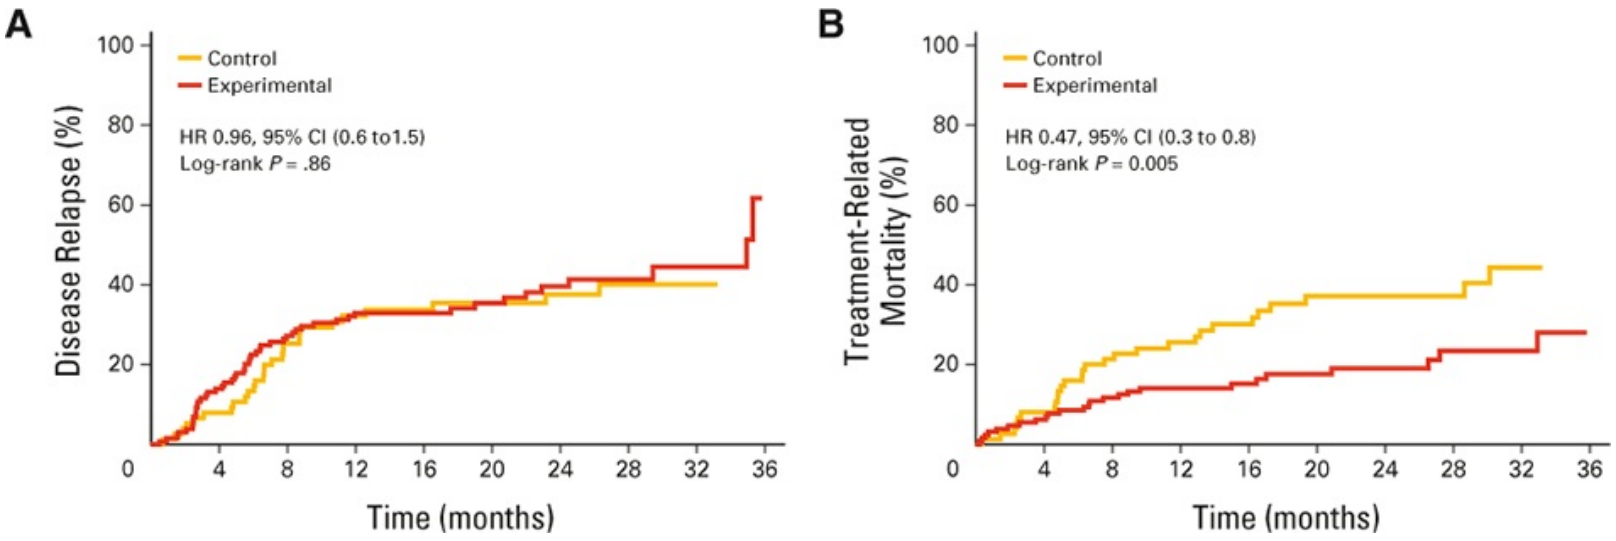

Fig. 5-6 Cumulative incidence curves and competing risks.

The data from Fig. 5-5 are decomposed into the two competing risks of relapse (A) and treatment-related mortality (B). Most of the improvement in disease-free survival in the experimental arm is attributable to a decrease in treatment-related mortality; there is no observed difference in the rate of relapse between arms among those at risk for relapse.

The intent of the previous example is not to imply that the HR analysis is correct or that the cumulative incidence analysis is misleading. The important point is that competing risks should not be evaluated in isolation. Factors that influence one type of event may or may not influence another type, and an informed interpretation of data from a competing-risks setting should consider each type of event. Further, a complete analysis should evaluate not only the underlying rates of the event types, which may be biologically more meaningful, but also the net outcome reflected in their cumulative incidence, which may bear on clinical interpretation.

Cox Regression

Although many clinical trials can be analyzed using only the previous methods, there are many settings in which one wishes to incorporate more information about patient characteristics than just the treatment arm to which they were assigned. This is particularly true in nonrandomized comparisons, where patient groups may not be homogeneous with respect to factors known to affect outcome. Although accounting for these imbalances is in no way a substitute for randomization, it is, nevertheless, helpful to evaluate the extent to which patient characteristics influence the difference, or lack of difference, among treatment groups. In other cases, the interest is not in comparing arms of a clinical trial, but in determining factors that are predictive of better or worse survival. This information is useful in designing trials, counseling patients about their likely prognosis, or gaining increased biologic understanding.

Like other regression models, the Cox regression model relates patient characteristics, called "covariates," to outcome. It is not the only model or method for doing this with time-to-event endpoints, but it is by far the most common regression model used in the context of medical research. As previously noted, one of the fundamental quantities defining survival is the hazard function, $\lambda(t)$, which is the rate at which events occur among patients at risk for the event. The Cox model, or proportional-hazards model, assumes that covariates multiplicatively influence a baseline hazard function, $\lambda_0(t)$, which applies when the covariates have a specified baseline or reference value. One reason for the popularity of the Cox model is that it makes no assumptions about the form of this baseline hazard. For example, suppose that the reference value for patient sex is female. The hazard rate for females is thus $\lambda_0(t)$, and that for males would be specified as $\lambda_0(t)e^{\beta male}$, so that the effect of being male is to multiply the hazard function by the quantity $e^{\beta male}$. The quantity β_{male} is a regression coefficient that captures the magnitude and direction of the effect. If β_{male} is greater than zero, then $e^{\beta male}$ is greater than one and the effect of being male (relative to being female) is an increased hazard rate. Assuming that the hazard rate is for an untoward event like mortality, this means a higher mortality hazard rate and poorer survival. If the coefficient is less than zero, then the hazard multiplier is less than one, and this would yield a lower mortality hazard and better survival. Note that $e^{\beta male}$ is also the ratio of the hazard function for males to the hazard function for females at any point in time, and it is called the HR. The basic Cox model implicitly assumes that this HR for males compared with females is the same at any time point (the proportional-hazards assumption); however, techniques are available for relaxing this assumption. Covariates need not relate to discrete groups but can be defined quantitatively. For example, suppose that the reference value for patient age is 50. Then the multiplicative effect of age on the hazard function could be expressed as $e^{\beta age}$; for every year of age older than 50 the hazard rate is multiplied by the quantity $e^{\beta age}$. When multiple covariates are included in the Cox model, the interpretations of the HRs are considered to be adjusted for the other factors in the model. For example, if a Cox model includes both sex and age, then $e^{\beta male}$ would represent the HR for males compared with females of a similar age.

The basic regression model assumes that the covariates affect the hazard independently—that is, that the effect of age is the same for males and females, but more complicated models can be constructed allowing interaction among covariates. Covariates for prognostic models are defined at the start of the survival period, but one can also allow the covariates to change over time, in which case they are called "time-dependent covariates." The Cox regression model also extends directly to the analysis of cause-specific hazard rates found in the

competing-risks setting, by incorporating censoring for events of other types.

BINARY DATA ANALYSIS

In contrast to time-to-event analysis, there are occasions when the outcome of a clinical trial or other exercise may be summarized by the presence or absence of an event, an outcome, or a characteristic. This dichotomization of outcome is said to be “binary data.” Such data do not necessarily exclude aspects of time: for example, if outcome can be ascertained on all patients, then the occurrence of an event during a defined period of time can be a binary outcome. This is referred to as “risk,” but binary outcomes can refer to things other than risk. For instance, two groups of patients with breast cancer might be compared with respect to the percentage of patients with estrogen receptor–positive disease. The same or similar statistical methods may be applied to both scenarios.

Chi-Square Analysis

For basic statistical analysis of binary endpoints, such as comparing one or more groups in terms of the risk of an event or the percentage with a certain characteristic, the most common methodology is based on the chi-square test (also mentioned in Table 5-1). For very small sample sizes, the accuracy of p values from the chi-square analysis may be in doubt, and the Fisher exact test is the most common alternative, although it is generally quite conservative.

Like the log-rank test for survival analysis, the basic methods associated with binary data provide a test of equality, but not necessarily a measure of effect. The most straightforward measure of effect is the simple difference in proportions. Other common measures of effect associated with binary outcomes[18] must be used with some caution in typical applications involving clinical data. For example, if p is the risk of an event, then the odds of the event are $p/(1 - p)$. Conversely, if ψ is the odds of an event, then the risk of the event is $\psi/(1 + \psi)$. In certain epidemiologic settings, where p is small, the ratio of the odds of an event between groups (odds ratio [OR]) will be approximately equal to the ratio of the risks (relative risk) and is a standard measure of association or effect. In clinical settings, however, the values of p associated with risk are not necessarily small. Although the same underlying statistical methods may be applicable, the OR in such settings may be nonintuitive or even misleading. For example, consider a patient group with a risk for recurrence of 90% compared with another group with a risk for recurrence of 80%. The OR for risk for recurrence is 2.25, but clearly the risk for recurrence is not nearly doubled. Similar considerations apply when interpreting an HR in survival analysis. If the risk for an event is not too large, then an HR will approximate a risk ratio; however, the divergence between a risk ratio and an HR is not as dramatic as that between a risk ratio and an OR. For example, a risk ratio of 2.0 (0.4/0.2) corresponds to an OR of 2.67 and to an HR of 2.25 (under an exponential assumption).

Logistic Regression

The most common method for incorporating covariate effects into binary data analysis is logistic regression. The formulation of the underlying statistical model is not that dissimilar from Cox regression. If $\psi_0 = p_0/(1 - p_0)$ is the odds of the event of interest for a specified baseline or reference value of the covariates (such as female sex), then the odds of the event for a male are specified as $\psi_0 e^{\beta male}$ so that the quantity $e^{\beta male}$ is the multiplicative effect on the baseline odds. It is also the OR for the risk for the event for males compared with females, although, as

noted, one must be cautious in interpreting that as a risk ratio. Similarly, the multiplicative effect of a continuous covariate like age on the baseline odds (odds at age 50) would be expressed as $e^{(\text{age} - 50)\beta\text{age}}$; for every year of age older than 50, the odds of the event are multiplied by the quantity $e^{\beta age}$.

ANALYSIS OF RECURRENT EVENTS

In the discussion of survival analysis, the time to an event that occurs only once, such as death, or that is generally only of interest the first time it occurs, such as relapse was considered. Of course, patients whose disease relapses may be re-treated, go into remission, and then relapse again, but this is usually a question for a different study. Other events may occur repeatedly over time, and the rate of occurrence of such events is of interest. Examples of this relate commonly to the study of treatment complications, such as infection, seizure, or any sequelae that occur in distinct, well-defined episodes.

One technique for analyzing data of this kind involves what is called Poisson regression. This is related to the Poisson process, the classic example of which is the emission of particles in the process of radioactive decay. This stochastic event is characterized by the fact that after one particle is emitted, the distribution of the time to the next particle is the same, regardless of how long the process has been going on. The rate of events over time is denoted λ, and during a period of the time *t,* the number of events that occurs follows a Poisson distribution, which is characterized by its mean, equal to $\lambda \cdot t$. Poisson regression allows one to model the effect of covariates on λ in a manner analogous to that for Cox regression and logistic regression. For example, if λ_0 is the rate of events for a specified baseline or reference value of the covariates (such as female sex), then the rate of events for a male are specified as $\psi_0 e^{\beta male}$ so that the quantity $e^{\beta male}$ is the multiplicative effect on the baseline rate, or the rate ratio for males relative to females. The same considerations apply to continuous covariates, such as age.

There are more complicated analytic strategies that can be applied when one is unwilling to assume that the event rate λ is constant over time; for example, by partitioning the time axis into intervals and modeling the counts in each interval separately. Cox regression also can be used to separately model the time to first event, time from first event to second event, time from second event to third event, etc.

LONGITUDINAL DATA ANALYSIS

In many studies, patients may be assessed repeatedly over extended periods of time. Data that arise from repeated measurement of the same patient over time are called “longitudinal data” or sometimes “clustered data.” The distinction from the previous section is that the quantity being studied is inherently measurable at any point in time. Common examples of such data would be quality-of-life assessments or the evaluation of biomarker levels over time. Pharmacokinetic data are a specialized case of longitudinal data, which have specific methods for analysis that are beyond the scope of this chapter.

It is possible to do useful analysis of longitudinal data using very basic statistical methods—for example, by comparing groups at a fixed point in time, or by comparing one time to another. However, such methods may not allow one to evaluate the trajectory of the quantity being studied as a whole and do not fully accommodate common features of longitudinal data, such as missing data, variable times of assessment, and risk factors that also change over time. In order to analyze all of the data simultaneously, one must take into account the fact that

repeated observations from the same patient are likely correlated. For example, one patient may report relatively high quality of life during the entire period of study and another low quality of life, although both patients may experience a similar change over time.

Appropriately accounting for this within-patient correlation is not necessarily straightforward, and the methods involved may be quite complex and are beyond what can be presented in detail here. There are two fairly common approaches to handling longitudinal data analysis. Although the nomenclature may vary, one is generally referred to as a "linear mixed models approach" and the other as a "generalized estimating equation approach." The term *mixed* in the former case refers to the simultaneous estimation of parameters that model the mean effects (the effects of clinical interest) and parameters that model the within-patient correlation structure of the data. One must make explicit assumptions about the latter, and the results may be sensitive to that assumption. The generalized estimating equation approach makes less explicit assumptions about the correlation structure. This is an advantage, particularly if one has no particular interest in the correlation structure itself, which is often the case when the interest is in comparing outcomes between groups or evaluating the effects of other factors on outcome.

KEY POINTS

- Survival analysis techniques are used to analyze outcomes describing the time until an event occurs, which may be subject to censoring or competing risks.
- Although Kaplan–Meier curves are the universal standard for graphically representing time-to-event endpoints, the statistical analysis of such curves is usually not based on a direct comparison of the curves themselves. Rather, the comparison is based on the underlying hazard rate—the rate of events among patients remaining at risk—using the log-rank test.
- Similar considerations apply to the comparison of cumulative incidence curves.
- Cox regression is used to model the hazard rate in survival analysis, where the effect of a covariate can be summarized through a hazard ratio or relative risk.
- Binary data analysis is used for outcomes with yes/no or binary responses. Chi-square or Fisher exact tests are used to compare proportions between groups. Logistic regression is used to model the odds of a response, where the effect of a covariate is summarized through an odds ratio.
- Analysis of recurrent events is done when patients can experience an event repeatedly over time. Poisson regression is often used to model the event rate, where the effect of a covariate is summarized through a relative risk.
- Longitudinal data analysis is used to model outcomes that are assessed repeatedly over time. These methods must account for missing data commonly occurring in this setting, as well as correlation between measurements on the same individual.

SUMMARY

Statistical considerations are a key component in both the design and the analysis of clinical

research studies. Proper study design allows one to control the systematic and random factors that affect patient outcomes in clinical studies, and proper analysis allows one to make the best possible judgment as to which is more important. Few oncologists engaged in clinical research have sufficient statistical training or knowledge to do this on their own, which is why statisticians are in high demand in medical research and are considered a vital part of the research endeavor. Statisticians are also frequently engaged in evaluating research proposals for funding purposes and in reviewing research papers for publication in medical journals.

Although most clinical studies published in major medical journals have likely involved a statistician in both the conduct of the study and in the review of the article, it is still essential for the practicing oncologist to have some rudimentary familiarity with common statistical concepts and terminology, which has been the goal of this chapter. Such knowledge will enhance his or her ability to evaluate the medical literature, explain treatment options to patients, and make informed decisions about joining research studies available to the community.

GENETIC TESTING FOR HEREDITARY CANCER SYNDROMES

Erin E. Salo-Mullen, MS, MPH, CGC, and Zsofia K. Stadler, MD

OVERVIEW

During the past two decades, the availability of clinical genetic counseling and testing for hereditary cancer predisposition syndromes has had a major impact on the practice of medical and preventive oncology. The identification and treatment of patients with an inherited predisposition to cancer is now one of the core elements of oncologic care, with statements and guidelines on genetic testing and management provided by the American Society of Clinical Oncology (ASCO) and other organizations.[1-6] Importantly, the taking of a family history by medical oncologists, and the continued updating of this dynamic information on a regular basis, allows for the identification of patients and families who may benefit from genetic counseling and testing and opportunities for precision prevention oncology, a strategy wherein cancer prevention recommendations are specifically tailored to the individual patient.

In this chapter, we review the major principles that guide genetic counseling and testing, highlight the differences between testing and counseling for high-penetrance versus moderate-penetrance cancer susceptibility genes, and discuss ways of integrating genetic test results into the care of oncology patients. The advent of next-generation sequencing (NGS) technologies has added further complexity to the assessment of the genetic risk of cancer, including implications for tumor and germline analysis, the widespread use of multigene (panel) testing for inherited cancer susceptibility, and the increased identification of incidental or uncertain genetic findings. Oncologists are encouraged to recognize the importance of both pretest and posttest genetic counseling and to build relationships with local genetic counselors and other genetic specialists and to see them as allies in the challenge of helping patients and their families through a diagnosis of cancer. Notably, genetic counseling is not just for patients who have already undergone testing and were found to have genetic alterations; rather, it is for patients and families who are considering the option of genetic testing in the future or for individuals who may simply benefit from a risk assessment discussion.[7] Resources for finding genetic specialists include the National Society of Genetic Counselors (NSGC), the American Board of Genetic Counseling, the National Cancer Institute Cancer Genetics Services Directory, and the GeneTests Clinic Directory .[8] Resources for learning more about cancer genetics and risk assessment include the ASCO University Cancer Genetics Program, NSGC, and the National Human Genome Research Institute.[9,10]

Although a detailed description for each of the cancer susceptibility genes and syndromes is outside the scope of this chapter, Table 6-1 is a concise reference for noteworthy high- and moderate-penetrance genes and their associated cancer risks. Table 6-2 includes a detailed

summary of noteworthy cancer susceptibility genes, including cancer risks, recommended interventions, and syndromic features. Additionally, because many of the more common cancer predisposition syndromes are discussed elsewhere, when appropriate, please refer to the specific chapters for additional information on breast cancer, gastrointestinal cancers, gynecologic cancers, and leukemias (Chapters 7, 10, 12, and 16, respectively).

Table 6-1 Overview of High- and Moderate-Penetrance Genes by Associated Cancers[11-13]*

	Breast	Ovary	Endometrium	Colorectum	Polyposis	Gastric and/or Small Bowel	Pancreas	Melanoma	Prostate	Renal	Thyroid	Other
APC				X	X (adenomatous)	X	(X)				X	X (desmoid tumors, hepatoblastoma, medulloblastoma)
*APC** I1307K				X†								
ATM	X	(X)					X					Autosomal recessive Ataxia telangiectasia
BAP1								X (uveal and cutaneous)		X		X (malignant mesothelioma)
BARD1	(X)	(X)										
BMPR1A				X	X (juvenile)	X						
BRCA1, BRCA2	X	X					X	(X)	X			
BRIP1		X										Autosomal recessive Fanconi anemia
CDH1	X (lobular)					X (diffuse gastric)						
CDKN2A							X	X				
CDK4							X	X				
CHEK2	X	(X)		X					(X)			
GREM1				X	X (mixed)							
FH										X (type 2 papillary, tubule-papillary, collecting-duct carcinoma)		
FLCN										X (oncocytoma, chromophobe, oncocytic hybrid tumor)		
MAX												X (pheochromocytoma, paraganglioma)
MEN1							X (gastro-entero-pancreatic tract, well-differentiated endocrine tumors)					X (pituitary tumors, parathyroid tumors, carcinoid tumors, adrenocortical tumors)
MET										X (type 1 papillary)		
MITF								X		(X)		
MLH1, MSH2, MSH6, PMS2, EPCAM		X	X	X		X	X			X (ureter and renal pelvis)		X (sebaceous gland neoplasms, brain)

	Breast	Ovary	Endo-metrium	Colorectum	Polyposis	Gastric and/or Small Bowel	Pancreas	Melanoma	Pros-tate	Renal	Thyroid	Other
MRE11A	(X)	(X)										
MUTYH (monoallelic)				X								
MUTYH (biallelic)				X	X	X						
NBN	(X)											Autosomal recessive Nijmegen breakage syndrome
NF1	(X)											High-penetrance neurofibromatosis type 1
PALB2	X	(X)					X					
POLD1, POLE				X	X							
PTEN	X		X	X	X (hamartomatous)					X	X (often follicular)	
RAD50	(X)	(X)										
RAD51C, RAD51D		X										*RAD51C*: Autosomal recessive Fanconi anemia
RET											X (medullary, C cell hyperplasia)	X (pheochromocytoma, parathyroid adenoma)
SDHB, SDHC, SDHD, SDHA, SDHAF2										X	(X)	X (pheochromocytoma, paraganglioma, GIST)
SMAD4				X	X (juvenile)	X						
STK11	X	X (SCTAT)	X	X	X (Peutz-Jeghers)	X	X					X (adenoma malignum of the cervix; testes Sertoli cell; lung)
TMEM127												X (pheochromocytoma)
TP53	X			X		X	X			X		X (sarcoma, leukemia, adrenocortical, brain, others)
TSC1, TSC2										X (renal cell carcinoma, angiomyolipomas, oncocytoma)		(X) (possible neuroendocrine tumors; subependymal giant cell astrocytomas)
VHL							X (neuroendocrine tumors)			X		X (pheochromocytoma, paraganglioma)

*Blue rows reflect high-penetrance genes; white rows reflect moderate-penetrance genes. X denotes that evidence supports the association; and (X), that to date, there is limited or insufficient data regarding the extent of the association.

†Risk estimate for *APC*I1307K* is based on Ashkenazi Jewish population.

Abbreviations: GIST, gastrointestinal stromal tumor; SCTAT, sex cord tumors with annular tubules

Table 6-2 Noteworthy Genes, Syndromes, and Management Considerations

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
APC Tumor suppressor Dominant inheritance	Familial adenomatous polyposis (FAP) Attenuated FAP (AFAP) Variant: Turcot syndrome	High	Colorectal lesions (adenomatous polyposis and cancer) Gastric and duodenal/ small bowel lesions (adenomatous polyps and cancer) Desmoid tumors Thyroid (typically papillary) Hepatoblastoma (usually ≤ 5 years old) Pancreatic Medulloblastoma (Turcot syndrome)	Colonoscopy and total colectomy based on polyp burden Upper endoscopy Consideration of small-bowel visualization Thyroid exam and consideration of ultrasonography Consideration of childhood liver palpation, abdominal ultrasound, AFP measurement (investigational)	Genotype-phenotype correlations between classic FAP and AFAP: mutations on the 5′ and 3′ ends of the gene correlate with AFAP High de novo mutation rate (~20-25%) Extracolonic features: congenital hypertrophy of the retinal pigment epithelium (CHRPE); osteomas, supernumerary teeth; desmoid tumors, epidermoid cysts; gastric fundic gland polyps Particularly cribriform-morula variant of papillary thyroid carcinoma Chemoprevention not a replacement for colonoscopy and colectomy	Lynch et al.[14]; Nieuwenhuis et al.[15]; Bisgaard et al.[16]
*APC**I1307K (c.3920T→A)		Moderate	Colorectal	Colonoscopy based on family history or similar to risk for first-degree relative	Ashkenazi Jewish founder mutation Not associated with polyposis	Ma et al.[11]; Laken et al.[17]; Locker et al.[18]
ATM	Ataxia telangiectasia	Moderate (monoallelic/ heterozygous carriers) Rare: High (biallelic)	Monoallelic carriers: Breast Possibly pancreas Biallelic carriers: Leukemia Lymphoma	Monoallelic carriers: Breast screening with annual mammogram and breast MRI starting at age 40 years or as per family history* Biallelic carriers: AT specialist for multidisciplinary management	Monoallelic carriers: limited evidence for pancreas or prostate cancer Risk of autosomal recessive AT condition in biallelic offspring of heterozygous carriers AT: Childhood cerebellar ataxia, telangiectasias of the conjunctivae, immunodeficiency, sensitivity to radiation	Tung et al.[10]; Gatti et al.[19]; Suarez et al.[20]; Renwick et al.[21]; Grant et al.[22]; Pritchard et al.[23]; Walsh et al.[24]
BAP1 Possible Tumor suppressor Dominant inheritance	*BAP1* Tumor Predisposition syndrome	Undetermined	Atypical Spitz tumors Uveal melanoma Malignant mesothelioma Cutaneous melanoma Clear cell renal cell carcinoma Basal cell carcinoma	Eye examinations Dermatologic examinations Consideration of abdominal ultrasonography and/or MRI of the kidneys	Limited evidence for possible other associated tumors: non-small cell lung adenocarcinoma, breast cancer, cholangiocarcinoma, meningioma, neuroendocrine carcinoma	Pilarski et al.[25]; Testa et al.[26]; Wiesner et al.[27]; Abdel-Rahman et al.[28]
BLM	Bloom's syndrome	Low/ undetermined (monoallelic/ heterozygous carriers) Rare: high (biallelic)	Biallelic: Myelodysplasia Variety of epithelial carcinomas (gastrointestinal, genitourinary), lymphoid, hematopoietic, sarcomas, central nervous system, etc.	Biallelic carriers: Bloom's syndrome specialist for management	Monoallelic carriers: Limited evidence for risk of colorectal and breast cancer Bloom's syndrome: chromosome breakage syndrome with growth deficiency, erythematous facial skin lesion, immunodeficiency, frequent infections Founder mutation in Ashkenazi Jewish population	Sanz et al.[29]; Bloom et al.[30]; German et al.[31]; Cunniff et al.[32]; de Voer et al.[33]; Prokofyeva et al.[34]
BMPR1A and *SMAD4*: Tumor suppressor Dominant inheritance	Juvenile polyposis syndrome	High	Gastrointestinal lesions (juvenile/ hamartomatous polyps and cancer [colorectal, stomach, small bowel])	Colonoscopy based on polyp burden Upper endoscopy Surgical management based on polyp burden HHT screening	*Juvenile* refers to polyp histology, not age at onset *SMAD4* mutations associated with HHT *SMAD4* mutations associated with massive gastric polyposis Limited evidence for association with pancreas	Larsen Haidle et al.[35]; Syngal et al.[36]; Brosens et al.[37]; Jass[38]; Chow and Macrae[39]; Iyer et al.[40]; Friedl et al.[41]

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
BRCA1 or *BRCA2* Tumor suppressor Dominant inheritance	Hereditary breast and ovarian cancer syndrome	High	Breast (*BRCA1*: often triple-negative tumor) Male breast Ovarian (epithelial; high-grade serous), fallopian tube, primary peritoneal Prostate (high Gleason score) Pancreatic (exocrine)	Breast screening with annual mammogam and breast MRI starting at age 25–30 Male self-exam and clinical breast exam Optional risk-reducing mastectomy Risk-reducing BSO PSA measurement and digital rectal exam Consideration of eligibility and pros/cons of chemoprevention with tamoxifen Consideration of eligibility for treatment with PARP inhibitors Investigational pancreas screening	Founder mutations in certain populations—Ashkenazi Jewish, Icelandic, etc. Autosomal recessive Fanconi anemia with biallelic germline mutations	Chen and Parmigiani[42]; Gonzalez-Angulo et al.[43]; Kauff et al.[44]; Gallagher et al.[45]; Fong et al.[46]; Levy-Lahad et al.[47]; SaloMullen et al.[48]; Meyer et al.[49]; King et al.[50]; see Chapters 7 and 12 for HBOC and PARP inhibitors
BRIP1 Possible tumor suppressor		Moderate (monoallelic/ heterozygous carriers) Rare: high (biallelic)	Ovarian (heterozygous carriers)	Consider risk-reducing BSO at age 50–55 or as per family history†	Risk of autosomal recessive Fanconi anemia in biallelic offspring of heterozygous carriers	Tung et al.[10]; Ramus et al.[51]; Pennington et al.[52]
CDH1 Tumor suppressor Dominant inheritance	Hereditary diffuse gastric cancer syndrome	High	Diffuse gastric cancer Lobular breast cancer	Prophylactic total gastrectomy Breast screening with annual mammography and breast MRI Optional risk-reducing mastectomy	Upper endoscopy not proven to be an effective method of screening for or detecting diffuse gastric cancer Insufficient evidence for colorectal cancer	Guilford et al.[53]; Kaurah et al.[54]; van der Post et al.[55]
CDKN2A Tumor suppressor *CDK4* Oncogene Dominant inheritance	Familial atypical multiple mole melanoma (FAMMM) syndrome	High	Melanoma and dysplastic nevi Pancreas	Dermatologic exam Investigational pancreas screening	Risk of melanoma may be independent of genetic test result *CDKN2a* (p16) founder mutation in the Netherlands	Vasen et al.[56]; Goldstein et al.[57]; Vasen et al.[58]
CHEK2 Tumor suppressor Dominant inheritance		Moderate	Breast Colon	Breast screening with annual mammography and breast MRI starting at age 40 or as per family history* Colonoscopy based on family history or similar to risk for first-degree relative	Genotype-phenotype: different risks for truncating mutations vs. missense mutations Limited evidence for association with prostate cancer	Tung et al.[10]; Ma et al.[11]; CHEK2[59]; Han et al.[60]; Weischer et al.[61]
DICER1 Dominant inheritance	*DICER1* syndrome	High	Pleuropulmonary blastoma (PPB) Ovarian sex cord stromal tumors (Sertoli-Leydig cell tumor, juvenile granulosa cell tumor, gynandroblastoma) Cystic nephroma Thyroid gland neoplasia (cancer, multinodular goiter, adenomas)	No guidelines have been established Consideration of annual physical exam with targeted systems review and possible imaging	Other features: ciliary body medulloepithelioma; botryoid-type embryonal rhabdomyosarcoma of the cervix or other sites; nasal chondromesenchymal hamartoma; renal sarcoma; pituitary blastoma; pineoblastoma Early-onset disease (before age 40) Maternal-fetal medicine care when lung cysts are identified prenatally Papillary or follicular thyroid cancer	Doros et al.[62]; Foulkes et al.[63]; Schultz et al.[64]; Slade et al.[65]; Faure et al.[66]

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
GREM1 (SCG5-GREM1) Dominant inheritance	Hereditary mixed polyposis syndrome	High	Colorectal lesions (polyps of mixed histologies and cancer)	Colonoscopy and surgical management based on polyp burden	Only a 40-kb duplication upstream of *GREM1* (spanning 3′ end of *SCG5* and region upstream of *GREM1*) implicated in disease; identified in Ashkenazi Jewish population	Whitelaw et al.[67]; Jaeger et al.[68]; Plesec et al.[69]
Fanconi anemia (multiple genes [at least 20]) Recessive inheritance (most genes) Dominant inheritance (*RAD51* gene) X-linked inheritance (*FANCB* gene)	Fanconi anemia	High: biallelic for the recessive genes and monoallelic for *RAD51*, *FANCB*, *BRCA2*, *PALB2*, *BRCA1* Moderate: monoallelic for *BRIP1*, *RAD51C*	Myelodysplastic syndrome Acute myeloid leukemia Squamous cell carcinoma of head and neck, esophagus, vulva Genitourinary (cervix, Wilms tumor, neuroblastoma) Other solid tumors: liver, brain, skin, breast, gastrointestinal Associated cancers for *BRCA2*, *PALB2*, *BRIP1*, and *RAD51C* carriers	Fanconi anemia specialist for management Hematopoietic stem cell transplantation (HSCT) Early detection and surgical management of solid tumors: oral/otolaryngology/ear-nose-throat examination; gynecologic examination. Human papilloma virus prevention Management for *BRCA2*, *PALB2*, *BRIP1*, and *RAD51C* carriers (discussed elsewhere)	Increased chromosome breakage in lymphocytes tested with diepoxybutane and mitomycin C (does not identify carriers) Physical abnormalities (not in all patients): short stature, abnormal skin pigmentation (café-au-lait or hypo- or hyperpigmentation), skeletal malformations of the upper and lower limbs (thumbs, radii, hands, ulnae), microcephaly, developmental delay, and ophthalmic, genitourinary, cardiac, gastrointestinal, central nervous system anomalies Progressive bone marrow failure (not in all patients): pancytopenia, thrombocytopenia, leukopenia Extreme toxic effects from chemotherapy or radiation Genes and complementation groups: *BRCA2* FA-D1, *BRIP1* FA-J, *PALB2* FA-N, *RAD51* FA-R, *RAD51C* FA-O, *BRCA1* FANCES, and *XRCC2* FANCU	Mehta and Tolar[70]; Kutler et al.[71]; Rosenberg et al.[72]; Auerbach et al.[73]; Kutler et al.[74]; Faivre et al.[75]; Brosh et al.[76]
FH Tumor suppressor Dominant inheritance	Hereditary leiomyomatosis and renal cell cancer (HLRCC)	High	Cutaneous leiomyomata Uterine leiomyomata Renal tumors (type 2 papillary, tubule-papillary, collecting-duct carcinomas; unilateral, solitary lesions)	Dermatologic and gynecologic examination; evaluate for changes suggestive of leiomyosarcoma Medication or resection of leiomyomata Imaging for and surgical management of renal tumors	Fumarate hydratase enzyme assay might be helpful in some situations Risk for uterine leiomyosarcoma is unclear Biallelic *FH* mutations cause a recessive disorder known as fumarate hydratase deficiency—metabolic disorder, profound developmental delay, seizures, fumaric aciduria	Pithukpakorn et al.[77]; Launonen et al.[78]; Tomlinson et al.[79]; Stewart et al.[80]; Sanz-Ortega et al.[81]; Schmidt and Linehan[82]; Barrisford et al.[83]
FLCN Tumor suppressor Dominant inheritance	Birt-Hogg-Dube syndrome	High	Cutaneous (fibrofolliculomas, trichodiscomas/angiofibromas, perifollicular fibromas, acrochordons) Pulmonary cysts Renal tumors (oncocytoma, chromophobe, oncocytic hybrid tumors)	No consensus at this time Dermatologic care Imaging for and surgical management (nephron-sparing) of renal tumors	Fibrofolliculomas are specific to BHD Lung cysts are multiple and bilateral Spontaneous pneumothorax Renal tumors are multifocal, bilateral, and slow-growing Other features: parotid lesions, oral papules, thyroid lesions Unclear data regarding colon cancer Possible genotype-phenotype correlations	Kutler et al.[71]; Toro et al.[84]; Hasumi et al.[85]; Kuroda et al.[86]; Furuya et al.[87]

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
KIT (c-Kit) Oncogene Dominant inheritance		High	GISTs	No consensus at this time Imaging and endoscopy might be considered	Diffuse interstitial cell of Cajal hyperplasia (ICCH) Skin hyper- or hypo-pigmentation Mast-cell disorders Related gene: *PDGFRA*	Nishida et al.[88]; Forde et al.[89]; Ricci[90]; Lasota et al.[91]; Ricci et al.[92]
MEN1 Tumor suppressor Dominant inheritance	Multiple endocrine neoplasia type 1 (MEN1)	High	Gastroenteropancreatic (GEP) tract well-differentiated endocrine tumors Pituitary tumors (prolactinoma) Parathyroid tumors Carcinoid tumors Adrenocortical tumors	Biochemical testing Imaging Surgical management Various medications	Primary hyperparathyroidism, hypercalcemia, oligomenorrhea/amenorrhea, galactorrhea, Zollinger-Ellison syndrome (gastrinoma), insulinoma, glucagonoma, VIP-secreting tumor (VIPomas) Other features: skin (angiofibromas, collagenomas), lipomas, central nervous system lesions (meningioma, ependymoma), leiomyomas	Giusti et al.[93]; Machens et al.[94]; Lemos et al.[95]; Thakker et al.[96]
MET (c-Met) Oncogene Dominant inheritance	Hereditary papillary renal carcinoma (HPRC)	High	Papillary renal cancer (multifocal, bilateral, type 1 papillary)	Imaging Surgical management		Kutler et al.[71]; Coleman et al.[97]; Rini et al.[98]
MLH1, MSH2, MSH6, PMS2, and *EPCAM* Tumor suppressor Dominant inheritance	Lynch syndrome (formerly, hereditary nonpolyposis colorectal cancer [HNPCC]) Variant: Muir-Torre syndrome Variant: Turcot syndrome Variant: Constitutional mismatch repair deficiency syndrome (biallelic mutations; recessive inheritance)	High	Colorectal Endometrial Ovarian (epithelial) Stomach Small bowel Upper urinary tract (renal pelvis, ureter) Pancreas Hepatobiliary tract Sebaceous neoplasms (Muir-Torre syndrome) Glioblastoma (Turcot syndrome)	Colonoscopy every 1-2 years starting at age 20-25 Consideration of prophylactic colectomy Hysterectomy and risk-reducing BSO Consideration of upper endoscopy Consideration of urinalysis or urine cytology Consideration of eligibility for treatment with cancer immunotherapy with checkpoint blockade Consideration of aspirin for chemoprevention	Tumor analyses with immunohistochemical (IHC) staining, microsatellite instability (MSI) analysis, somatic tumor genetic analysis, *BRAF* V600E somatic analysis, *MLH1* promoter hypermethylation analysis Amsterdam criteria I and II; revised Bethesda guidelines Recent recommendations for universal screening of colorectal and endometrial cancers Genotype-phenotype correlations emerging but not significant enough to alter management Limited evidence for moderate risk of breast and prostate cancer Autosomal recessive inheritance (biallelic [homozygote or compound heterozygote]) with childhood onset of severe CMMR-D syndrome (café-au-lait macules, solid tumors, hematologic cancers)	Aarnio et al.[99]; Lynch et al.[100]; de Vos tot Nederveen Cappel[101]; Hampel et al.[102]; Bupathi et al.[103]; Castro et al.[104]; Bum et al.[105]; Shia[106]; Zhang[107]; Bouzourene et al.[108]; Vasen et al.[109,110]; Umar et al.[111]; Pérez-Carbonell et al.[112]; Lu[113]; South et al.[114]; Hamilton et al.[115]; Bakry et al.[116]; Raymond et al.[117]; Walsh et al.[118]; see Chapter 10: Gastrointestinal Cancers
MUTYH Recessive inheritance	*MUTYH*-associated polyposis (MAP)	High	Colorectal lesions (adenomatous polyposis and cancer; serrated and hyperplastic polyps also described) Stomach Duodenal lesions (adenomatous polyps, cancer)	Colonoscopy and total colectomy based on polyp burden Upper endoscopy	Phenotypically similar to *AFAP* Two Northern European founder mutations Controversy regarding risk in heterozygous carriers (see *MUTYH* monoallelic/heterozygous carrier)	Al-Tassan et al.[119]; Sieber et al.[120]; Cleary et al.[121]; Lubbe et al.[122]; Aretz et al.[123]; Nielsen et al.[124]

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
MUTYH monoallelic/ heterozygous carrier		Moderate	Colorectal	Colonoscopy based on family history or similar to risk for first-degree relative	Controversy regarding risk	Ma et al.[11]; Lubbe et al.[122]; Win et al.[125]; Jenkins et al.[126]
NBN	Nijmegen breakage syndrome (NBS)	Moderate (monoallelic/ heterozygous carriers) Rare: High (biallelic)	Monoallelic carrier: breast Biallelic carrier: lymphoma	Monoallelic carriers: breast screening with annual mammography and breast MRI starting age at age 40 or as per family history* Biallelic carriers: NBS specialist for multidisciplinary management	Heterozygous carrier breast cancer risk; limited evidence for prostate cancer Slavic founder mutation Risk of autosomal recessive condition in offspring of heterozygous carriers (NBS) NBS: chromosomal breakage, microcephaly, dysmorphic features, immunodeficiency, lymphomas	Tung et al.[10]; Pritchard et al.[23]; Walsh et al.[24]; Zhange et al.[127]; Dembrowska-Bagińska[128]
NF1 Tumor suppressor Dominant inheritance	Neurofibroma-tosis type 1	High (moderate risk for breast cancer)	Cutaneous neurofibromas Plexiform neurofibromas Optic nerve and other CNS gliomas Malignant peripheral nerve sheath tumors Breast (moderate risk) Others: GIST, leukemia	NF1 specialist for management Physical exam; ophthalmologic exam; imaging; surgical management Breast screening with annual mammography and breast MRI as per family history*	Café-au-lait macules, axillary and inguinal freckling, iris Lisch nodules, learning disabilities, scoliosis, tibial dysplasia, vasculopathy	Ricci[90]; Friedman[129]; Madanikia et al.[130]; Seminog et al.[131]; Walker et al.[132]
PALB2 Tumor suppressor Dominant inheritance		High	Breast Limited evidence for pancreatic cancer	Breast screening with annual mammogram and breast MRI starting at age 30 or as per family history* Optional risk-reducing mastectomy based on family history Investigational pancreas screening	Insufficient evidence for ovarian cancer Risk of autosomal recessive Fanconi anemia in biallelic offspring of heterozygous carriers	Salo-Mullen et al.[45]; Antoniu et al.[133]; Easton et al.[134]; Jones et al.[135]; Slater et al.[136]; Stadler et al.[137]
POLD1 *POLE* Dominant inheritance	Polymerase proofreading-associated polyposis (PPAP)	High	Colorectal lesions (polyps and cancer)	Colonoscopy and surgical management based on polyp burden	Disease-causing mutations occur in the exonuclease domain Limited data regarding extracolonic cancer risk	Palles et al.[138]; Valle et al.[139]; Church et al.[140]; El Sayed et al.[141]; Spier et al.[142]; Bellido et al.[143]
PRSS1 *SPINK1* *CFTR* *CTRC* Various modes of inheritance	Hereditary pancreatitis	High (*PRSS1*) Variable (*SPINK1*, *CFTR*, *CTRC*)	Pancreas	Pancreatitis management	Pancreatitis (recurrent, acute, chronic throughout lifetime) More severe disease if biallelic mutations are present Biallelic (homozygote or compound heterozygote) *CFTR* mutations associated with cystic fibrosis	LaRusch et al.[144]; Solomon et al.[145]; Solomon and Whitcomb[146]; Rosendahl et al.[147]
PTCH Tumor suppressor Dominant inheritance	Gorlin syndrome/ nevoid basal cell carcinoma syndrome	High	Jaw (odontogenic) keratocysts Basal cell carcinomas Medulloblastoma (primitive neuroectodermal tumor [PNET]–desmoplastic)	Referral to a specialist for management Physical examination Avoidance of sun exposure and at least annual dermatologic examination Surgical management	Other features: congenital skeletal anomalies, cleft lip/ palate, cerebral/falx calcifications, macrocephaly with frontal bossing, polydactyly, intellectual disability, lymphomesenteric or pleural cysts, palmar/plantar pits, cardiac fibromas, ovarian fibromas, ocular abnormalities Related gene: *SUFU*	Evans and Farndon[148]; Soufir et al.[149]; Athar et al.[150]; Smith et al.[151]

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
PTEN Tumor suppressor Dominant inheritance	Cowden syndrome/ *PTEN* hamartoma tumor syndrome	High	Breast Thyroid (most often follicular) Endometrial Colorectal lesions (hamartomas, ganglioneuromas, cancer) Genitourinary tumors (renal cell carcinoma)	Breast screening with annual mammography and breast MRI Optional risk-reducing mastectomy Thyroid exam and ultrasound Endometrial screening with random biopsy and ultrasonography Optional hysterectomy Colonoscopy Renal imaging	Major and minor criteria (tumors, physical and dermatologic/ mucocutaneous findings, developmental disability) Macrocephaly Bannanyan-Riley-Ruvalcaba syndrome *PTEN*-related Proteus syndrome Autism spectrum disorder Lhermitte-Duclos disease	Eng[152]; Nelen et al.[153]; Tan et al.[154]; Heald et al.[155]; Eng[156]; Tan et al.[157]; Pilarski et al.[158]; McBride et al.[159]; Haiback et al.[160]; Schrager et al.[161]; Pilarski[162]
RAD51C and *RAD51D* Tumor suppressor		Moderate Rare: high (biallelic *RAD51C*)	Ovarian	Consider risk-reducing BSO at age 50-55 or as per family history†	Risk of autosomal recessive Fanconi anemia in biallelic *RAD51C* offspring of heterozygous carriers	Tung et al.[30]; Meindl et al.[163]; Loveday et al.[164]; Song et al.[165]; Loveday et al.[166]
RB1 Tumor suppressor Dominant inheritance	Retinoblastoma	High	Retinoblastoma (trilateral disease = cooccurrence of pinealoblastoma) Bone or soft-tissue sarcomas Melanoma Others	Ophthalmologic examination and imaging; care by a multidisciplinary team Avoidance of radiation	Knudson's two-hit hypothesis Usually bilateral or multifocal disease Mosaic forms, therefore, analysis of both tumor tissue and blood important RNA studies may also be recommended Low-penetrance mutations identified Parent-of-origin effect in some families	Lohmann et al.[167]; Knudson[168]; Abramson et al.[169]; Abramson et al.[170]; Dimaras et al.[171]; Kleinerman et al.[172]; Klutz et al.[173]; Price et al.[174]
RET Oncogene Dominant inheritance	Multiple endocrine neoplasia type 2 Three subtypes: MEN2A (aka Sipple syndrome) Familial medullary thyroid carcinoma MEN2B	High	Medullary thyroid carcinoma (multifocal, bilateral) and primary C-cell hyperplasia Pheochromocytoma (bilateral) (MEN2A and 2B) Parathyroid adenoma/ hyperplasia (hyperparathyroidism, hypercalcemia, renal stones) (MEN2A)	Prophylactic thyroidectomy (varies from infancy to age 5 or older depending on specific *RET* pathogenic mutation; genotype-phenotype correlations) Surgical management of identified disease Serum calcitonin concentration Consideration of eligibility for treatment with kinase inhibitors Biochemical screening and imaging for pheochromocytoma and parathyroid abnormalities	Genotype-phenotype correlations MEN2A: MTC in early adulthood FMTC: MTC in middle age MEN2B: MTC in early-childhood mucosal neuromas (lips, tongue), dysmorphic features (large lips, "marfanoid" body habitus), gastrointestinal ganglioneuromatosis *RET* gene also associated with Hirschsprung disease	Marquart and Eng[175]; American Thyroid Association et al.[176]; Eng[177]; Wells et al.[178]
SDHB, *SDHC*, *SDHD*, *SDHA*, and *SDHAF2* Tumor suppressors Dominant inheritance	Hereditary paraganglioma-pheochromocytoma syndrome	High (particularly *SDHB* and *SDHD*)	PGL–sympathetic and parasympathetic PCCGISTs Renal clear cell carcinoma Papillary thyroid carcinoma (unclear data)	Biochemical screening, physical exam, and imaging Screening may begin as early as age 10 Pharmacologic treatment Surgical management	Secretory and non-secretory PGL High blood pressure, headache, anxiety, profuse sweating, palpitations, pallor *SDHB*: high risk of malignant transformation *SDHD*: parent-of-origin effect–disease-causing when paternally inherited *SDHAF2*: possible parent-of-origin effect (paternal inheritance)	Ricci[90]; Kirmani et al.[179]; Lenders et al.[180]; Gottlieb and Tomlinson[181]; Pai et al.[182]; Neumann et al.[183]

Genes and Details	Syndrome	Penetrance	Associated Neoplasms	Management Considerations	Other Notes	Key References
STK11 (LKB1) Tumor suppressor Dominant inheritance	Peutz-Jeghers syndrome	High	Gastrointestinal lesions (PJS-type hamartomatous polyps; colorectal, stomach, small bowel cancer) Breast Pancreas Gynecologic (ovarian, cervix, uterus) Testes (Sertoli cell) Lung	Colonoscopy Upper endoscopy with small-bowel visualization Breast screening with annual mammography and breast MRI Investigational pancreas screening Gynecologic exam Testicular exam	Mucocutaneous hyperpigmentation of mouth, lips, nose, eyes, genitalia, fingers; may fade after puberty Females: Sex cord tumors with annular tubules (SCTAT); adenoma malignum of the cervix	Syngal et al.[36]; McGarrity et al.[184]; Beggs et al.[185]; Tomas et al.[186]; Giardiello and Trimbath[187]; Jasperson and Burt[188]; Stoffel et al.[189]

THE HEREDITARY NATURE OF CANCER

Although the heritability of cancer has long been recognized and described by astute physicians, the past four decades have witnessed significant strides in our understanding of the genetic basis of cancer susceptibility. By studying cancer-prone families who demonstrate Mendelian modes of inheritance, over 100 rare, high-penetrance cancer predisposition genes have now been identified; these include *BRCA1* and *BRCA2* in hereditary breast and ovarian cancer (HBOC) syndrome, the DNA mismatch repair genes in Lynch syndrome, *TP53* in Li–Fraumeni syndrome, and *APC* in familial adenomatous polyposis (FAP).[217] Identification of such cancer predisposition syndromes has resulted in the incorporation of genetic testing into the treatment of oncology patients, marking one of the first applications of personalized medicine and allowing for tailored cancer screening, prevention, and more recently, even therapeutic measures. Only a fraction of the familial risks of cancer are explained by the known high-

penetrance cancer predisposition syndromes. For example, in the case of breast cancer, 10% of diagnoses are related to high-penetrance pathogenic genetic variants (e.g., *BRCA1* and *BRCA2* pathogenic genetic variants), whereas the remainder are due to familial factors (e.g., additional shared hereditable factors and/or shared environmental factors) or other endogenous or exogenous factors (e.g., age and hormone exposure).[218] Estimates of the extent to which familial cancer risk contributes to cancer incidence have come from the Nordic twin studies, which evaluated the risk of cancer in monozygotic and same-sex dizygotic individuals.[219,220] In the largest familial study of cancer to date, including more than three decades of follow-up, the heritability (the proportion of disease risk variability in a population due to genetic factors) was estimated to be 33%, with significant heritability observed for cancers of the prostate, ovary, kidney, breast, and uterus as well as melanoma and nonmelanoma skin cancer.[220]

Over the past decade, the emergence of new genomic technologies, along with prior candidate gene studies, has started to redefine the genetic architecture of cancer beyond the classic Mendelian single-gene syndrome model (Fig. 6-1). In fact, we are now aware of dozens of moderate-penetrance genes that generally confer a modest degree of cancer risk, with a relative risk (RR) of 2 to 5. Although screening for such moderate-penetrance genes was not routinely undertaken in the past, with the availability of next-generation sequencing, screening for mutations in many genes simultaneously, often in multigene panels, has become readily available. The value of screening for moderate-penetrance genes remains controversial, as neither the clinical validity (the accuracy with which a genetic test predicts the development of cancer) nor the clinical utility (the degree to which the use of the genetic test informs clinical decision-making and leads to improved health outcomes) has been clearly proven.[222]

In addition to the high- and moderate-penetrance cancer genes, hundreds of additional genetic loci have been identified for nearly all the common malignancies; this has been possible largely with the use of genomewide association studies, with each genetic variant, usually in the form of single-nucleotide polymorphisms (SNPs), being associated with only a slightly increased risk of cancer (RR, ~1.1–1.5) (Fig. 6-1).[223] Given the limited clinical validity and utility of SNPs with such small effect sizes, clinical testing for individual risk loci is not performed, although research efforts to incorporate low-penetrance risk alleles into models for risk stratification for public health programs and cancer screening may eventually be feasible.

Finally, as our genetic understanding of cancer susceptibility has evolved, we have come to appreciate that, like other common human diseases, including heart disease, diabetes, and obesity, the vast majority of cancer diagnoses do not have a single genetic cause but are likely associated with the effects of multiple genes in combination with lifestyle and environmental factors. These polygenic and gene-environment interactions make cancer a multifactorial disease whose complexity we are just beginning to unfold.

KEY POINTS

- The high-penetrance cancer susceptibility genes account for only a small proportion of all cancer diagnoses, most notably in breast, ovarian, and colorectal cancers. Based on evidence from twin studies, familial risks for cancer exist outside of the high-penetrance cancer susceptibility syndromes, particularly prostate, ovary, breast, uterus, and melanoma skin cancer.
- Clinical validity (the accuracy with which a genetic test predicts the development of

disease) and clinical utility (the degree to which the use of the genetic test informs clinical decision-making and leads to improved health outcomes) should be taken into account when genetic testing is being considered.

- Genetic testing for moderate-penetrance cancer susceptibility genes associated with a 2- to 5-fold increased risk of specific cancers has become more commonplace, although the clinical validity and utility of testing for many of these genes is not yet fully defined.

GENETIC COUNSELING

Genetic counseling and genetic testing are considered an integral part of the management of individuals with cancer and have been incorporated into practice guidelines of several medical authorities including ASCO, American Gastroenterological Association (AGA), American College of Obstetricians and Gynecologists (ACOG), Society of Gynecologic Oncology (SGO), and the National Comprehensive Cancer Network (NCCN).[1-6] The National Society of Genetic Counselors (NSGC) has defined genetic counseling as the "process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease."[224] Genetic counseling with or without genetic testing provides an opportunity for discussion of concerns regarding one's family cancer history and possible implementation of cancer screening and prevention efforts based on family history alone.

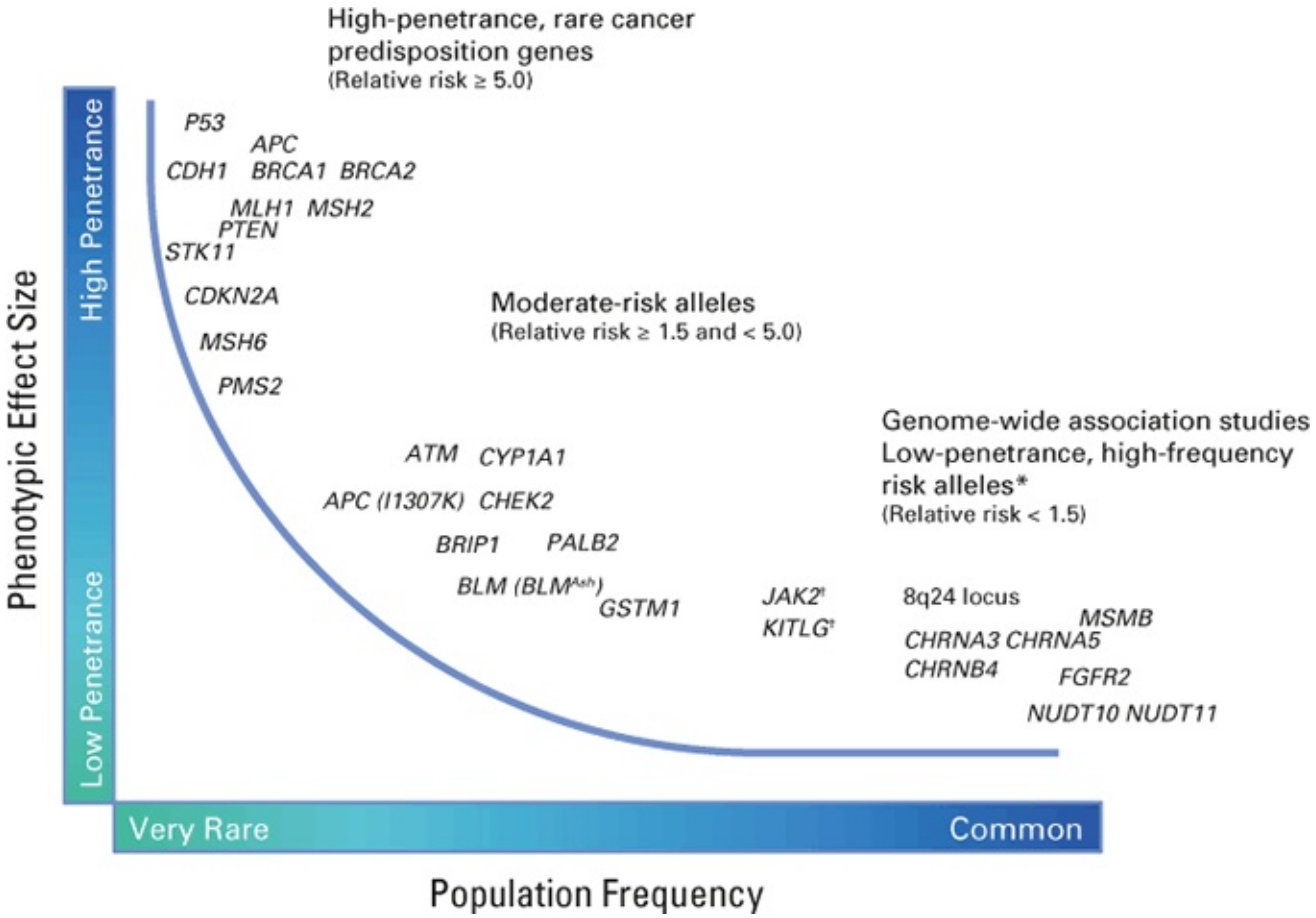

Fig. 6-1 Phenotypic effect size and frequency of occurrence.

*Named genes reflect only the most likely candidate genes to be implicated by the marker single nucleotide polymorphisms (SNPs) identified from the genomewide association studies.

†The marker SNPs mapping to *JAK2* in myeloproliferative neoplasms and *KITLG* in testicular germ cell tumors have odds ratios of approximately 3.0, with allele frequencies ranging from 20 to 40%.

The traditional model of genetic counseling for hereditary cancer syndromes includes both pre- and post-test consultations with a genetic counselor and often a geneticist. While the number of board-certified genetic counselors has grown by 85% since 2006,[224] a workforce shortage does exist. Given this, expanded models of service delivery are now being used, including tele-medicine, telephone-based methods, and genetic counseling provided by other practitioners in the context of coordinated patient care.[1,225] Many oncology patients are now offered genetic testing through next-generation sequencing analyses of tumor and sometimes nontumor specimens for the purpose of clinical trial eligibility. Expanding the role of medical oncologists and nurses to include genetic counseling to and testing of oncology patients when appropriate is one model to meet patients' needs. Importantly though, no matter which clinician provides genetic risk assessment, the principles of genetic counseling should be at the foundation of the patient interaction.

PRETEST GENETIC COUNSELING

Pretest genetic counseling is often considered to be analogous to the informed consent process and is therefore a vital step in helping patients and families determine whether genetic testing (and to what extent) is appropriate[226] (Table 6-3). Some states require informed consent prior to genetic testing (e.g., New York),[227,228] and genetic counseling is one of the ways to fulfill this requirement. Elements of pretest genetic counseling include data collection (medical and family histories, pertinent physical examination), data analysis and risk assessment, education regarding differential diagnoses/genes, evaluation of testing options and various results, selection of appropriate analyses and laboratories, and exploration of the medical, psychosocial, familial, and possible financial consequences of testing.[8] In the context of genetic counseling, psychosocial assessment of a patient may overlap with psychosocial considerations in oncologic care and include investigation of familial communication, the need for additional forms of support, and a patient's understanding of and ability to respond to the various possible ramifications of genetic testing.

The collection and construction (using standardized nomenclature) of family pedigrees is a highly important part of genetic cancer risk assessments. It is standard to evaluate at least three generations of a patient's maternal and paternal lineages, along with the family's ancestral background.[229] Individuals of certain ancestries may have higher risks for specific hereditary syndromes because of the presence of founder mutations;[230] therefore, the knowledge of ancestral background is often critical. In addition to ancestry, the number of relatives, sexes, ages at disease onset, ages at death, multiple primary tumors versus metastatic disease, endogenous and exogenous risk factors, past interventions such as oophorectomies or colorectal polypectomies, and the presence of unusual features or preneoplastic lesions (such as colon polyps, dysplastic moles) are all important pieces in the collection of a family history.[7,9] Pathology reports and medical records from family members' cancer diagnoses are often reviewed by genetic counselors, as inaccuracies in patient-reporting may occur.[231] Family structures may be truncated for a variety of reasons, including number of births and miscarriages, sexes (a paucity of females may explain a lack of gynecologic cancers), adoption, divorce, early death, or estrangement.[232]

Table 6-3 **Components of Informed Consent and Pretest Education in Clinical Cancer Genetics**[227]

Traditional Pretest Counseling for Susceptibility Testing (Purpose of Testing)	Pretest Counseling for Multigene Panel Testing*	Pretest Education for Somatic Mutation Profiling with Potential for Incidental Germline Findings (Purpose of Testing)
Information on specific genetic mutation(s) or genomic variant(s) being tested, including whether range of risk associated with variant will affect medical care	Discussions of specific genes may need to be batched, because it may not be feasible to review each gene individually; high-penetrance syndromes being evaluated should be described (e.g., hereditary breast and ovary, Lynch, hereditary diffuse gastric, Li-Fraumeni); patients should be made aware of possible detection of high-penetrance mutations not suggested by personal or family history; genes of uncertain clinical utility may need to be described more generally.	Discussion of possibility of discovering information relevant to inherited risk and range of possible germline risks that may be identified (differs for targeted sequencing vs. whole-exome or whole-genome sequencing); if there will be a mandatory search for secondary findings, this should be explained, and the option to decline to learn results should be provided.
Implications of positive (mutation confirmed to be deleterious), negative (no identified change in genetic sequence), or uncertain (genetic variant of unknown clinical significance) result	Particular attention should be paid to implications of positive results in less well-understood or lesser-penetrance genes and findings of mutations in genes associated with syndromes not suggested by personal or family history.	Criteria that will be used to identify germline variants that would be returned to patient or family should be described.
Possibility test will not be informative	Attention should be paid to current high rate of variants of uncertain significance.	Emphasis that purpose of test is not to identify germline risk and that dedicated testing directed by personal or family history is available
Risk that children and/or family members have inherited genetic condition	Highlight potential reproductive implications to family of mutations in genes linked to recessive disorders (e.g., *ATM*, Fanconi [*BRCA2*, *PALB2*], *NBN*, *BLM*)	Discussion about how incidental findings may be relevant to other family members
Fees involved in testing and counseling; for DTC testing, whether counselor is employed by testing company		
Psychological implications of test results (benefits and risks)		
Risks and protections against genetic discrimination by employers or insurers		
Confidentiality issues, including DTC testing companies and policies related to privacy and data security		
Possible use of DNA samples for future research		
Options and limitations of medical surveillance and strategies for prevention after genetic or genomic testing		
Importance of sharing genetic and genomic test results with at-risk relatives so they may benefit from this information		Consider identifying surrogate who could receive incidental results on behalf of patient in event patient has died or is otherwise unable to receive results.
Plans for disclosing test results and providing follow-up		

*Same general components as traditional counseling, with special considerations as listed.
Abbreviations: DTC, direct-to-consumer.
Source: Robson ME, Bradbury AR, Arun B, et al. American Society of Clinical Oncology policy statement update: genetic and genomic testing for cancer susceptibility. J Clin Oncol. 2015;33:3660-3668. Epub 2015 Aug 31. PMID: 26324357.

While such an extensive assessment is not expected from an oncologist, it is important to note that oncologists are uniquely positioned to identify individuals who may have an inherited predisposition to cancer or are at a higher risk for additional primary cancers. In fact, obtaining a family history of cancer at an initial patient consultation, as well as periodic reassessment of the dynamic family history during long-term follow-up, is an integral part of oncologic care. The recommended key elements for a minimum adequate cancer family history are highlighted in an ASCO expert statement and should help oncologists identify patients who would benefit from referral to clinical cancer genetics specialists (Table 6-4).[233]

POSTTEST GENETIC COUNSELING

Posttest genetic counseling includes disclosure and interpretation of test results; education about medical implications, management options (screening, risk reduction, therapeutic implications), and appropriate referrals and resources; investigation of the psychological reaction and familial repercussions related to the test results; and the opportunity to provide emotional support.[8] Even for patients who have negative or inconclusive results on genetic testing, posttest genetic counseling is still critically important, as patients and families may still be considered at increased risk for disease and for negative psychological reactions. Importantly, most family histories of cancer are not explained by pathogenic mutations in the known high-penetrance cancer predisposition genes. As such, many cases of familial breast cancer or familial colorectal cancer remain unexplained, but individuals in these families may still be at increased risk for cancer. In the absence of an identified familial mutation, genetic counselors may use various models to help predict risk for family members; this may in turn help inform the use of certain screening methods (see Chapter 7: Breast Cancer). For example, even in the absence of a *BRCA1* or *BRCA2* pathogenic mutation, sisters and daughters of a woman with breast cancer may still be at high enough risk to warrant breast MRI screening.[234] Failure to understand the uninformative nature of a negative or inconclusive genetic test result may lead to nonadherence to medical recommendations.[7] Lastly, posttest genetic counseling should include planning for communication of the genetic test results, disease risks, and medical recommendations to at-risk family members.

Table 6-4 Recommended Key Elements for Minimum Adequate Cancer Family History[233]

First-degree relatives: siblings, parents, children
Second-degree relatives: grandparents, aunts, uncles, grandchildren, nieces, nephews, half siblings
Both maternal and paternal sides
Ethnicity
For each cancer case in the family, establish: Age at cancer diagnosis Type of primary cancer
Results of any cancer predisposition testing in any relative

NOTE. Family history should be taken at diagnosis and updated periodically.

INCORPORATING GENETIC COUNSELING AND TESTING INTO THE CARE OF THE ONCOLOGY PATIENT

Genetic counseling can occur at multiple points in the oncology setting, and it is important for an oncologist to determine, in conjunction with the patient, when genetic counseling and testing is most appropriate (Fig. 6-2).

Genetic counseling and testing at the time of cancer diagnosis (i.e., peridiagnosis, pretreatment) has multiple benefits. Identification of an inherited cancer predisposition syndrome may impact treatment decisions including extent of surgery, chemotherapy and targeted therapeutic options, eligibility for clinical trials, and the risks of radiation. For example, women with *BRCA1*- and/or *BRCA2*-associated breast cancer may decide to pursue risk-

reducing bilateral mastectomy as opposed to breast-conserving surgery, and women interested in mastectomy with reconstruction, if clinically reasonable, may opt to avoid radiation in order to achieve a better aesthetic outcome.[235] Additionally, individuals with Lynch syndrome–associated colon cancer may consider extensive colectomy instead of segmental colon resection to reduce the risk of metachronous colon cancer.[236] For patients with advanced cancers, genetic testing may help to tailor treatment plans and could have implications for clinical trial eligibility. For example, targeted therapies with PARP inhibitors may be an option for patients with *BRCA*-associated ovarian or metastatic breast cancer[237] and programmed cell death 1/programmed cell death ligand 1 (PD-1/PD-L1) checkpoint blockade may be an effective treatment in a patient with a mismatch repair–deficient colorectal cancer.[238] Because the peridiagnostic period may be emotional and overwhelming for patients, genetic counseling and testing may be deferred to a later time. Also, obtaining genetic test results within the desired time frame may not be logistically possible if the disease is extensive and there is a need for immediate intervention.

Genetic counseling and testing may also occur during the treatment period or shortly thereafter (i.e., posttreatment). Genetic testing at this time allows patients to make informed decisions about future cancer surveillance and prevention to help manage the risk for new primary cancers. For example, a woman treated for *BRCA*-associated breast cancer may pursue risk-reducing bilateral salpingo-oophorectomy to reduce her risk of a future ovarian cancer.[44] A woman treated for Lynch syndrome–associated endometrial cancer may consider the use of daily aspirin (chemoprevention) to help reduce the risk of a future colorectal cancer.[105]

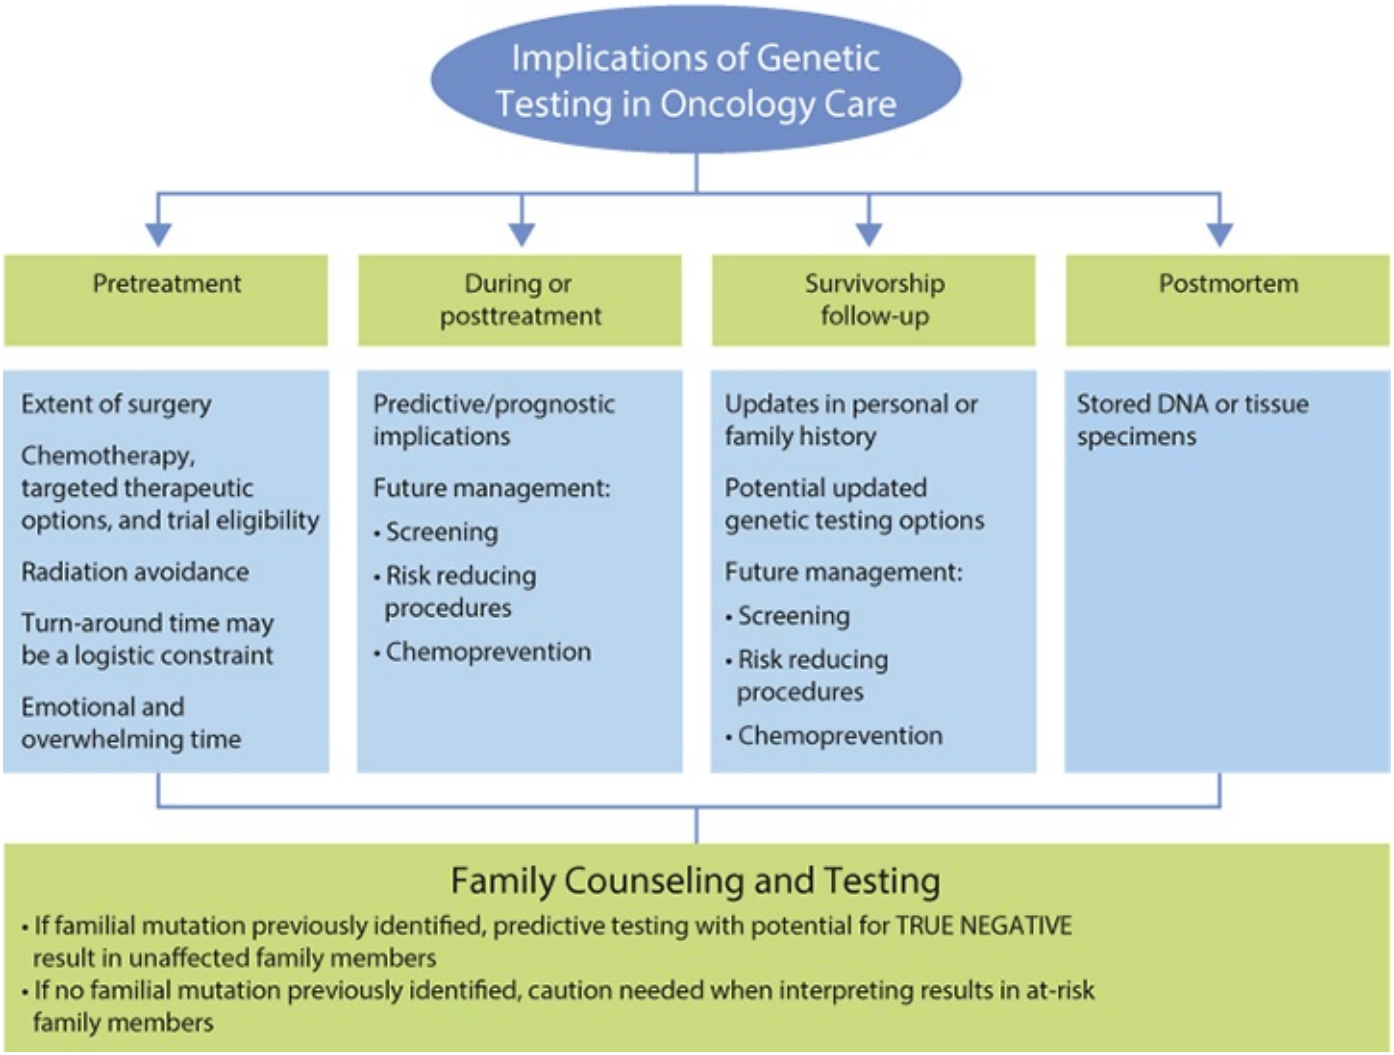

Fig. 6-2 Incorporating genetic counseling and testing into the management of patients with cancer.

IDENTIFYING APPROPRIATE PATIENTS FOR REFERRAL TO GENETIC COUNSELING AND TESTING

Although most cancers are not due to high-penetrance cancer predisposition syndromes, it is crucial for oncologists to be familiar with common “red flag” indications for referral to genetic specialists. Early or unusual age at cancer onset is a key indicator often associated with hereditary cancers. Cancer type and its natural history need to be taken into account when determining if a particular age at onset is unusual. For example, breast cancer in a woman in her 30s warrants referral to genetic counseling and testing, whereas a papillary thyroid cancer diagnosis in a woman of the same age is not particularly unusual and does not necessarily warrant referral. Multiple primary cancers, including bilateral, synchronous, and/or metachronous diagnoses may indicate a genetic susceptibility and warrant genetic risk assessment. A family history of the same type of cancer or multiple related cancers (i.e., colorectal and endometrial cancers; sarcomas and adrenocortical tumors) seen in successive generations should also be a red flag for referral. Additional unique features, such as certain types of gastrointestinal polyps, dermatologic features, ancestries (i.e., those known to have founder mutations), and neoplastic pathologies may also indicate a need for a cancer genetics consultation.[239] In Table 6-5 information on select cancer syndromes and commonly associated neoplastic or preneoplastic pathologies is provided for helping to recognize key features for particular syndromes. NCCN has published criteria for when referrals for genetic counseling and testing should be considered.[240] Also, some third-party payers have established their own criteria for when genetic testing is deemed medically indicated and may not necessarily be congruent with the aforementioned NCCN guidelines. Not all patients and families who undergo genetic counseling proceed with genetic testing, for various reasons (e.g., a lack of medical necessity/indication, not meeting one’s insurance provider’s testing criteria, or declination by the patient/family); however, genetic consultation may provide the opportunity to discuss concerns about a family’s cancer history and, in certain cases, cancer screening and prevention efforts may be implemented based on family history alone.

While taking a thorough medical and family history is important and will aid in the process of identifying possible red flags, it is important for clinicians to realize that not all individuals or families found to have a mutation actually fit into the classic syndrome phenotype descriptions. With next-generation sequencing being performed on patients’ tumor and sometimes germline specimens, a significant number of patients are found to carry germline mutations in genes that would have not been suspected on the basis of their personal or family histories. For example, targeted next-generation sequencing of matched tumor and germline specimens for 76 known cancer predisposition genes identified that 17.5% (182 of 1040) of patients with advanced cancer had an actionable germline mutation; 55.5% of these would not have been detected using clinical genetic testing guidelines alone.[241] Given this finding, it is important that genetic counseling models evolve and that clinicians who provide cancer-focused genetic counseling be skilled in discussing the implications of identified germline mutations with patients and families in the absence of a significant history of cancer.

Table 6-5 **Genetic Cancer Predisposition Syndromes and Selected Associated Pathologies**	
Neoplastic or Preneoplastic Pathologies	**Associated Genetic Syndromes and Genes**
High-grade or poorly differentiated ductal breast cancer with estrogen-receptor, progesterone-receptor, and HER2-neu negativity	*BRCA1*, hereditary breast and ovarian cancer syndrome
Lobular breast cancer	Hereditary diffuse gastric cancer syndrome (*CDH1*)
High-grade serous (papillary serous) ovarian cancer	Hereditary breast and ovarian cancer syndrome (*BRCA1*, *BRCA2*)
Clear cell or endometrioid ovarian cancers	Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*)
Ovarian sex cord tumors with annular tubules (SCTATs)	Peutz-Jeghers syndrome (*STK11*)
Clear cell or endometrioid endometrial cancers	Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*)
Uterine leiomyomas	Hereditary leiomyoma renal cell carcinoma syndrome (*FH*)
Adenoma malignum of the cervix	Peutz-Jeghers syndrome (*STK11*)
Colorectal cancer with tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring cells, medullary growth pattern	Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*)
Lauren's diffuse type/signet ring cell/linitus plastica gastric cancer	Hereditary diffuse gastric cancer syndrome (*CDH1*)
Hamartomatous gastrointestinal polyps	Peutz-Jeghers syndrome (*STK11*); juvenile polyposis syndrome (*BMPR1A*, *SMAD4*); Cowden syndrome (*PTEN*)
Pancreatic neuroendrocine tumors	Multiple endocrine neoplasia type 1 (*MEN1*); von Hippel-Lindau (*VHL*)
Renal papillary type I carcinoma	Hereditary papillary renal cancer syndrome (*MET*)
Renal papillary type II, collecting duct, tubulopapillary carcinomas	Hereditary leiomyoma renal cell carcinoma syndrome (*FH*)
Renal clear cell carcinoma	von Hippel-Lindau (*VHL*)
Renal oncocytoma	Birt-Hogg-Dube syndrome (*FLCN*); tuberous sclerosis complex (*TSC1*, *TSC2*)
Renal angiomyolipoma	Tuberous sclerosis complex (*TSC1*, *TSC2*)
Renal chromophobe	Birt-Hogg-Dube syndrome (*FLCN*)
Sertoli cell tumors of the testes	Peutz-Jeghers syndrome (*STK11*)
Medullary thyroid cancer	Multiple Endocrine Neoplasia type 2 (*RET*)
Cribriform-morula variant of papillary thyroid carcinoma	Familial adenomatous polyposis (*APC*)
Follicular thyroid cancer	Cowden syndrome (*PTEN*)
Medulloblastoma	Turcot syndrome variant of familial adenomatous polyposis (*APC*); Gorlin syndrome (*PTCH*)
Glioblastoma	Turcot syndrome variant of Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*)
Basal cell carcinoma	Xeroderma pigmentosum (multiple XP-associated genes); Gorlin syndrome (*PTCH*)
Sebaceous adenoma, sebaceous carcinoma, keratoacanthoma	Muir-Torre syndrome variant of Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*)
Fibrofolliculomas	Birt-Hogg-Dube syndrome (*FLCN*)
Facial tricholemmomas	Cowden syndrome (*PTEN*)

CONSIDERATIONS IN GENETIC COUNSELING AND TESTING FOR FAMILY MEMBERS

For families identified as harboring a pathogenic cancer–predisposing genetic mutation, unaffected family members can pursue predictive genetic testing with single amplicon (i.e., site-specific) mutation analysis to determine whether they also inherited the familial mutation. For individuals in the family who are found to be carriers of the mutation, increased and early cancer surveillance and preventive and/or risk-reducing measures can be implemented. Oncologists may be involved in the care of a deceased patient's unaffected relatives. If DNA from affected patients can be stored prior to death, these specimens may be used by family members for appropriate genetic evaluations in the future. In circumstances in which affected patients are deceased or not available for genetic testing and no DNA specimens are available, unaffected family members may proceed with individualized genetic evaluation. However, such

results should be interpreted with caution. For example, if a patient dies from breast cancer without undergoing genetic testing and her surviving daughter later tests negative for pathogenic mutations in the *BRCA1* and *BRCA2* genes, how are these results to be interpreted? The daughter's result is considered an "uninformative negative" result. Explanations for this situation include the possibility that the patient/mother actually did harbor a *BRCA1* or *BRCA2* pathogenic mutation, which the daughter did not inherit, consistent with a "true negative" test result. Alternatively, the patient/mother carried an unidentifiable *BRCA1* or *BRCA2* gene mutation or a pathogenic mutation in a different breast cancer predisposition gene that the daughter may or may not also carry. Lastly, the patient/mother's cancer may have been due to sporadic/nonhereditary factors.

ETHICAL PRINCIPLES AND CHALLENGES IN GENETIC COUNSELING

The field of genetic counseling is guided by multiple ethical principles. Four key concepts include autonomy, nonmaleficence, equity, and duty to warn. In the genetic counseling and testing process, an individual has autonomy, or the right to decide whether or not to learn what is coded in his or her DNA. Respect for individual autonomy applies to the testing of minors. If medical treatment of the child would not be altered by the knowledge of an inherited cancer predisposition syndrome, the future autonomy of the child is often taken into consideration.[242] A guiding criterion for when genetic testing should be considered is when the test result may impact medical management.[1,243] For syndromes that involve disease onset or preventive measures in childhood, such as classic FAP or Li–Fraumeni syndrome, genetic testing in the context of genetic counseling and with assent from the child (often ages ~7–17) is accepted.[7] Nonmaleficence is translated into "do no harm," and this concept is particularly relevant to the process of genetic test result interpretation.[244] There are several different possible types of genetic test results (detailed later in this chapter) and each may come with distinct implications for a patient and his or her family members. Therefore, it is critical for clinicians who provide genetic counseling and testing services to understand the various possible results and to translate this information into appropriate treatment recommendations for the patient and family in order to avoid unnecessary medical intervention and psychosocial ramifications. Another emerging issue within the field of hereditary cancer is the determination of risk estimates and clinical management recommendations for moderate-penetrance genes. Many of the moderate-penetrance genes are now routinely incorporated into genetic evaluations in the setting of multigene panels. However, cancer risks associated with these mutations often remain uncertain and result in medical management recommendations that are not evidence-based and potentially pose a risk of harm to patients and family members. With regard to equity, it is noted that access to genetic counseling services and testing is not uniform, as a variety of social and economic barriers, such as physical access (rural vs. urban settings), cost, insurance coverage, fear of discrimination and/or social stigma, and mistrust of the medical system, often come into play.[242] Investigation of these barriers and finding ways to mitigate them will continue to become increasingly important for the responsible translation and use of genetic technologies in our society.[242] Knowledge of a cancer predisposition syndrome requires familial communication, which, not uncommonly, in many families is less than ideal. The concept of a "duty to warn" and the extent of a clinician's responsibility to a patient's family remain controversial in the field of genetics. Previous court rulings have taken different stances on clinicians' duty to warn patients' at-risk family members of inherited risks for cancer.[242,245-247] It is vital for clinicians to understand that there is clearly a direct responsibility to discuss a

patient's genetic test results, to inform the patient that family members may be at risk for an inherited cancer syndrome and that there is a strong recommendation that family members be made aware of and warned of this risk, and to clearly document this communication with the patient.[243,247]

KEY POINTS

- Genetic counseling is a communication process that helps patients understand and adapt to the various implications of having a genetic condition.
- Genetic counseling should include both pre- and posttest discussions and can be performed at various times during the management of oncology patients.
- Thorough medical and family histories are vital for accurate genetic risk assessments.
- The field of genetic counseling is guided by multiple ethical principles, including autonomy, nonmaleficence, equity, and duty to warn.

TUMOR ANALYSES

Although many patients may be identified for genetic counseling and testing on the basis of their personal and/or family history of cancer, for medical oncologists, review of a patient's tumor pathology could also provide the initial clue that a particular tumor may be occurring in the setting of a cancer predisposition syndrome. For example, triple-negative (estrogen-, progesterone-, and HER2/neu-negative) breast cancers are associated with an increased incidence of *BRCA1* germline pathogenic variants, and genetic testing is considered medically indicated for all women at or under age 60 who have this type of cancer according to NCCN and many third-party payers. Patients with medullary thyroid cancer should be referred for genetic testing of the *RET* gene. Table 6-5 reviews additional important cancer predisposition syndromes and tumor pathology associations. For some cancer predisposition syndromes, like Lynch syndrome, analysis of tumor tissue is an integral step in helping to identify at-risk patients. As tumor sequencing technologies rapidly advance and become more commonplace in medical oncology, the importance of tumor tissue analysis as it applies to informing germline genetics must be emphasized.

TUMOR ANALYSIS INFORMS GERMLINE SUSCEPTIBILITY: THE CASE OF LYNCH SYNDROME

The hallmark feature of Lynch syndrome (previously known as HNPCC [hereditary nonpolyposis colorectal cancer)–associated tumors is the presence of microsatellite instability (MSI) resulting from the accumulation of mismatch mutations in the genome, especially at regions of repetitive DNA known as microsatellites, driven by an underlying defect in the mismatch repair pathway (MMR-D). Identification of MMR-D may either be pursued through a polymerase chain reaction–based technique that assesses MSI at a designated set of markers[107,111,248] or through immunohistochemical (IHC) staining of the four DNA mismatch-repair proteins (MLH1, MSH2, MSH6, PMS2) to assess for protein loss in one or more of the MMR proteins.[106] Whereas MSI and MMR-IHC analyses are highly concordant, MMR-IHC has surpassed MSI testing as the

initial screening test for Lynch syndrome because the pattern of protein loss can help direct germline genetic testing.

In the most common Lynch syndrome–associated cancers, including colorectal and endometrial cancers, the need for tumor screening for Lynch syndrome has traditionally been based on the age at cancer diagnosis or on the strength of the personal and family history, as outlined in the revised Bethesda guidelines.[111] However, as per the most recent guidelines from EGAPP (Evaluation of Genomic Applications in Practice and Prevention Working Group) and NCCN, screening of all colorectal tumors (or at least all colorectal tumors in patients less than age 70 at diagnosis or those over age 70 meeting revised Bethesda guidelines) and endometrial tumors via MSI or MMR-IHC analysis is now recommended.[249,250] For patients with abnormal screening test results (MSI-high or MMR-D tumor), various algorithms have been developed to help guide subsequent evaluations; these may include germline genetic testing or further tumor analyses, such as *MLH1* promoter hypermethylation and/or *BRAF* V600E somatic mutation.[249,250]

NEXT-GENERATION TUMOR SEQUENCING: IMPLICATIONS FOR GERMLINE-SUSCEPTIBILITY

Next-generation sequencing of tumors (i.e., somatic mutation profiling) for helping to define therapeutic targets has become increasingly common in the field of medical oncology. Somatic mutation profiling is available via a number of commercial laboratories and academic institutions and generally consists of a multigene panel that incorporates numerous genes previously implicated in carcinogenesis, many of which are also associated with germline cancer predisposition syndromes.

If tumor-only sequencing is undertaken, the majority of sequence variants identified in the patient's tumor will represent acquired/somatic mutations resulting from tumor development, but importantly, mutations in the germline DNA will also be unmasked. For example, tumor-only sequencing of a 25-year-old woman with breast cancer may identify a missense *TP53* mutation. Given the patient's very early age at breast cancer diagnosis, this mutation may represent a germline mutation consistent with Li–Fraumeni syndrome, as opposed to an acquired mutation, with implications for future cancer risk for the patient and her family members. If more extensive tumor analysis, such as exome or whole-genome sequencing is performed, predispositions to nononcologic diseases may also be revealed. Although these are considered to be incidental results, the identification of such genetic changes may be clinically significant, and the medical oncologist who requests the tumor-only sequencing, along with the patient, should be aware that somatic mutation profiling may result in germline findings for which referral to genetics specialists and confirmatory germline testing is recommended.

Somatic mutation profiling may also be undertaken through the analysis of both tumor and normal DNA. Laboratories using this method analyze the tumor and normal DNA simultaneously and apply informatic analyses to subtract the inherited (germline) variants from the tumor sequence. This results in the reporting of only tumor-specific or tumor-acquired variants. Importantly, in this tumor/normal sequencing approach, since the germline genetic information is not reported, pathogenic germline mutations in known cancer susceptibility genes would remain masked, requiring the medical oncologist to refer the patient for clinical genetic counseling and testing based on traditional criteria, including personal and family cancer histories.

Lastly, somatic mutation profiling may also reveal mutational patterns that predict the presence of a cancer susceptibility syndrome. For example, mutational load on somatic profiling

may identify hypermutated tumors, which may result from MMR-D/MSI-H, a marker of Lynch syndrome.[251] As such, somatic mutation profiling that reveals the presence of a hypermutated endometrial tumor should prompt MMR-IHC or MSI testing and, if appropriate, genetic referral. Bioinformatic tools that predict MSI from somatic mutation profiling have been developed and are being incorporated into the somatic mutation profiling pipelines to help clinicians correctly identify tumors with MMR-D/MSI.[252,253]

KEY POINTS

- Evaluation for Lynch syndrome typically starts with tumor screening for microsatellite instability or DNA mismatch–repair deficiency. In the case of an abnormal screening test, subsequent tumor and/or germline evaluation is warranted to make the diagnosis of Lynch syndrome.
- Next-generation sequencing of tumors (i.e., somatic mutation profiling) for the identification of therapeutic targets can be performed with or without the inclusion of parallel normal (nontumor) DNA sequencing. In order to appropriately interpret the results and determine potential hereditary risks for the patient, a clinician ordering tumor somatic mutation profiling must be aware of the testing approach used.
- Genetic evaluation of somatic (tumor) tissue can potentially reveal germline pathogenic variants that may be of significance for a patient and/or family members.

GERMLINE ANALYSES

SPECIMENS AND LABORATORY STANDARDS

For germline genetic testing, the most commonly used specimen is blood because of its high DNA yield. Some commercial laboratories now offer germline genetic analyses on sputum specimens; however; not all analyses may be validated for such use. For patients who have undergone allogeneic bone marrow or stem cell transplantation, tissue, rather than blood, is necessary for germline analysis, and frequently a skin punch biopsy is obtained for fibroblast culture, which can then be used for germline analysis. Lastly, when single amplicon analysis or targeted mutation analysis is needed, some laboratories may perform the analysis on paraffin-fixed tissue (tumor or normal). For example, a deceased individual's paraffin-fixed tissue could be used for analysis of the three common Ashkenazi Jewish founder mutations in the *BRCA1* and/or *BRCA2* genes, thus helping to inform a family member's risk assessment.[254]

Laboratories performing molecular genetic testing are subject to the general Clinical Laboratory Improvement Amendments (CLIA) regulations and must meet standards for quality, accuracy, and reliability.[255] In addition, the Centers for Disease Control and Prevention (CDC) and the Centers for Medicare and Medicaid Services (CMS) have taken additional steps to ensure quality management with regard to molecular genetic testing for heritable disease and conditions.[256] Variations in state regulations of genetic and genomic tests also exist, with some states requiring laboratory certificates and licensure exceeding CLIA standards (i.e., New York, Washington).[257] Notably, CLIA requires that tests not regulated by the U.S. Food and Drug Administration (FDA) meet criteria for analytic validity, but demonstration of clinical utility and clinical validity are not required components. As a result, multigene panels for cancer

susceptibility testing may include genes with limited scientific evidence with regard to cancer risk.[1,258] At the federal level, the FDA serves as an additional regulatory pathway for certain genetic tests. The FDA has promoted draft guidance for the future regulation of such laboratory-developed tests.[259]

GERMLINE GENETIC TEST RESULTS

On germline analysis, patients must be prepared for several different types of test results (Fig. 6-3):

- Pathogenic/deleterious mutation (variant)
  - In high-penetrance genes, pathogenic mutations are presumed to be responsible for the patient's personal or family history of cancer. (This may not always be the case, though, when multigene panel testing with moderate-penetrance genes is performed; see subsequent section entitled Genetic Testing Using Multigene Panels for further discussion.)
- Suspected pathogenic/ deleterious mutation (variant)
  - With this result, there is high suspicion, but not complete certainty regarding the pathogenicity of the genetic alteration. Caution must be taken when counseling a patient and family members regarding this result.
  - If presymptomatic/predictive testing for the alteration is performed for a family member, increased cancer surveillance recommendations may still be indicated even in the absence of a positive result.
- Genetic variant of uncertain clinical significance (VUS)
  - An alteration is detected, but the laboratory does not have enough data to allow for clinical classification/interpretation of the alteration's effect on the gene's function or protein product or clinical relevance. Patients and family members should be counseled about the ambiguous nature of the result and the continued need for all family members to consider themselves at risk.
  - Communication with the testing laboratory regarding what is known about the genetic variant is a reasonable first step for any clinician. Various resources, tools, and research analyses may be used by genetic counselors and geneticists to help provide further clarification. With time and access to additional data, many labs reclassify these variants; and many, perhaps most, are reclassified as being benign.[260]
- Likely benign variant
  - An alteration is detected, but the laboratory has a low suspicion of it being associated with disease.
- Negative/normal result
  - No alterations of clinical significance or uncertain significance identified. Negative results may not be informative and a patient and family members may still harbor a pathogenic mutation in a different cancer predisposition gene.
  - *True negative:* In the case that an individual is being tested for a previously identified familial pathogenic mutation, a negative result is considered a "true negative result," and for the associated cancers, the individual is presumed to be at the same risk as the general

population.

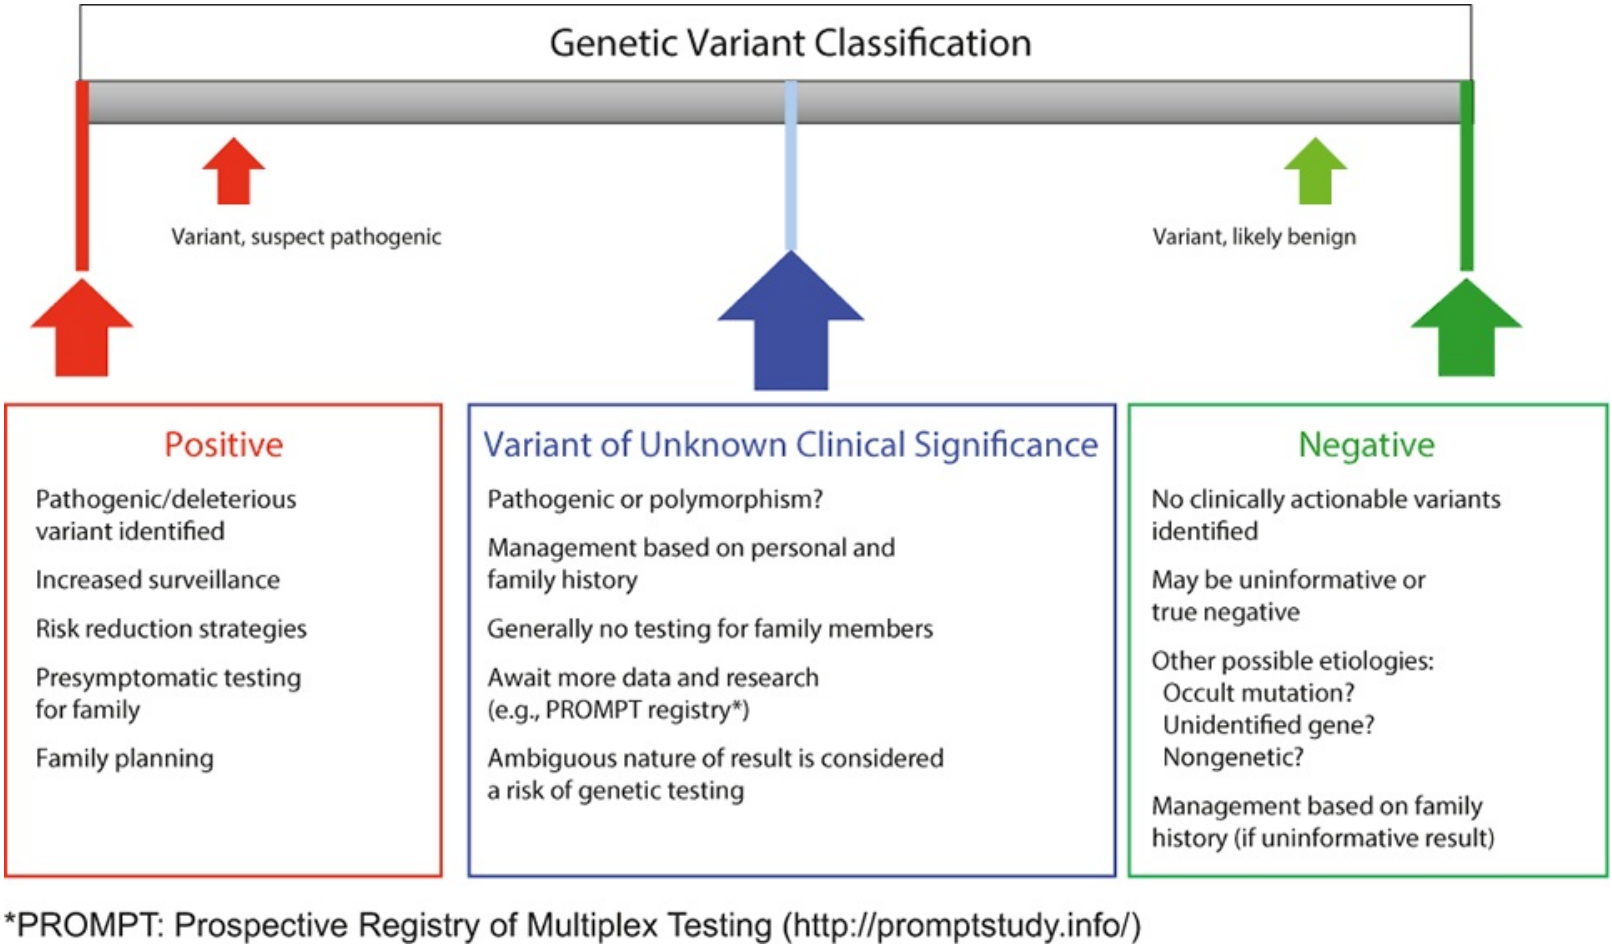

Fig. 6-3 Spectrum of genetic test results.

APPROACHES TO GERMLINE GENETIC TESTING

Phenotype-Directed Genetic Testing

The field of cancer genetic testing and counseling has traditionally followed a phenotype-based approach for genetic testing wherein the selection of genes to be analyzed is based on the patient's personal or family cancer history and would include only genes associated with the demonstrated phenotype. A related, second approach is to focus on ancestry-specific founder mutations. Founder mutations are genetic alterations observed with high frequency in a distinct group that is or was geographically or culturally isolated and in which one or more of the ancestors was a carrier of an altered gene. With reexpansion of the population, the founder mutation is perpetuated, usually at a higher prevalence. Founder mutations have been identified in several populations.[230,261-266] A common example pertains to individuals of Ashkenazi Jewish descent, in whom the prevalence of the three founder mutations in *BRCA1* and *BRCA2* is 2.5%, leading to a lower threshold for genetic testing of Ashkenazi Jewish patients affected with HBOC-related cancers compared to individuals from nonfounder populations; this is supported by NCCN and third-party payers.[230] A third approach pertains to families with a previously identified familial mutation; in these cases, predictive/presymptomatic testing for the site-specific mutation can be undertaken for accurate cancer risk assessment.

Genetic Testing Using Multigene Panels

In contrast to sequential single-gene and phenotype-driven testing, next-generation sequencing technologies have enabled the use of multigene panels for germline analysis, wherein multiple cancer susceptibility genes are assessed simultaneously. Disease-specific multigene panels for nearly all of the common cancers (breast, ovary, uterine, colon, kidney, advanced prostate) as well as pan-cancer panels are now widely available through commercial laboratories.[222] The ease of use, cost, and time efficiency associated with multigene panel testing for cancer susceptibility has resulted in a dramatic increase in the application of this testing approach over the past 5 years. It is an especially useful approach when significant genetic heterogeneity exists or multiple genes/syndromes may be implicated on the basis of phenotype or family history.[222] For example, in individuals with early-onset or hereditary pheochromocytoma/paraganglioma, simultaneous as opposed to sequential testing for 10 genes has proven to be an efficient testing method for this genetically heterogeneous syndrome.

On the other hand, multigene panels also have several limitations. This approach to genetic testing poses a significant challenge for the traditional pretest counseling model discussed previously, as the in-depth counseling that is provided for single-gene testing is not possible for a panel that may include as many as 20 to 30 genes (Table 6-1). If the panel contains high-penetrance genes, especially those with implications for multiple tumors or childhood cancers (e.g., *TP53*), or drastic risk-reducing measures like gastrectomy (e.g., *CDH1*), an unexpected positive result without pretest discussion and preparation may result in distress and anxiety. This is particularly the case when a patient's personal or family history is not in line with the hereditary syndrome identified using the multigene panel. For example, if a *CDH1* pathogenic mutation is unexpectedly identified in a patient who has no personal or family history of diffuse gastric cancer or lobular breast cancer, the patient and physician are left in a clinical conundrum as to whether historical cancer risk estimates based on ascertainments of familial hereditary diffuse gastric cancer kindreds are applicable and whether to pursue risk-reducing gastrectomy, which is associated with significant morbidity. Additionally, multigene panels also generally include genes associated with moderate-penetrance cancer risk (Table 6-4), where the associated cancer spectrum, lifetime risks, age-associated penetrance, and appropriate management recommendations have not yet been fully defined. Importantly, the presence or absence of a mutation in a moderate-penetrance gene may not provide clarity with respect to cancer risk. In fact, a patient with a positive test result may not require additional surveillance, while a patient with a negative result, especially in the context of a significant family history, may still be recommended to undergo increased cancer surveillance. Multigene testing also results in a higher incidence of an uncertain/ambiguous genetic test results (as previously described) leading to further difficulties with the interpretation of results. A genetic registry called PROMPT (Prospective Registry of Multiplex Testing) has been created to help clarify some of the questions raised by multigene panel testing.[267] Interestingly, an initial finding from PROMPT highlighted the conflicting classifications of a number of genetic alterations across different commercial laboratories resulting in varying clinical interpretations of genetic variants with implications for medical management recommendations. [268]

A final point on multigene panel analyses that is important for provider and patient to understand is that some of the genes included on the panel may have reproductive implications. For example, the *NBN* gene is associated with a rare, but severe autosomal recessive condition (Nijmegen breakage syndrome). Although the presence of a monoallelic mutation may have limited implications, it may point to a risk for offspring to have a more severe condition, and preconception/prenatal genetic counseling for the family may be indicated.

GENOME AND EXOME ANALYSES

The aforementioned approaches to genetic testing have in common a distinct focus on cancer-related genes. However, with the advent of clinical exome and whole-genome sequencing, pathogenic or suspected pathogenic mutations may be uncovered in genes unrelated to the primary medical reason for testing; these findings have been termed "secondary findings."[269] Considerable debate and discussion has been prompted with regard to the extent to which primary data should be analyzed for secondary findings and which, if any, pathogenic variants discovered should be disclosed to patients. In an effort to standardize the reporting of actionable information from clinical genomic sequencing, in 2013, the American College of Medical Genetics and Genomics (ACMG) published a list of 56 medically actionable genes,[270] updated to 59 genes in 2016,[271] in which pathogenic mutations are recommended to be reported because of the high likelihood of severe disease that may be preventable if identified before symptoms occur. The ACMG's initial 2013 recommendation for a "mandatory" return of clinical genomic sequencing results for these genes was met with considerable debate, and the recommendations were later updated to provide patients the opportunity to "opt out" of the analyses of genes unrelated to the indication for testing, with the decision to be made during the process of informed consent before testing (Table 6-1). Notably, 24 of the current 59 ACMG reportable genes are associated with cancer predisposition syndromes, highlighting the relevance of these recommendations to the field of medical oncology.

Genomic sequencing is a powerful tool; however, significant further challenges include standardization of variant classification, filtering, and curation of variant pathogenicities. Inconsistencies among clinical molecular laboratories and clinical genomic sequencing analyses have been highlighted,[272] and integration of multiple lines of support using standardized methods is necessary for classifying genetic alterations into one of five categories: pathogenic, likely pathogenic, uncertain significance, likely benign, and benign.

To meet this challenge, the National Institute of Health has supported the formation of ClinGen, an authoritative central resource aimed at defining the clinical relevance of genomic variants for use in precision medicine and research.[273] ClinGen is often used by genetic counselors and geneticists; this resource aims to answer critical questions regarding clinical validity, pathogenicity, and clinical usefulness or medical actionability of a particular genomic finding. The cornerstone of ClinGen is ClinVar, a freely available web-based archive that is maintained by the National Center for Biotechnology Information (NCBI) and reports on interpretations of clinical significance of variants and allows for both deposition and retrieval of variant data and annotations.[274,275]

The BRCA Challenge is an international project that aims to further knowledge regarding the genetic underpinnings of breast and other cancers through worldwide data sharing.[276] Integrated efforts, such as ClinGen/ClinVar and the BRCA Challenge, are crucial to ensuring appropriate interpretation of genomic variants before incorporation into patient care.

DIRECT-TO-CONSUMER GERMLINE GENETIC ANALYSES

Direct-to–consumer (DTC) genetic testing has challenged the traditional practical and ethical frameworks established in the field of clinical genetics. DTC genetic tests are advertised and sold directly to individuals, generally without supervision by a healthcare professional. Saliva-collection kits allow consumers to send their specimens directly to commercial laboratories with results generally returned by mail, e-mail, or phone. DTC testing is available for both disease- and non–disease-related phenotypes, including "recreational genomic" testing for genetic traits

such as detecting asparagus odor in urine. The FDA, the CDC, and the Federal Trade Commission have issued consumer warnings about the claims of certain genetic tests and their use for medical management. Nonetheless, many DTC tests are currently available and patients undergoing such analysis for cancer or medical risk assessment should be directed to genetics specialists for assistance with interpretation of the results.

OTHER CONSIDERATIONS RELATED TO GERMLINE GENETIC ANALYSES

For oncology patients unable or unwilling to undergo genetic testing during their lifetime, and in those with uninformative results, commercial DNA banking may be a reasonable consideration. Many commercial laboratories now work with patients, families, physicians, and hospice-care providers to have a sample of blood (or other tissue) collected before death and stored for future use by a designated individual/family member. The affected individual's DNA can be used when the family is ready to have testing performed or if science advances with regard to the availability of additional clinical genetic tests.

Some individuals may consider using genetic test results to help inform reproductive decisions. For example, instead of conceiving naturally, some individuals may consider the use of assisted reproductive technologies such as in vitro fertilization (IVF) with preimplantation genetic diagnosis (PGD) or the use of donor gametes (eggs or sperm). IVF with PGD has been used for multiple inherited cancer syndromes.[277] Other reproductive options that may be considered include adoption or prenatal diagnosis via chorionic villus sampling (CVS) or amniocentesis, with consideration of pregnancy termination.

Many individuals may express concerns over insurance coverage and insurance-related repercussions of genetic counseling and testing. Most third-party payers include some level of coverage for genetic counseling and testing services. Some payers have established personal and family history criteria that must be met in order for medical necessity to be established; others may follow suggested testing guidelines that have been published by groups such as the NCCN.[278,279] Some payers require the involvement of a genetic counselor in the pretesting counseling and testing process. Many commercial laboratories offer insurance coverage determination before performing genetic testing. Federal legislation through the Genetic Information Nondiscrimination Act (2008), and in some cases additional state legislation, provides protection against genetic discrimination by one's employer and health insurance provider.[280] Unfortunately, protection against discrimination by life, disability, and long-term care insurance providers is not universal in the United States at this time. The potential risks for out-of-pocket costs related to genetic counseling and testing services and genetic discrimination are a necessary part of the pretest counseling and informed consent process.[7]

KEY POINTS

- Clinical molecular genetic testing must be performed according to Clinical Laboratory Improvement Amendments (CLIA) regulations and must meet standards for quality, accuracy, and reliability. Additional state-specific regulations for genetic testing laboratories may also apply.
- Germline genetic test results typically fall into one of five categories of genetic variants: pathogenic, likely pathogenic, uncertain clinical significance, likely benign, and benign. Recommendations for management of cancer risk and predictive testing for family

members differ significantly based on the classification of the variant and should be assessed carefully.

- Multigene panel cancer susceptibility testing is challenging the traditional phenotype-directed and often serial approach to genetic testing. When appropriate, multigene panel testing may be both a cost and time efficient method for genetic testing.
- Multigene panel testing poses challenges for pretest counseling and may result in unexpected pathogenic variants and a higher incidence of variants of unknown clinical significance.
- Genome and exome analyses may identify pathogenic or suspected pathogenic genetic variants in genes unrelated to the primary medical reason for testing, termed “secondary findings.”
- The Genetic Information Nondiscrimination Act, enacted in 2008, provides protection against genetic discrimination by an individual’s employer and health insurance provider.

GENETICS IN MEDICAL ONCOLOGY PRACTICE

The collection of family history data, and the continued updating of this dynamic information on a regular basis, is an important task for medical oncologists and allows for the identification of patients and families who may benefit from genetic counseling and testing. Genetic counseling is not just for patients who have already undergone testing and were found to have genetic alterations; rather, it is for patients and families who are considering the option of genetic testing in the future or for individuals who may simply benefit from a risk-assessment discussion.[7] Oncologists are encouraged to recognize the importance of both pretest and posttest genetic counseling and to build relationships with local genetic counselors and other genetic specialists and see them as allies in the challenge of helping patients and their families through a diagnosis of cancer. Resources to find genetic specialists include the National Society of Genetic Counselors (NSGC), the American Board of Genetic Counseling, Inc., the National Cancer Institute Cancer Genetics Services Directory, and the GeneTests Clinic Directory.[8] Resources to learn more about cancer genetics and risk assessment include the ASCO University Cancer Genetics Program, NSGC, and the National Human Genome Research Institute.[9,227]

BREAST CANCER

Tufia C. Haddad, MD, and Charles L. Loprinzi, MD

Recent Updates

Breast Cancer Staging

- Because the specific prognosis for an individual cannot be determined solely by anatomic staging, revisions to breast cancer staging in the AJCC 8th edition (to be implemented January 1, 2018) notably incorporate prognostic molecular markers including histologic grade, hormone receptor and HER2 status, and 21-gene assay results, with classic TNM anatomic criteria. (*AJCC Cancer Staging Manual.* 8th ed. New York: Springer; 2017)

Molecular Prognostic and Predictive Markers

- Results from independent prospective evaluation of the 21-gene recurrence score assay (Oncotype DX) and the 70-gene signature (MammaPrint) provide early but still incomplete validation of these tools as prognostic indices that may furthermore be predictive of adjuvant chemotherapy benefit. (Sparano JA, *N Engl J Med* 2015; Cardoso F, *N Engl J Med* 2016)
- In 2016, ASCO published clinical practice guidelines on the use of biomarkers to guide adjuvant systemic therapy for early-stage invasive breast cancer. (Harris LN, *J Clin Oncol* 2016)

Adjuvant Systemic Therapy

- The MA.17R trial evaluated extended therapy with an aromatase inhibitor (AI) in postmenopausal women with ER-positive operable breast cancer. Continuing the AI for a total of 10 years improved 5-year disease-free survival (DFS) (defined by recurrence and contralateral breast cancer events), by a couple of percentage points, compared with those who discontinued their AI after the initial 5 years. There was no difference in 5-year OS or quality-of-life measures; however, bone-related toxicities (bone pain, fractures, and new-onset osteoporosis) were more frequent among those taking letrozole. (Goss PE, *N Engl J Med* 2016)
- In NSABP B-42, however, after an initial 5 years of adjuvant endocrine therapy in postmenopausal women, there was no significant difference in 5-year DFS (defined by recurrence, contralateral breast cancer, nonbreast cancer, and death) for those who discontinued therapy compared with those who received an AI for an additional 5 years. Extended endocrine therapy did significantly reduce the risk of distant relapse and improve the breast cancer–free interval. Two additional phase III studies did not demonstrate a DFS benefit from extended therapy with an AI beyond an initial 5 years of adjuvant endocrine treatment. (Mamounas EP, San Antonio Breast Cancer Symposium 2016)
- The APHINITY trial randomly assigned 4805 patients with HER2-positive, node-positive or high-risk node-negative breast cancer to adjuvant chemotherapy with trastuzumab and placebo/pertuzumab. Pertuzumab reduced the risk of an invasive DFS event by 19% compared with placebo (hazard ratio [HR], 0.81; 95% CI; 0.66, 1.00; p = 0.045) at a median follow-up of 45.4 months. Treatment was effective in all subgroups; however, those with node-positive and/or hormone receptor–negative disease appeared to derive the most benefit. Diarrhea was increased in the pertuzumab arm, predominantly during chemotherapy and with the TCH regimen. Cardiac toxicity was low and not different between the two arms. (vonMinckwitz G, *J Clin Oncol* 2017)
- In the phase III ExteNET trial, 2840 patients with early-stage HER2-positive breast cancer were randomly assigned in a double-blind, placebo-controlled study of neratinib following completion of adjuvant trastuzumab treatment. One year of adjuvant neratinib was associated with a 2-year invasive DFS rate of 94.2% compared with a rate of 91.9% in those receiving placebo (HR, 0.66; 95% CI; 0.49, 0.90; p = 0.008). These results led to the FDA approval of neratinib in 2017. (Chan A, *Lancet Oncol* 2016)

- A joint Cancer Care Ontario and American Society of Clinical Oncology Clinical Practice Guideline on the use of adjuvant bisphosphonates and other bone-modifying agents in breast cancer recommended that zoledronic acid or clodronate be considered as adjuvant therapy for postmenopausal patients with breast cancer who are deemed candidates for adjuvant systemic therapy. Postmenopause includes natural menopause or that induced by ovarian suppression or ablation. (Dhesy-Thind S, *J Clin Oncol* 2017)

Neoadjuvant Systemic Therapy

- While the addition of carboplatin to neoadjuvant anthracycline- and taxane-based chemotherapy in patients with stage II and III triple-negative breast cancer significantly increased pathologic complete response rates in two large prospective trials, the 3-year DFS and overall survival (OS) results were conflicting, with only one trial demonstrating improved clinical outcomes. Its use remains investigational. (Sikov WM, San Antonio Breast Cancer Symposium 2015; von Minckwitz G, San Antonio Breast Cancer Symposium 2015)

Locoregional Therapy

- The 2016 ASCO/ASTRO/SSO guidelines recommend postmastectomy radiotherapy (PMRT) to those with T1–2 breast cancer with one to three positive lymph nodes and to those with positive lymph nodes following neoadjuvant systemic therapy. There is currently insufficient evidence to recommend whether PMRT should be administered or can be routinely omitted in those with clinically negative nodes who receive neoadjuvant systemic therapy or in those with a complete response in the lymph nodes with neoadjuvant systemic therapy. (Recht A, *J Clin Oncol* 2016)

Recurrent or Metastatic Disease

- The OlympiAD trial evaluated the PARP inhibitor olaparib as monotherapy compared with single-agent chemotherapy of physician choice in patients with germline *BRCA*-mutant, HER2-negative advanced breast cancer. Olaparib was associated with an objective response rate of 60% and a superior median progression-free survival (PFS) of 7.0 months, compared with 4.2 months for patients receiving conventional chemotherapy (HR, 0.58; p = 0.0009). (Robson ME, *J Clin Oncol* 2017)
- The PALOMA-2 trial evaluated letrozole alone and combined with the CDK4/6 inhibitor palbociclib as first-line therapy for hormone receptor–positive, HER2-negative advanced breast cancer. This trial demonstrated an improvement in median PFS from 14.5 months with letrozole alone to 24.8 months for the combination therapy (p < 0.001). Objective response rates were also higher. OS data remain immature. (Finn RS, *N Engl J Med* 2016)
- The PALOMA-3 trial evaluated fulvestrant alone and combined with palbociclib after progression on prior endocrine therapy for hormone receptor–positive, HER2-negative advanced breast cancer. This trial demonstrated an improvement in median PFS from 4.6 months with fulvestrant alone to 9.5 months for the combination therapy (HR, 0.46; p < 0.0001). (Cristofanilli M, *Lancet Oncol* 2016)
- The MONALEESA-2 trial evaluated letrozole alone and combined with the CDK4/6 inhibitor ribociclib as first-line therapy for postmenopausal, hormone receptor–positive, HER2-negative advanced breast cancer. A preplanned interim efficacy analysis demonstrated an improvement in PFS (HR, 0.556; 95% CI; 0.429, 0.720; p < 0.0001). The results of this study led to FDA approval of ribociclib in combination with an AI as first-line therapy in this patient population. (Hortobagyi G, *N Engl J Med* 2016)
- The FALCON trial evaluated fulvestrant compared with letrozole as first-line therapy for hormone receptor–positive, HER2-negative advanced breast cancer. This trial demonstrated an improvement in PFS from 13.8 months with letrozole to 16.6 months with fulvestrant (p = 0.0488). (Robertson JFR, *Lancet* 2016)

Supportive Care

- A randomized trial that compared up-front zoledronate at monthly or every-3-month intervals for 2 years demonstrated equivalent skeletal-related outcomes in patients with bone metastases. (Himelstein AL, *JAMA* 2017)
- In 2016, ASCO and the American Cancer Society developed a comprehensive set of guidelines that extend beyond cancer surveillance recommendations to further address symptom management, surveillance and management of late toxicities of cancer therapy, and general wellness (weight management, nutrition, activity, etc.) recommendations. (Runowicz CD, *J Clin Oncol* 2016)

OVERVIEW

The incidence of breast cancer, the most common cancer in U.S. women, has remained steady over the past decade; mortality from breast cancer has consistently declined annually since

approximately 1990, primarily as a result of advances in systemic therapy. For early-stage breast cancer, advances in surgery and radiation oncology have led to the deescalation of locoregional therapy. In select patients, axillary lymph node dissection may be avoided, and partial-breast irradiation or hypofractionated whole-breast irradiation may be alternatives to traditional whole-breast irradiation. Improvements in the efficiency of drug development have led to the rapid study of several new targeted, investigational agents. As a result, in the past 5 to 10 years, several new treatment options for patients with metastatic hormone receptor–positive or HER2-positive breast cancer have appeared. Better therapeutic options are still needed for patients with estrogen-receptor–negative, progesterone-receptor–negative, HER2-negative ("triple-negative") disease. Advances in supportive care have reduced serious complications of breast cancer treatment and improved symptom management and patient quality of life.

EPIDEMIOLOGY

Breast cancer remains the most common malignancy diagnosed among women in the world, with about 1.7 million women worldwide diagnosed in 2012, accounting for 25% of all new cancer cases.[1] The incidence rates are higher in economically developed regions such as North America, Western Europe, and Australia/New Zealand and lower in economically developing areas such as sub-Saharan Africa and Asia. The incidence rates of breast cancer in developed countries increased between 1980 and 1990 because of the increased use of breast cancer screening and changes in reproductive factors. Since 2000, the postmenopausal breast cancer incidence has decreased in these countries, attributed to the decline in the use of menopausal hormone therapy.[2]

Worldwide, breast cancer was the most common cause of cancer death in women, and it accounted for 521,817 of the total estimated 8.2 million cancer-related deaths in 2012.[3] Since 1990, the United States, the United Kingdom, and France have experienced a reduction in breast cancer–related deaths, primarily thought to be due to more effective systemic therapies and improvements in early detection. In contrast, changes in reproductive patterns, increased obesity, and decreased physical activity are thought to have contributed to a 2- to 3-fold increase in the incidence of breast cancer in African and Asian countries, with a corresponding increase in breast cancer deaths.[4] In the United States, an estimated 249,260 new cases of invasive breast cancer were expected to be diagnosed in 2016, involving 2600 men and 246,660 women.[5] It was also estimated that there were 61,000 new cases of in situ breast cancer diagnosed in 2016. There are more than 2.8 million breast cancer survivors in the United States. Breast cancer continues to be the most common malignancy among women in the United States, and it remains the second most common cause of cancer-related death among women (behind lung cancer), with an estimated 40,450 deaths in women attributed to breast cancer in 2016.

In the United States, following an initial increase in the incidence of localized (node-negative) and regional disease in the 1980s to 1990s, the incidence of each category has decreased by 2.3% and 2.8% per year, respectively. Between 1998 and 2007, the overall incidence of breast cancer decreased by 0.5% per year. Following a striking 7% decrease in incidence between 2002 and 2003, the rate remained relatively stable from 2003 to 2011.[6] There has been no noticeable annual change in the 6% incidence of metastatic disease diagnosed at the time of presentation.[5] The mortality from breast cancer decreased by 36% from 1989 to 2012, and the rate has been level among women younger than age 50.[7]

Race and ethnicity are important considerations in the evaluation of breast cancer incidence and mortality in the United States. The incidence of breast cancer is higher among white women than among black women (e.g., 128 non-Hispanic white women vs. 124 non-Hispanic black women per 100,000 were diagnosed with breast cancer from 2008 to 2012). Some factors that contribute to the higher incidence seen among white women include more frequent use of menopausal hormone therapy and more widespread use of screening mammography. When mortality data are evaluated the incidence is reversed (e.g., 22 white women vs. 31 black women per 100,000 died of breast cancer from 2008 to 2012).[8] Multiple factors play a role in this observation. Breast cancer is more likely to develop before the age of 40 in black women than in white women; black women are also more likely to be diagnosed at a more advanced stage of breast cancer and to have high-grade, triple-negative tumors. In addition, it may be that more nonsignificant breast cancers—those that would never have caused clinically apparent or life-threatening disease—are diagnosed in white women because of higher rates of screening. Breast cancer–related incidence and death are lower among Asian, Native American, and Hispanic women living in the United States compared with non-Hispanic white women.[9]

KEY POINTS

- The incidence of breast cancer is increasing in nonindustrialized countries because of lifestyle changes (i.e., obesity and decreased physical activity).
- The incidence of breast cancer has decreased in the United States since 2002, likely as a result of a reduction in the use menopausal hormone therapy.
- Compared with non-Hispanic white women, black women have a lower overall incidence of breast cancer but a higher rate of breast cancer–related mortality, attributed to more advanced stage at diagnosis and higher prevalence of the triple-negative subtype of breast cancer.

RISK FACTORS

AGE AND GENDER

In the United States, older age and female sex are the most important risk factors for the development of breast cancer. The lifetime risk for breast cancer among women in the United States is estimated at 1:8 (12%), with multiple risk factors identified (Table 7-1).

Table 7-1 **Established Risk Factors for Breast Cancer: Fixed Factors**	
Factor	**Relative Risk**
Gender (female vs. male)	100
Age (≤ 50 vs. > 50)	6.7
Endocrine factors	
Age at menarche (< 10)	1.4–1.9
Age at first birth (> 35)	1.7
Nulliparity	1.4
Age at menopause (> 55)	1.3
Benign breast disease	
ADH, LCIS	4.0–5.0
Family history	
First-degree relatives	2.0–7.0
BRCA1 or BRCA2 mutation	10–30
PALB2 mutation	5.0–9.0
p53 (Li-Fraumeni)	1.5–6.0
Cowden syndrome	2.0–4.0
Ashkenazi Jewish ethnicity	1.4
Therapeutic radiation	35

Abbreviations: ADH, atypical ductal hyperplasia; LCIS, lobular carcinoma in situ.

Male breast cancer is uncommon, accounting for approximately 1% of all breast cancers.[3] Men are usually diagnosed after age 60; the specific risk factors for this disease among men include genetic predisposition associated with *BRCA2* or *PALB2* mutations, Klinefelter syndrome, testicular alterations that result in testosterone deficiency (such as undescended testes or testicular injury), and syndromes that increase the estrogen-to-testosterone ratio (such as obesity or cirrhosis).[10-12]

FAMILIAL

A family history of breast and/or ovarian cancer, particularly if onset occurred at younger than age 50, is associated with a higher risk of breast cancer. Approximately 5 to 10% of all breast cancers are associated with highly penetrant gene mutations, such as *BRCA1* and *BRCA2.* An additional 15 to 20% of women diagnosed with breast cancer have a positive family history, which may be the result of inheritance of several low-penetrance genes that increase risk, or alternatively, to shared environmental exposures. In some families, both the inheritance of low-penetrance genes and shared environmental factors may operate synergistically. Having first-degree relatives with breast cancer portends a 2-fold higher risk of developing breast cancer.[13] This risk can increase 3- to 4-fold if a first-degree relative was diagnosed at an age younger

than 50 or when two first-degree relatives are affected.[13,14] Having a previous diagnosis of breast cancer is also associated with a higher risk of developing contralateral disease, which can be compounded when a family history of breast cancer is present.

GENETIC

Hereditary breast cancer is characterized by the presence of high-penetrance genotypes, inheritance through maternal and/or paternal ancestry, and associations with other malignancies and/or familial situations (as indicated in Fig. 7-1).[15] Optimally, the individual to undergo genetic testing within a family would be the youngest woman who carries the diagnosis of either ovarian or breast cancer. If a genetic linkage is not found in that individual, further testing among family members is usually not beneficial, unless there is a suspicion that the tested individual has a spontaneous breast cancer (phenocopy). In that setting, a second affected individual within the family should be tested.

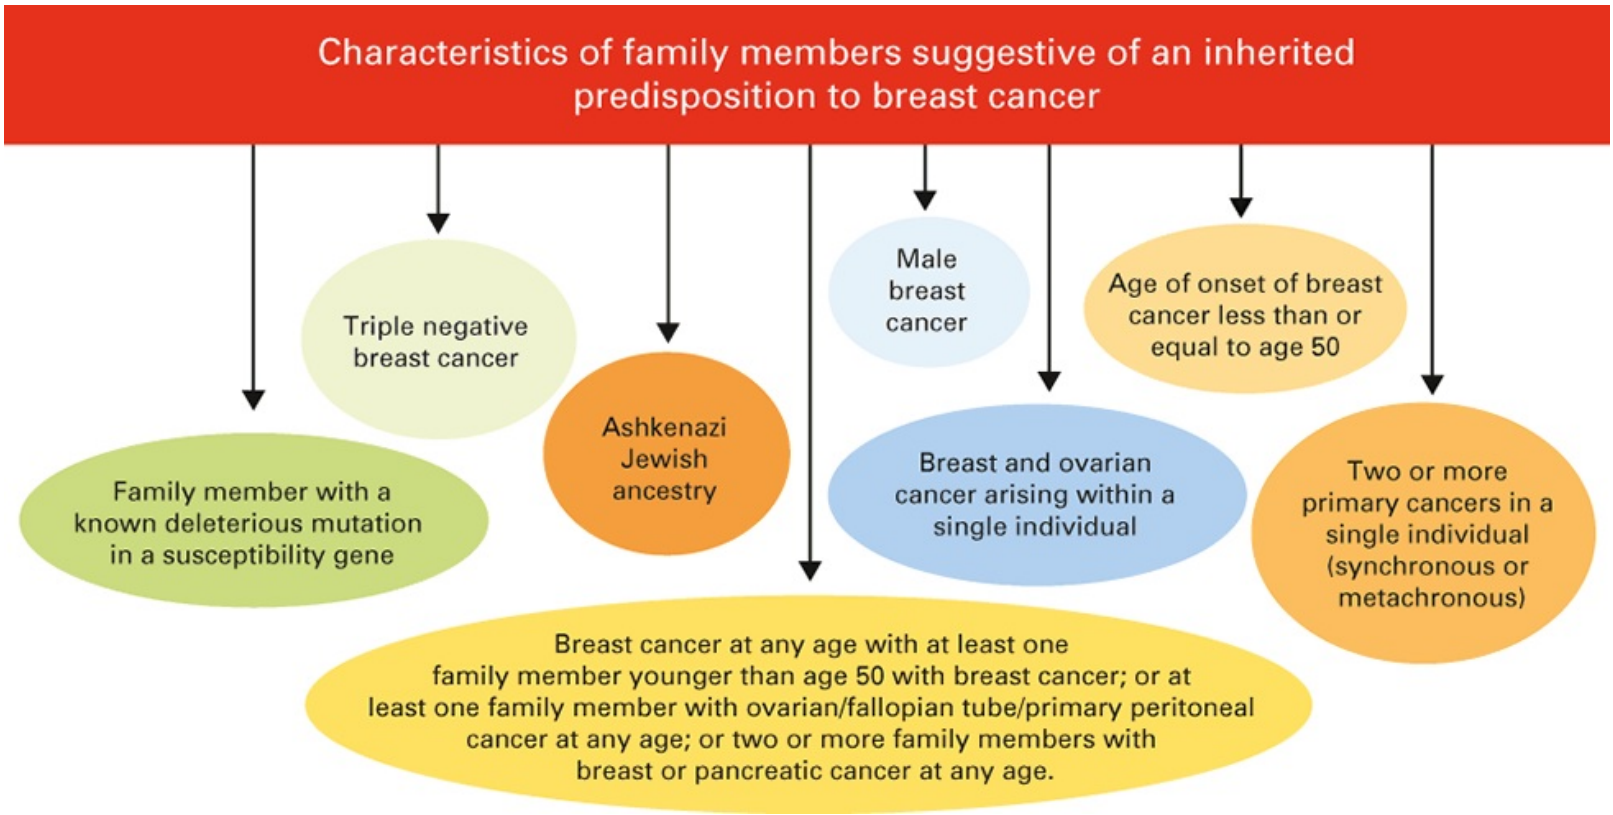

Fig. 7-1 Factors associated with higher risks of an index patient carrying a genetic predisposition for breast cancer.

Germline mutations in several genes have been identified as being associated with a high probability of breast and/or ovarian cancer developing. The most common genes are *BRCA1* and *BRCA2,* which are transmitted in an autosomal-dominant pattern. The protein products of *BRCA1* and *BRCA2* function as tumor suppressors that protect chromosomal stability by enabling homologous recombination following double-stranded DNA breaks. *BRCA2* binds directly to RAD51, an enzyme that is essential for homologous recombination. *BRCA2* is also the gene related to Fanconi anemia, and it works in concert not only with RAD51 and *BRCA1,* but also with *PALB2,* to facilitate recruitment of these enzymes to sites of DNA damage, resulting in repair.[16]

Mutations in *BRCA1* appear to be associated primarily with breast and ovarian cancer risk, whereas *BRCA2* mutations are associated with other malignancies, such as prostate cancer

(relative risk [RR] with age younger than 65, 7.33), pancreatic cancer (RR, 3.51), malignant melanoma (RR, 2.58), gallbladder and bile duct cancer (RR, 4.97), and stomach cancer (RR, 2.59).[17,18] The risk of male breast cancer before age 80 is approximately 7% among *BRCA2* mutation carriers.[19] Among women with *BRCA1* or *BRCA2* mutations, the risk of breast cancer over a lifetime is estimated to be 50 to 75%. The risk of developing ovarian cancer is higher with a *BRCA1* mutation (30 to 40%) than with a *BRCA2* mutation (10 to 20%).[20] The development of contralateral breast cancer is also increased (RR for *BRCA2*, 3.4; RR for *BRCA1*, 4.5), although this risk is less pronounced among women older than age 50 (10.8%) than among patients who were diagnosed at younger than age 30 (28.2%).[21] In addition, the use of more effective systemic therapies contributes to a reduction in the development of contralateral breast cancer.[17]

Approximately 2.5% of individuals of Ashkenazi Jewish ancestry carry one of three "founder" mutations—5382insC or 185delAG for *BRCA1* or 617delT for *BRCA2*. These account for 12% of breast cancers and 35% of ovarian cancers in this population. An additional 2 to 4% have nonfounder mutations.[22]

Certain subtypes of breast cancer occur more commonly with specific genetic mutations. For example, *BRCA1* mutations are associated with triple-negative breast cancer (TNBC); invasive lobular carcinoma seen in conjunction with a family history of diffuse gastric carcinoma can occur with mutations in the E-cadherin gene *CDH1;* and HER2-positive breast cancer is more prevalent in *TP53* mutations (Li–Fraumeni syndrome).[23-25]

PALB2 (partner and localizer of *BRCA2*) has emerged as a relevant gene associated with predisposition to breast cancer.[26,27] Loss-of-function mutations in *PALB2* are observed in 0.6 to 3.9% of families with a history of breast cancer. As compared to the general population, women who harbor a *PALB2* mutation have a 5- to 9-fold risk of breast cancer, with the magnitude of risk inversely correlated with age. The cumulative risk of breast cancer by age 70 is about 35% for *PALB2* mutation carriers, and this is further influenced by birth cohort and other familial factors.[28]

The Li–Fraumeni syndrome is related to germline mutations in *TP53.* These highly penetrant mutations are very rare (1 in 5000 people) and are associated with a 90% lifetime risk of a malignancy developing, which includes breast cancer in very young women (younger than age 30), sarcoma, leukemia, adrenocortical carcinomas, and brain tumors. Cowden syndrome is also a rare, autosomal-dominant syndrome; 80% of cases are caused by mutations in the *PTEN* tumor suppressor gene (10q23). In this syndrome, breast cancer can occur in conjunction with thyroid, kidney, and endometrial cancer in addition to specific physical findings such as macrocephaly, hamartomas, autism, and trichilemmomas of the face, hands, and feet.[29]

There are now a number of multiplex test panels that assess both high- and moderate-penetrance genes for use in families who test negative for a known familial cancer syndrome, yet have characteristics suggestive of an inherited risk. The challenges of using these panels include a limited understanding of risk associated with moderately penetrant genes and high prevalence of detecting variants of uncertain significance.[30]

REPRODUCTIVE/ENDOGENOUS HORMONES

Estrogens clearly play a role in breast cancer risk and development. Increased levels of premenopausal endogenous hormones are associated with an increased risk of disease among postmenopausal women.[31] Terminal differentiation of breast epithelium occurs following a full-

term pregnancy. This histologic change in breast parenchyma appears to be protective and associated with a reduction in breast cancer risk when first full-term pregnancy occurs at a younger age (younger than 30). Lactation may also convey protection; however, the duration of lactation required for this benefit is not well defined. A greater understanding of molecular subtypes of breast cancer (i.e., hormone receptor–positive vs. triple-negative) has led to greater specificity in defining the role of reproductive risk factors. An early onset of menarche, late age of menopause, and nulliparity are all related to extended estrogen exposure and elevated risk of hormone receptor-positive disease (estrogen receptor [ER]–positive and/or progesterone receptor [PR]–positive).[32] In contrast, triple-negative disease is associated with an increasing number of births and is not associated with nulliparity or age at first full-term delivery.[33]

EXOGENOUS HORMONES

Menopausal hormone therapy in the form of combination estrogen and progesterone is associated with an increased risk of developing invasive breast cancer (hazard ratio [HR], 1.26); however, the risk returns to normal within 2 years after discontinuation of menopausal hormone therapy (Table 7-2).[34] Women taking combination menopausal hormone therapy have also been found to have a more advanced stage of breast cancer at the time of diagnosis. The global cessation of combination menopausal hormone therapy in 2002 was associated with an 8.6% reduction in the annual incidence of invasive breast cancer, primarily observed in HR-positive disease and in women older than age 50.[2] Breast cancer risk does not appear to be related to a limited duration of unopposed estrogen use (< 10 years) or oral contraceptive use; however, oral contraceptive use may be associated with an increased risk in the setting of a *BRCA* mutation.[35,36]

Table 7-2 Established Risk Factors for Breast Cancer: Modifiable Factors

Factor	Relative Risk
Exogenous hormones	
Oral contraceptive pills	0.9–1.0
Estrogen replacement (> 10 years)	1.1
Estrogen and progesterone	1.4–3.0
Postmenopausal obesity (BMI > 30)	2.5
Exercise (> 3 hours/week)	0.6
Alcohol use	1.1–2.2
Diet	1.0
Extremely dense mammographic tissue	4.0–6.0

Abbreviation: BMI, body mass index.

RADIATION EXPOSURE

Low-level radiation exposure is associated with an increased risk of breast cancer, as high as 3.6-fold, and can occur with multiple fluoroscopic examinations, frequent diagnostic radiographs for scoliosis, and historically, as treatment for thymic enlargement, skin hemangiomas, and benign breast disease. Survivors of Hodgkin lymphoma and other hematologic malignancies who received therapeutic mediastinal or mantle-field radiation have a higher risk of breast cancer, which is dependent on dose of radiation and the radiation field volume. The relative risk can range from 37 to 57, accompanied by a greater propensity for bilateral breast cancer to develop. The risk is greatest when treatment occurred during active proliferation of breast tissue (i.e., between ages 15 and 25). The median time to the development of breast cancer after treatment is approximately 18 years; however, increased risk can start as early as 8 years after treatment. The risk continues to increase over time, wherein the estimated cumulative incidence of breast cancer after 25 to 30 years of follow-up ranges from 12 to 26%. Use of lower doses of therapeutic radiation involving smaller volumes has resulted in lower risks of breast cancer.[37-39]

MAMMOGRAPHIC DENSITY

Mammographic density is classified according to the proportion of radiopaque areas on a mammogram, representing epithelial and stromal tissue, relative to radiolucent areas, representing fat. While quantitative measures of mammographic density exist, they are not routinely used in clinical practice. The Breast Imaging Reporting and Data System (BI-RADS) Atlas issued by the American College of Radiology categorizes breast density composition into four lettered categories based on a visual assessment of the mammogram.[40]

a. The breasts are almost entirely fatty.
b. The breasts have scattered areas of fibroglandular density.
c. The breasts are heterogeneously dense, which may obscure small masses.
d. The breasts are extremely dense, which lowers the sensitivity of mammography.

Mammograms classified as heterogeneously or extremely dense are considered dense, whereas as mammograms in the other two categories are not. There is a linear trend associated with increasing mammographic density and risk of breast cancer, wherein women with greater than 75% breast density have a 4- to 6-fold higher risk of disease.[41] Exogenous hormone use, such as menopausal hormone therapy or oral contraceptives, results in increased mammographic density, whereas endogenous estrogen levels have not shown a consistent association with mammographic density. Lower mammographic density may be a reflection of involution of the terminal ductal lobular units, a natural aging process of the breast that is associated with a lower breast cancer incidence.[42,43] Mammographic density and mammographic sensitivity are inversely related, primarily because of the masking of cancer by superimposition of overlapping radiopaque dense breast tissue. Mammographic density has been found in some studies to be a principle factor in the failure of mammography to detect cancer as well as in the presentation of interval cancers.[44,45] Addition of tomosynthesis to digital mammography for screening is associated with an increased cancer detection rate for women with both dense and nondense breast tissue; in one study, the benefit was largest for the group of women with heterogeneously dense breasts, but there was no benefit in women with extremely dense breasts.[46]

Twenty-eight states have legislation requiring that women be notified about breast density after screening mammography, although there is currently no consensus on whether women

with dense breasts should be advised to pursue supplemental screening. Supplemental screening modalities, including whole-breast screening ultrasound, molecular breast imaging, and screening breast magnetic resonance imaging (MRI), have been shown to increase cancer detection as compared with mammography alone in women with dense breasts, but the impact on breast cancer outcomes is unknown. Insurance coverage for supplemental screening is variable.

BENIGN PROLIFERATIVE BREAST DISEASE

Pathologic changes within the breast have been shown to be independent risk factors for breast cancer. Benign proliferative lesions without atypia do not necessarily fall into this category, whereas benign proliferative breast disease with atypia, such as atypical ductal hyperplasia, atypical lobular hyperplasia, and lobular carcinoma in situ (LCIS), is associated with a 4-fold increased risk of breast cancer developing in either breast.[47] Lobular neoplasia (atypical lobular hyperplasia and LCIS) is associated with about a 30% risk of breast cancer developing over 25 years. The risk is increased in patients with multiple foci of disease and in women who do not have any evidence of breast involution.[48] Thus, following a diagnosis using core needle biopsy, it is recommend that most individuals undergo an excisional procedure to determine whether ductal carcinoma in situ (DCIS) or invasive disease is present. The histologic type of atypical hyperplasia (i.e., ductal vs. lobular) does not affect risk, although the number of foci of atypia is associated with a higher incidence of risk.[49] Women younger than age 45 with atypical hyperplasia have a higher RR (6.76) for the development of breast cancer. Interestingly, some data suggest that a family history of breast cancer does not appear to be additive to risk in the setting of benign proliferative disease.[48]

BEHAVIORAL FACTORS

Consumption of one alcoholic beverage per day is associated with a 12% increased risk of breast cancer and has a linear correlation such that a 10% increase in risk is associated with every additional 10 g/day of alcohol (or 0.75 to 1 alcoholic beverage per day) consumed. The risk is independent of type of alcohol consumed and may be related to an increase in serum hormone levels.[50-52]

Obesity (body mass index [the weight in kilograms divided by the square of the height in meters], > 30) increases the risk of breast cancer in postmenopausal women by more than 63%, but is inversely correlated with risk in premenopausal women.[53] However, when used as an indicator of body fat distribution, a larger waist circumference is associated with a greater incidence of premenopausal ER-negative breast cancer.[54] Waist circumference and body mass index are markers of visceral adiposity associated with the metabolic syndrome—a condition of hyperglycemia, hyperinsulinemia, and insulin resistance. The association of obesity with both increased breast cancer risk and mortality from breast cancer appears to be due to the effects of obesity on the increased production of estrogen and insulin activation of tyrosine kinase growth receptor pathways.[55,56]

Physical activity appears to be inversely related to breast cancer risk, in that 4 to 7 hours per week of recreational exercise is associated with a 12 to 60% reduction in risk among both premenopausal and postmenopausal women. A number of epidemiologic observations suggest that the beneficial effects of exercise may be due to weight control, hormonal effects, and/or changes in immune function.[57]

Isoflavones (i.e., phytoestrogens most commonly found in soy), vitamin D, dairy products,

and high-fat diets have unclear relationships to the incidence of breast cancer.[58]

RISK-DETERMINATION MODELS

Several models are available to predict the risk of breast cancer based on family history and/or to determine the probability of carrying a *BRCA* mutation (Table 7-3). The Claus model includes first- and second-degree relatives with breast and/or ovarian cancer and incorporates the age at diagnosis.[59] BRCAPRO,[60] the Tyrer–Cuzick model (the IBIS),[61] and the BOADICEA model[62] all calculate risk based on the probability of carrying a genetic mutation.[63]

Table 7-3 Risk Factors Used in Risk Assessment Models

Modified Gail model	Age, age at menarche, age at first live birth, number of breast biopsies, history of atypical hyperplasia, number of first-degree relatives with breast cancer, race
Claus model	Age, first- and second-degree relatives with breast cancer, age at onset of breast cancer, ovarian cancer in a relative, paternal family history
BRCAPRO model	Age, first- and second-degree relatives with breast cancer, age at onset of breast cancer in a relative, bilateral breast cancer in a relative, ovarian cancer in a relative, breast cancer in a male relative
International Breast Cancer Intervention Study (IBIS) model (Tyrer-Cuzick model)	Age, body mass index, age at menarche, age at first live birth, age at menopause, HR therapy, number of prior breast biopsies, presence of atypical hyperplasia, lobular carcinoma in situ, number of first- and second-degree relatives with breast cancer, age at onset of breast cancer in a relative, bilateral breast cancer in a relative, ovarian cancer in a relative
Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA)	Age, first-, second-, and third-degree relatives with breast cancer, age at onset of breast cancer in a relative, bilateral breast cancer in a relative, ovarian cancer in a relative, breast cancer in a male relative

The modified Gail model is the most widely used risk-assessment tool; it incorporates nongenetic factors such as current age, age at menarche and first full-term pregnancy or nulliparity, number of breast biopsies and presence of atypical hyperplasia, number of first-degree relatives with breast cancer, and race (www.cancer.gov/bcrisktool). The original Gail model was modified and validated to incorporate race as a risk factor, specifically assessing breast cancer risk in black women (Contraceptive and Reproductive Experience [CARE] model).[64] The modified Gail model is an excellent tool to determine risk on a population basis; however, the 5-year or lifetime risk of disease calculated for an individual woman is not robust.[65] This model will also underestimate risk if there is a significant genetic predisposition. Prevention strategies are often considered when the modified Gail model calculates a 5-year risk exceeding 1.67%; however, this calculation does not take into account factors such as breast density or presence of LCIS, and it may also underestimate the risk associated with atypia.[66]

KEY POINTS

- Atypical hyperplasia and lobular carcinoma in situ are associated with a 30% risk of breast cancer over 25 years.
- *BRCA1* and *BRCA2* mutations are associated with a 50 to 75% lifetime risk of the development of breast cancer and a 30 to 40% risk *(BRCA1)* or 10 to 20% risk *(BRCA2)*

of the development of ovarian/fallopian tube–type cancer.

- Postmenopausal obesity and alcohol use are associated with a higher risk of breast cancer.
- Increased breast density is associated with higher risk of breast cancer.
- Increased physical activity is associated with a lower risk of breast cancer.

PREVENTION

The current goal of breast cancer prevention is to reduce the risk of the development of disease with minimal toxicity. Women with the following characteristics may consider risk-reducing surgery: a positive test for a high-penetrance genetic mutation, a strong family history of breast cancer that is not associated with a pathogenic mutation in a breast cancer susceptibility gene, or a strong family history of breast cancer and have not been tested for a hereditary breast cancer syndrome. Both lifestyle and medical risk-reducing strategies can be discussed with women at any degree of breast cancer risk. Additionally, surgical approaches are available for women with higher risks.

RISK-REDUCING SURGERY

Because of the difficulty in detecting ovarian or fallopian tube cancer at an early stage, it is recommended that women with *BRCA* mutations (hereditary breast and ovarian cancer syndrome) undergo risk-reducing bilateral salpingo-oophorectomy (RRSO), typically between age 35 and 40 and upon completion of childbearing. The National Comprehensive Cancer Network (NCCN) guidelines specifically note that it is reasonable to delay until age 40 to 45 in patients with a *BRCA2* mutation, since the median age at onset of ovarian cancer tends to occur 8 to 10 years later than in patients with a *BRCA1* mutation. RRSO has been shown to decrease the risk of ovarian cancer (which includes primary peritoneal and fallopian tube cancers) by approximately 85% (HR, 0.14), and reduce the risk of a first diagnosis of breast cancer among both *BRCA1* and *BRCA2* mutation carriers (HR, 0.63, and HR, 0.36, respectively). It is furthermore associated with a lower breast cancer–specific mortality (HR, 0.44), lower all-cause mortality (HR, 0.40), and lower ovarian cancer–specific mortality (HR, 0.21).[67] Subsequent to RRSO, there remains a small risk of primary peritoneal carcinoma among *BRCA* mutation carriers. In one study of 509 *BRCA* mutation carriers who underwent RRSO, at median follow-up of 38 months, peritoneal cancer had developed in only 3 (0.6% of patients, all with the *BRCA1* mutation).[68] There appears to be an age effect of RRSO on breast cancer risk, wherein women who undergo RRSO after age 50 do not obtain a significant reduction in the risk of breast cancer. RRSO does not seem to affect the risk of contralateral breast cancer after a prior diagnosis of breast cancer;[69] however, RRSO is associated with a significant reduction in mortality in women with ER-negative breast cancer who have a *BRCA1* mutation (HR, 0.38; $p = 0.007$).[70] The concern about the adverse effect on mortality from inducing early menopause may be safely ameliorated with short-term menopausal hormone therapy given until age 50 without an apparent compromise in the overall benefit of RRSO on breast cancer risk.[71]

Bilateral risk-reduction mastectomy (RRM) has been shown to reduce the risk of breast cancer by more than 90% in women with hereditary breast and ovarian cancer syndromes.[72] Women at high or moderate risk of breast cancer (i.e., known genetic linkage or a significant

family history without a known genetic predisposition) should have a discussion with their doctors concerning prevention. Skin-sparing mastectomy appears to be as effective as total mastectomy, and early data indicate that nipple-sparing mastectomy may be reasonable in this patient population.[73] Reconstructive surgery following mastectomies does not appear to increase breast cancer risk. In the absence of a *BRCA* mutation, contralateral prophylactic mastectomy performed following the diagnosis of invasive breast cancer has not been associated with an improvement in overall survival (OS).

MEDICAL RISK REDUCTION (CHEMOPREVENTION)

When used for the treatment of invasive breast cancer, endocrine therapy has resulted in a significant reduction in the risk of contralateral breast cancer. The 15-year follow-up of the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview analysis demonstrated a 39% reduction in the development of a primary contralateral breast cancer with 5 years of adjuvant tamoxifen use.[74] This observation prompted several randomized trials examining the efficacy of selective estrogen-receptor modulators (SERMs), such as tamoxifen, in reducing the risk of breast cancer among high-risk women. The National Surgical Adjuvant Breast and Bowel Project BCPT P-1 trial defined a high-risk cohort as pre- or postmenopausal women older than age 60, women age 35 or older with a 5-year predicted disease risk of 1.66% or higher as predicted by the Gail model (see the Risk-Determination Models section), or women with a diagnosis of LCIS. A 7-year follow-up report of 13,388 women enrolled in the BCPT who were randomly assigned to receive 20 mg of tamoxifen or placebo daily for 5 years[75] demonstrated that tamoxifen reduced the risk of invasive breast cancer by 43%. The incidence of ER-positive invasive breast cancer was reduced by 62%, but there was no effect on the risk of ER-negative breast cancer. The risk of noninvasive breast cancer (DCIS) was also reduced by 37%.

These results were supported by several other randomized trials involving tamoxifen, including the IBIS-1 trial (34% risk reduction), the Royal Marsden Tamoxifen Prevention trial (39% risk reduction), and the Italian Randomized Tamoxifen Prevention trial (76% risk reduction).[76-78] The eligibility requirements of these studies varied, as did the acceptance of concurrent menopausal hormone therapy or bilateral oophorectomy among participants, making cross-study conclusions more difficult. None of the studies demonstrated an effect on all-cause mortality.[79]

Both the prevention studies and the studies using tamoxifen for the treatment of breast cancer demonstrated an association between tamoxifen use and an increased incidence of endometrial cancer, thromboembolic phenomena, cataracts, and gynecologic and vasomotor symptoms (vaginal discharge and hot flashes). In the P-1 trial, tamoxifen also has been shown to reduce the incidence of osteoporotic bone fractures (of the hips, spine, or radius) by 29% among women age 50 or older (RR, 0.71; 95% CI; 0.52, 0.97).[75] The risk of endometrial cancer was increased with tamoxifen use (RR, 3.28; 95% CI; 1.87, 6.03), which translated to a 1.6% risk with tamoxifen compared with a baseline 0.7% risk over 7 years.[75] The majority of tamoxifen-associated endometrial cancers present with postmenopausal bleeding, are typically adenocarcinomas, are early stage, and affect women older than age 50. There are no data to support routine screening for endometrial cancer using transvaginal ultrasound or biopsy, unless abnormal vaginal bleeding is present.[80] The risk of venous thromboembolic events was also significantly increased with tamoxifen use (deep venous thrombosis RR, 1.44; pulmonary embolism RR, 2.15). The risk of stroke is not consistently increased among the tamoxifen studies, and this association is not supported by large population studies.

A second-generation SERM, raloxifene, was shown to reduce the incidence of invasive breast cancer by 69 to 72% when investigated as a treatment for osteoporosis in two clinical trials, the MORE and CORE trials.[80] The use of raloxifene was not associated with an increased risk of endometrial cancer, which made it a promising SERM to use for breast cancer prevention among postmenopausal women. The NSABP P-2 STAR trial compared the efficacy of 5 years of tamoxifen to raloxifene among postmenopausal women who met the same high-risk criteria defined in the BCPT.[81] The initial evaluation, after a median follow-up of 4 years, demonstrated no difference between the effects of the two SERMs in the development of invasive breast cancer among the 19,747 women enrolled in the STAR trial. However, after an extended follow-up of nearly 8 years, raloxifene retained only 76% of the effectiveness of tamoxifen in reducing the risk of invasive cancer. Whereas the initial evaluation of the STAR trial showed no statistical effect of raloxifene on DCIS risk, the 9.7-year follow-up revealed raloxifene to be only about 18% as effective as tamoxifen in reducing the risk of DCIS.[82,83] There was no difference in mortality outcome between the two SERMs. Raloxifene use was associated with significantly less toxicity than tamoxifen—specifically, fewer endometrial cancers and thromboembolic events. Thus, while raloxifene did not appear to decrease breast cancer risk as well as tamoxifen did, its better safety profile makes it a reasonable chemoprevention alternative to tamoxifen in postmenopausal women.

A recent meta-analysis of the individual participant data from all randomized prevention trials involving SERMs, including arzoxifene and lasofoxifene (nine trials, 83,399 participants), demonstrated a 10-year cumulative incidence of breast cancer that equaled 6.3%, versus 4.2% among patients who received placebo or the SERM.[84] The reduction in breast cancer was evident both during years 0 to 5 (42%), and during years 5 to 10 (25%). The increased risk of endometrial cancer was confined to tamoxifen use during years 0 to 5 (HR, 1.64), and although the number of venous thromboembolic events was increased overall, there was no effect on incidence of myocardial infarction, stroke, or transient ischemic attacks. SERM use had no effect on the risk of ER-negative breast cancer or on overall mortality.

Clinical trials exploring the efficacy of adjuvant aromatase inhibitors (AIs), compared with tamoxifen, for the treatment of early-stage breast cancer have shown a 48% relative reduction in risk of contralateral breast cancer with the use of an AI.[80] In addition, the AIs lacked an association with the risk of endometrial cancer and thromboembolic phenomena. These data prompted the investigation of exemestane, a steroidal third-generation AI, in the prevention of invasive breast cancer among postmenopausal women at high risk. The general eligibility criteria for enrollment in the placebo-controlled National Cancer Institute of Canada CTC MAP.3 trials were essentially the same as those used for the BCPT and the STAR trial.[85] Ethical justification for this placebo-controlled trial stemmed from the lack of benefit in mortality seen with the use of U.S. Food and Drug Administration (FDA)–approved SERMs for prevention. The results of the MAP.3 prevention trial, at 35-month follow-up, demonstrated a 65% reduction in the incidence of invasive breast cancer and a 73% reduction in the incidence of ER-positive invasive breast cancer among women taking exemestane for 5 years as compared with those taking placebo. Although adverse events were more common in the exemestane group (88% vs. 85%; $p = 0.003$), arthritis and menopausal symptoms were statistically more frequent. The international, randomized placebo-controlled trial known as IBIS-II, supports the finding that AIs, in this case, 5 years of anastrozole, reduce the risk of hormone receptor–positive invasive breast cancer and DCIS by more than 50% (HR, 0.47; $p < 0.0001$) among postmenopausal women at high risk for the development of breast cancer.[86] As was seen in the prevention studies using SERMs, anastrozole neither conveyed a risk reduction for ER-negative breast

cancer nor improved survival.

SUMMARY OF RECOMMENDATIONS FOR MEDICAL PREVENTION

Both tamoxifen and raloxifene have been approved by the FDA for use in the prevention of breast cancer; however, raloxifene is approved for use only in postmenopausal women.[87] Tamoxifen (20 mg daily for 5 years) can be offered to women who are at high risk of breast cancer. Raloxifene (60 mg daily for 5 years) can also be offered to postmenopausal women who are at high risk of breast cancer. Women can use raloxifene for longer than 5 years if the medication is used to treat osteoporosis; however, the studies examining its effect on breast cancer risk used a treatment duration of only 5 years.[80] Very few women with *BRCA* mutations have been specifically evaluated in prevention trials; therefore, the role of primary medical prevention in this population is not well known. However, data suggest that tamoxifen can reduce the development of contralateral breast cancers in *BRCA1* (42% risk reduction) or *BRCA2* (52% risk reduction) mutation carriers following the diagnosis of breast cancer.[88] Extrapolating from these data, tamoxifen can be offered as a medical prevention strategy among *BRCA*-positive patients who have not been diagnosed with breast cancer, similar to the strategy for high-risk women who are not mutation carriers. Exemestane and anastrozole have been shown to reduce the risk of invasive breast cancer among high-risk postmenopausal women, and they are supported by ASCO and NCCN guidelines for breast cancer prevention; however, they have not yet been FDA-approved for this indication (Table 7-4). The use of other medications for breast cancer prevention (e.g., metformin, aspirin) remains investigational.

Table 7-4 Breast Cancer Medical Prevention Trials

Trial	Patients	Comparison	RR (95% CI)	RR for HR+ (95% CI)
STAR[81]	19,747	Raloxifene vs. tamoxifen	1.24 (1.065, 1.47)	NA
MAR3[85]	4,560	Exemestane vs. placebo	0.35 (0.18, 0.70)	0.27 (0.12, 0.60)
IBIS-II[86]	1,920	Anastrozole vs. placebo	0.50 (0.32, 0.76)	0.42 (0.25, 0.71)
Italian[78]	5,408	Tamoxifen vs. placebo	0.84 (0.60, 1.17)	0.61 (0.38, 0.99)
Royal Marsden[77]	2,471	Tamoxifen vs. placebo	0.78 (0.58, 1.04)	0.48 (0.29, 0.79)
IBIS-I[76]	7,145	Tamoxifen vs. placebo	0.73 (0.58, 0.91)	0.66 (0.50, 0.87)
BCPT P-1[75]	13,338	Tamoxifen vs. placebo	0.57 (0.46, 0.70)	0.38 (0.28, 0.50)

Abbreviations: RR, relative risk for invasive breast cancer; RR for HR+, relative risk for hormone receptor-positive invasive breast cancer; NA, data not available for most recent evaluation.

LIFESTYLE MODIFICATIONS

Physical Activity

A substantial amount of data associating lifestyle modification with a reduction in risk of breast cancer stems from extrapolation of studies that link lifestyle factors and risk of a second primary contralateral breast cancer or a systemic breast cancer recurrence. Moderate exercise (2 to 3 hours per week) has been reported to reduce breast cancer recurrence and all-cause mortality by approximately 40 to 67%.[89] Three prospective cohort studies demonstrated that current total or recreational exercise can reduce the incidence of breast cancer by 20 to 30%, primarily among premenopausal women.[90] All types of activity appear to be beneficial and associated with risk reduction when performed at any point in life. Some data endorse a greater benefit with activity if it is performed later in life (after age 50), is more vigorous, occurs

more frequently and for a longer duration, and occurs among postmenopausal women.[91] The biologic mechanism behind physical activity and risk reduction is unknown, although some studies support an interaction among estrogen, fasting insulin levels, insulin resistance, and lipid metabolism.[89] Although it can be argued that the true effect of physical activity on breast cancer recurrence has not yet been conclusively proven, exercise has far-reaching benefits for improvement in overall quality of life, fatigue scores, and sleep quality.

Diet and Weight Change

The correlation among alcohol consumption, obesity, and the risk of breast cancer is well established. However, the current data that support risk reduction as it applies to alcohol and obesity focus on avoidance of the exposure or attribute, rather than the introduction of specific interventions. Although moderate alcohol intake may increase breast cancer risk, it decreases heart disease mortality. Good data are lacking as to whether moderate alcohol use after a diagnosis of breast cancer influences mortality.[92,93] The majority of studies have not conclusively supported a reduction in risk from an increased consumption of fruits and vegetables. Although a study from the Women's Health Initiative suggested a 9% reduction in risk when women consumed a low-fat diet, prospective studies evaluating dietary changes and their effect on breast cancer risk have not been conclusive.[90,94] Vitamin supplements, specifically vitamin D and calcium, have not been shown to affect the development of breast cancer to date.[95] Ongoing studies are addressing this question.

KEY POINTS

- RRSO, if performed before age 50, reduces the risk of ovarian cancer by 85% and reduces the risk of breast cancer by 40 to 60% for women who are *BRCA* mutation carriers.
- Bilateral risk-reducing mastectomy reduces the risk of breast cancer by more than 90%.
- Five years of tamoxifen or raloxifene reduces the risk of primarily ER-positive invasive breast cancer by approximately 40% but does not affect overall mortality.
- The AIs, exemestane and anastrozole, are other options for breast cancer risk reduction in postmenopausal women.

SCREENING

AVERAGE RISK

Effective screening for breast cancer detects disease during the preclinical phase (i.e., prior to the development of symptoms) and, therefore, has a favorable effect on breast cancer–related mortality based on the premise that earlier-stage disease is associated with a more favorable prognosis. Decades of controversy have surrounded standard screening recommendations for breast cancer because the published randomized trials are plagued by inconsistent quality of imaging, flawed study design or execution, insufficient duration of follow-up, and problems regarding lead-time bias. Mammographic screening has been available for more than 30 years. During this time there has been progressive improvement in image quality, causing screening

trial results to be outdated before adequate follow-up is completed. Results have been further complicated by highly variable rates of acquisition and implementation of these technologic advances at different medical facilities and in different locations. Unfortunately, as additional randomized trials will never be performed, we are limited to the data at hand.

Data from a 2002 evaluation of the randomized trials suggested a 22% reduction in breast cancer mortality among women older than age 50 who are undergoing mammographic screening. An updated evaluation of these randomized trials in 2009 demonstrated a 14% reduction in breast cancer mortality among women ages 50 to 59 and a 32% reduction in breast cancer mortality among women ages 60 to 69.[96] The effect of mammographic screening on breast cancer mortality among women ages 40 to 49 or older than age 70 is less robust. An evaluation of eight randomized trials demonstrated a 15% reduction in breast cancer mortality with screening among women ages 39 to 49; however, no strong data exist that show a statistical benefit of screening women older than age 70.

The optimal interval for mammographic screening is not known. The advantage of shorter intervals is an increased chance of detecting faster-growing cancer at an earlier stage, but this comes with the disadvantage of a higher false positive rate. Based on six modeling groups that estimated benefits, risks, and use of resources, a biennial screening interval was preferred to annual screening, as it achieved 81% of the benefit with nearly half of the false-positive results.[97] The optimal age at which to begin screening remains unclear and is based upon personal risk. The U.S. Preventive Services Task Force (USPSTF) recommends initiating biennial screening at age 50 and continuing until age 74.[98] The American Cancer Society (ACS) updated their recommendations in 2015 and supports annual imaging beginning at age 40 and strongly recommends annual screening from ages 45 to 54 followed by a transition to biennial screening, which continues as long as a woman's overall health is good and she has a life expectancy of 10 years or longer.[99]

The DMIST trial conducted by the American College of Radiology Imaging Network (ACRIN) compared digital images with film-screen mammographic images among 49,528 women.[100] The overall diagnostic accuracy for digital and film-screen images was similar; however, digital mammography was superior in the accuracy of malignancy detection among pre- or perimenopausal women, women younger than age 50, and women with dense breast tissue. This translated into an improved sensitivity of digital mammography over film-screen mammography by 3 to 24%. There has been a gradual and now nearly complete conversion to digital from film screen technology in the United States. Although digital imaging provides only a small increase in sensitivity compared with optimally performed film imaging, the move to digital imaging has greatly improved and standardized image quality across all sites.

Digital breast tomosynthesis (DBT) mammography is a newer technology that enables three-dimensional imaging of the breast, similar to computed tomography (CT).[101] Investigators have found that DBT results in slightly greater sensitivity, but more importantly, they have also seen a significant reduction in recall rates. Interpretation times are longer with DBT than with digital imaging, but the amount of radiation exposure is now equivalent to standard mammography when synthesized 2D technology is utilized.

There has been increasing interest in using additional screening tests for women with dense breast tissue, given that they are at increased risk of breast cancer and have decreased mammographic sensitivity. Some advocate whole-breast ultrasound, molecular breast imaging, or MR exams as supplemental screening for these patients. All of these techniques increase detection at the expense of higher cost and higher rates of false-positive results. It is still to be determined which, if any, may become the procedure of choice. None of these techniques has

been considered as an alternative to mammography.

Breast self-examination has not been found to improve the detection of early-stage breast cancer on a population basis. Two population studies from Leningrad and Shanghai showed no difference in the rate of cancer detection, tumor characteristics, or breast cancer–related mortality when breast self-examination was performed after instruction, compared with no breast self-examination.[102,103] Clinical breast examinations also do not appear to have affected breast cancer detection or mortality from a population perspective.[104] However, numerous health organizations, including the ACS and the USPSTF, recommend clinical breast examination in conjunction with mammographic screening among women older than age 40.[105] Beginning at age 20, health care providers should encourage women to become familiar with their breasts and report any changes to a health care professional.

HIGH RISK

The routine use of MRI screening for the general population of asymptomatic women is not recommended by the ACS because of its high cost, limited access, and high false-positive rates. Given its substantial sensitivity, the optimal use for this method is in screening a high-risk population. Among patients with *BRCA* mutations, screening mammography can miss more than 50% of all breast cancers. Supplementing mammography with MRI has been shown to improve the sensitivity from 25% to 59% and to 80% to 100% when MRI is added.[106] The specificity of combined mammography and MRI is lower (73 to 93%) than the specificity of mammography alone. Annual MRI screening among *BRCA* carriers has been shown to detect more interval cancers and earlier-stage cancers (DCIS and stage I, 13.8% with MRI, vs. 7.2% without MRI) compared with women not screened with MRI.[107] Adding annual MRI screening to mammography is associated with a 70% reduction in the incidence of lymph node–positive or large invasive breast cancers.

This impressive improvement in detection of earlier-stage disease in high-risk women prompted the ACS to review and present recommendations for annual MRI screening in conjunction with mammography for specific high-risk groups.[99,108] Clear evidence exists to support the recommendation for annual MRI screening with mammography for *BRCA* carriers. First-degree relatives of a *BRCA* carrier who are untested are considered high-risk and should be offered annual MRI screening. Women with other inherited risk factors, such as Li–Fraumeni or Cowden syndrome, are also recommended to have MRI screening, as are women who received mantle radiation for the treatment of lymphoma prior to age 30. Caution must be used in recommending annual MRI screening for women whose estimated lifetime risk of breast cancer is greater than 20%, since ACS guidelines specifically state that this risk should be determined by calculations obtained using risk models that are dependent on family history, such as BRCAPRO. The Gail model does not meet these criteria (see the Risk-Determination Models section). To date not enough evidence supports annual MRI screening for women with dense breast tissue or the diagnosis of LCIS, atypical ductal hyperplasia, or DCIS. In addition, data are insufficient to support routine MRI screening for all women whose only risk factor is a history of invasive cancer.

Nuances of Breast Cancer Screening in High-Risk Women

The majority of the data supporting recommendations for breast cancer screening among women at high risk because of hereditary factors stems from studies among *BRCA* carriers. However, the recommendations for screening apply to all of the hereditary breast cancer

syndromes. In general, screening for hereditary breast cancer begins at age 25 and includes annual mammography and annual breast MRI with biannual clinical breast exams. Since an estimated 29% of *BRCA*-associated cancers present as "interval" cancers (i.e., cancers presenting during the interval following a normal mammogram), women will often have their breast imaging (mammogram and MRI) alternate every 6 months coincidently with their clinical breast examination, although no data support that this screening schedule is superior to that of concurrent breast imaging.[109] Women who have received chest radiation treatment for lymphoma are screened in a similar fashion, beginning approximately 10 years after completing radiation therapy.[110] For women at high risk because of familial (nonhereditary) reasons, initiation of screening should begin approximately 10 years earlier than the age of the youngest woman in the family diagnosed with breast cancer, but not later than age 40.

DIAGNOSIS

Neither physical examination nor imaging can correctly identify whether a breast mass is malignant. Only 60% of the diagnoses of palpable breast masses by physical examination are correct. This reinforces the necessity of tissue biopsy for pathologic evaluation in order to confirm malignancy. Ultrasonography is usually the first diagnostic procedure performed to evaluate palpable breast masses in women younger than age 30. Diagnostic mammography is used for this purpose in women older than age 30. Diagnostic mammography differs from screening mammography in that it adds images to the standard two-view imaging used with screening (i.e., craniocaudal and mediolateral oblique). If a suspicious finding is seen on a diagnostic mammogram or if the palpable breast mass is mammographically occult, a targeted ultrasound is used to obtain specific characteristics that will differentiate a suspicious solid mass from a benign cyst.

Although a fine-needle aspiration (FNA) biopsy of a palpable breast mass is less invasive than a core-needle biopsy, FNA specimens often yield insufficient tissue for analysis and cannot differentiate invasive from noninvasive carcinoma.[111] FNA of suspicious palpable axillary lymph nodes is acceptable given the limited variability of tissue present within a lymph node. It is also appropriate to use FNA in the evaluation of a simple cyst detected by ultrasound, since drainage of the cystic fluid without reaccumulation can imply a benign etiology and eliminate the need for further evaluation.

Core needle biopsies can be obtained via ultrasound guidance or stereotactically when suspicious calcifications are seen on mammography and do not have an associated density. The amount of tissue obtained by core needle biopsy is usually sufficient to characterize the lesion and, when cancer is identified, to perform quantitative immunohistochemical (IHC) analysis of hormone receptors (ER/PR) and HER2 protein status. This provides sufficient information about the cancer to allow the initiation of neoadjuvant systemic therapy, if needed, without compromising future treatment. Core biopsies also provide enough detail about the pathology to permit decisions concerning surgical options, such as the need for sentinel lymph node biopsy and breast conservation. The need to identify the site of biopsy is crucial, so a radiolucent clip is commonly placed in the lesion as a locator. The specific aspects of the procedure of core needle biopsy depend on location of the abnormality within the breast, size of the abnormality, including extent of calcifications, and breast size. Some high-risk benign lesions may require additional tissue excision in order to avoid missing an area within the breast that has more potential to be malignant.

MRI can also be used to evaluate the extent of disease within the breast following the

detection of invasive breast cancer. A meta-analysis of 19 studies assessing the role of MRI in revealing multifocal or multicentric disease found a 16% incidence of additional disease within the affected breast.[112] This was associated with an 8.1% conversion from breast conservation to mastectomy and an 11.3% need for additional surgery following wide excision. MRI is also able to detect multicentric DCIS, but it is not very accurate in assessing noninvasive tumor size. Caution must be used when assessing the contralateral breast with MRI after the diagnosis of breast cancer because it has been shown to detect an occult contralateral malignancy in approximately 3% of patients. This results in a high rate of biopsies and contralateral mastectomies, despite a lack of evidence that these findings will result in a survival advantage.[27]

KEY POINTS

- Mammographic screening has been shown to result in a 23% reduction in breast cancer–related mortality among women ages 50 to 70 and a 15% reduction in breast cancer mortality among women ages 40 to 50.
- Annual mammography and annual magnetic resonance imaging of the breasts should be performed among women with known inherited predispositions to breast cancer (e.g., *BRCA* mutations) beginning at age 25 and in women who have received mantle radiation for the treatment of lymphoma, beginning 10 years after the completion of radiation.
- A core biopsy of a suspicious breast finding is preferable to a fine-needle aspiration in order to accurately assess the histology of the tissue and the status of estrogen receptor, progesterone receptor, and HER2.

PROGNOSTIC INDICATORS

TUMOR/NODE/METASTASIS (TNM) STAGING

The TNM system, under the direction of the American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control (UICC), is the standard staging system used for cancer.[113] With reference to breast cancer, as of 2017, the AJCC 7th edition staging is applicable (Table 7-5). This and previous editions have focused entirely on anatomic criteria, a measurement of disease extent, which aids in grouping patients with generally similar prognoses who may need similar therapy. To some degree, the TNM system enables clinical trial activity and the assessment of outcomes. In some situations, the TNM stage can provide a great deal of information in and of itself. For example, the prognosis for stage 0 disease, or DCIS, can be applied from TNM staging, since biologic characteristics of DCIS have little impact on survival. Another application of the TNM staging system in breast cancer is in differentiating stage IV (metastatic) disease (which is incurable in the vast majority of patients) from all other stages of disease that are associated with curative-intent treatment.

Table 7-5 **TNM Classifications and Staging System of the American Joint Committee on Cancer, Version 7 (AJCC)[113]**

a. The stage of a multifocal cancer is based upon the size of the largest foci.

b. The pathologic staging after neoadjuvant therapy has a "y" preceding the TNM stage.

c. The nodal staging after surgical dissection is preceded by "p"

Classification	
Primary Tumor (T)	
TX	Cannot be assessed
T0	Tumor is not present
Tis	Carcinoma in situ
T1	≤ 2.0 cm
T1mi	≤ 0.1 cm
T1a	> 0.1 cm but ≤ 0.5 cm
T1b	> 0.5 cm but ≤ 1.0 cm
T1c	> 1.0 cm but ≤ 2.0 cm
T2	> 2.0 cm but ≤ 5.0 cm
T3	> 5.0 cm
T4	Any size tumor with extension through the chest wall (T4a) or skin ulceration/nodules (T4b) or both (T4c)
T4d	Inflammatory breast cancer
Regional Lymph Nodes (N)	
NX	Cannot be assessed
N0	Nodal involvement absent
N0(i+)	Isolated tumor cells: size ≤ 0.2 mm or fewer than 200 cells
N1	Clinical: movable ipsilateral axillary lymph nodes
pN1mi	Micrometastasis: > 0.2 mm (or > 200 cells) but ≤ 2.0 mm
pN1a	One to three positive axillary lymph nodes; at least one > 2.0 mm
pN1b	Pathologically positive internal mammary lymph nodes
pN1c	Criteria of both N1a and N1b
N2	Clinical: ipsilateral axillary lymph nodes that are fixed or matted; or clinically apparent internal mammary lymph nodes in the absence of clinically positive axillary lymph nodes

pN2a		Four to nine positive axillary lymph nodes; at least one > 2.0 mm	
pN2b		Clinically apparent internal mammary lymph nodes in the absence of axillary lymph node involvement	
N3		Clinical: ipsilateral infraclavicular lymph node involvement with or without axillary lymph node involvement; or clinically apparent internal mammary lymph nodes with axillary lymph node involvement; or involvement of ipsilateral supraclavicular lymph nodes	
pN3a		> 10 positive axillary lymph nodes, or infraclavicular lymph node involvement	
pN3b		Positive axillary lymph nodes with clinical or pathologic involvement of internal mammary lymph nodes	
pN3c		Ipsilateral supraclavicular lymph node involvement	
Metastases (M)			
M0		No clinical or radiographic evidence of distant metastasis	
MI		Distant detectable metastasis as determined by classic clinical and radiographic means and/or histologically proven to be larger than 0.2 mm	
Staging			
Stage	Tumor (T)	Node (N)	Metastasis (M)
0	Tis	N0	M0
IA	T1*	N0	M0
IB	T0–1*	Nlmic	M0
IIA	T0–T1*	N1	M0
	T2	N0	M0
IIB	T2	N1	M0
	T3	N0	M0
IIIA	T0–2*	N2	M0
	T3	N1–2	M0
IIIB	T4	N0-2	M0
IIIC	Any T	N3	M0
IV	Any T	Any N	M1

*T1 includes T1mi.

Because the specific prognosis for an individual cannot be determined solely by the TNM staging system and also requires an analysis of the tumor biology, revisions to breast cancer staging in the AJCC 8th edition (to be implemented January 1, 2018) notably incorporate prognostic molecular markers with classic TNM anatomic criteria.[114] The 8th edition has resulted in significant changes for breast cancer staging. While there remains an anatomically staged group (which is essentially the same as in the 7th edition, with minor updates and clarifications), it is only to be utilized in countries where biomarkers are not available. The prognostic staged group is noted to be preferred and required in the United States. It uses a combination of traditional TNM staging and data from biomarkers, including histologic grade, hormone receptor and HER2 status, and Oncotype DX results (see the Molecular Prognostic and Predictive Markers section).

With this new prognostic stage grouping and inclusion of the biomarker data, the staging of

41% of breast cancer stages has changed as compared with the 7th edition. For example, T1-2 ER-positive cancers with one to three involved lymph nodes and an Oncotype DX recurrence score less than 11 is now stage IB (previously stage IIB). Additionally, T1b TNBC with negative lymph nodes is now stage IIA (previously stage IA).

It will take some time for the breast cancer community to discuss and adapt their thinking to this new tumor staging system. With regard to this ASCO-SEP chapter, unless specifically stated, the designated stages will be per the AJCC 7th edition.

ANATOMIC PROGNOSTIC INDICATORS

Prognostic features of breast cancer can be divided into two categories: anatomic and biologic. Data suggest that the biologic characteristics of this disease offer considerable information to aid in the decision-making process about systemic therapies.

Lymph Node Involvement

The most important anatomic prognostic indicator for localized breast cancer is tumor involvement within axillary lymph nodes. Intramammary lymph nodes are found within the breast parenchyma and are included in the axillary lymph node category when they contain breast cancer metastasis. The clinical detection of ipsilateral internal mammary or supraclavicular lymph node involvement is associated with a greater risk of local disease recurrence as well as a risk of distant metastasis. Regardless of other characteristics of the breast cancer, the number of axillary lymph nodes involved with disease is linearly related to the risk of systemic recurrence and disease-specific survival.

In the past, the number of lymph nodes involved with metastasis has been grouped into three categories: 1 to 3 positive lymph nodes (N1), 4 to 9 positive lymph nodes (N2), and 10 or more positive lymph nodes (N3). The size of the tumor contributes to prognosis for N0 and N1 disease, whereas prognosis is predominantly governed by the nodal involvement once four or more nodes are positive. Without adjuvant systemic therapy, systemic metastasis will develop in more than 70% of patients with N3 disease; approximately 60% of patients with N2 disease and 25 to 55% with N1 disease will experience relapse, whereas only 20 to 35% of patients without lymph node involvement will experience relapse within 20 years.[115] These data are based on routine level I and level II axillary lymph node dissections (ALNDs) in which at least 6 to 10 lymph nodes were evaluated.

For well over a decade, the evaluation of the clinically negative ipsilateral axilla has been performed by sentinel lymph node (SLN) surgery, this procedure usually identifies one or more lymph nodes draining the primary tumor and is used for intense histopathologic assessment. In the past, patients with a positive SLN routinely underwent a completion ALND. The American College of Surgeons Oncology Group (ACOSOG) Z0011 trial demonstrated the equivalence in OS between a completion ALND and observation for women with one or two positive axillary lymph nodes after SLN surgery.[116,117] Eligible women in Z0011 had clinical T1-2N0 disease and were all treated with breast-conserving surgery and tangential whole-breast irradiation (WBI). The acceptance of these results is related largely to an understanding that breast cancer treatment decisions can be made on the basis of biologic characteristics of the tumor and do not require the quantification of the specific number of lymph nodes.

The size of the metastatic component within the axillary lymph node is also prognostically important. Macrometastasis (> 2 mm) and micrometastasis (> 0.2 mm or > 200 cells, but none > 2 mm) are classified as positive nodal involvement. There is a greater risk for disease

recurrence and death with macrometastatic disease as compared with micrometastatic involvement.[118] Isolated tumor cell clusters (clusters of cells not > 0.2 mm, or < 200 cells) found within a sampled axillary lymph node are believed to represent cells in transit, and they are associated with a prognosis comparable to that of lymph node-negative disease.

Tumor Size

Tumor size, referring to the invasive component only, is measured microscopically and is one of the most important prognostic indicators for breast cancer. The size of associated DCIS does not influence the risk of systemic disease, but may contribute to the risk of ipsilateral cancer recurrence following breast conservation. Larger sizes of invasive cancer are associated with a shorter recurrence-free survival and higher breast cancer–specific mortality. Multifocal (two or more foci of disease within one quadrant of the breast) or multicentric (two or more foci of disease in separate quadrants) disease occurs in 10 to 30% of cases and is associated with a higher frequency of positive lymph nodes and risk of ipsilateral breast recurrence following breast conservation therapy. Tumor staging is based on the size of the largest tumor, and does not take into account other smaller foci.

BIOLOGIC PROGNOSTIC INDICATORS

Histology

The majority of invasive mammary carcinomas are either infiltrating ductal carcinomas (IDCs; 75%), infiltrating lobular carcinomas (ILCs; 10%), or a combination of the two. Compared to IDC, ILC is characterized by more difficult mammographic detection, increased frequency of multifocality and indistinct borders, older age at onset, larger tumor size, lower grade, and a higher incidence of bilateral breast involvement at the time of diagnosis.[119] There is a significant early advantage in disease-free and overall survival for patients with ILC; however, this is followed by a significant late advantage for patients with IDC 10 years after diagnosis.[120] Rarer subtypes of IDC include pure tubular (1 to 4%), mucinous, medullary, papillary, and adenocystic. These subtypes have distinct pathologic criteria for classification, and are often associated with a more favorable prognosis; whereas the rare subtype of metaplastic carcinoma has an extremely unfavorable prognosis.[121,122]

The histologic grading system for breast cancer is a semiquantitative evaluation of morphologic features consisting of the percentage of tubular formation, degree of nuclear pleomorphism, and mitotic count within a predefined area.[123] Based on the scoring of these characteristics, three grades reflect breast cancer differentiation: low, intermediate, and high. Several grading systems have been accepted for breast cancer, namely the modified Bloom–Richardson system and the Nottingham system. These grading systems have acceptable reproducibility and they have been validated in multiple studies demonstrating a correlation between disease-free survival (DFS) and breast cancer–specific survival with the tumor grade.[119,124] The histologic grade is an independent prognostic indicator that has been closely linked to the molecular biology of breast cancer.

Lymphovascular Invasion

The presence of tumor emboli within lymphatic or vascular channels is associated with a less favorable prognosis, and all the more so with ipsilateral breast recurrence than with systemic recurrence; however, their presence does not preclude breast conservation. Dermal lymphatic

involvement is present in 75% of patients with inflammatory breast cancer, which is associated with a poor prognosis and requires mastectomy and ALND for locoregional treatment. An incidental finding of dermal lymphatic involvement, even in the absence of other clinical criteria defining inflammatory breast cancer, may be associated with a higher risk of local disease recurrence.

Proliferation Rate

In the past, S-phase fraction and DNA flow cytometry were used to assess the proliferation rate of breast cancer. The complexity of the technology required to perform these analyses resulted in difficulties with quality control, and the clinical value of these indicators declined. Ki67 is a nuclear antigen specific for proliferating cells. IHC staining of the antigen is used as a marker of proliferation, with increased proliferation correlating with adverse prognostic indicators such as tumor size, nodal involvement, and histologic grade. The interpretation of the proliferation rate by Ki67 is somewhat subtle, and there is a lack of reproducibility of results among pathologists. Furthermore, there is a lack of standardization of testing between pathology labs. Thus, more data are required before it is widely accepted as an independent prognostic indicator. ASCO Biomarker guidelines specifically advise that the Ki67 labeling index by IHC should not be used to guide the choice of adjuvant chemotherapy,[125] although some institutions do use it.

MOLECULAR PROGNOSTIC AND PREDICTIVE MARKERS

We are gaining a greater understanding of the biology of breast cancer. The advantage of this greater understanding is that it provides basic prognostic information, but more importantly, these features are valuable in predicting response to targeted therapeutic interventions. The following sections provide more detail regarding molecular prognostic and predictive factors.

Hormone Receptors: Estrogen and Progesterone Receptors

The ER and PR are weak prognostic indicators, but they are highly predictive of response to endocrine therapy. The ER functions as a ligand-dependent transcriptional factor that regulates gene expression through interaction with hormone response elements.[126] The two isoforms of ER are ER-alpha and ER-beta. The IHC method of detecting functional ER measures ER-alpha levels. The PR also has two isoforms and regulates gene expression. The IHC analysis of PR is essentially a functional assay, with a positive PR representing an active ER pathway, even if ER expression is negative.

The majority of hormone receptor–positive breast cancers have functional ER and PR, whereas cancers that are ER-positive/PR-negative are less frequent but still respond to endocrine therapy. ER-negative/PR-positive cancers are uncommon, occurring in 1 to 5% of cases, and recently updated data suggest that they may not derive significant benefit from endocrine therapy.[127] Among all breast cancers, 55% are ER-positive/PR-positive, 16% are ER-positive/PR-negative, and 4% are ER-negative/PR-positive.[124] Approximately 25% are hormone receptor–negative. There is a proportional response to endocrine therapy with respect to the amount of hormone positivity observed with IHC. The definition for positive hormone receptor status remains controversial; however, data support efficacy with endocrine therapy in the setting of any percentage of ER-positive disease.[128]

The prognostic utility of hormone receptors is generally overshadowed by their frequent

association with older patient age and lower tumor grade with negative lymph nodes. However, ER-positive/PR-positive disease is associated with a modestly superior disease-free interval, local recurrence rate, and OS compared with ER-negative/PR-negative disease, particularly within the first 5 to 10 years following diagnosis. The single hormone receptor–positive subtypes (ER-positive/PR-negative and ER-negative/PR-positive) have outcomes that lie between those of the ER/PR-positive and ER/PR-negative subgroups. The risk of disease recurrence is greatest within the first 5 years for patients with hormone receptor–negative disease and then it dramatically declines.[129] Hormone receptor–positive breast cancer has a tendency toward a slower rise in risk of recurrence and a more gradual decline, with only half of all relapses occurring within the first 5 years after diagnosis. Late distant recurrences (more than 10 years after diagnosis) can occur in patients with hormone receptor–positive disease despite optimal therapy.[130]

The androgen receptor has more recently been a focus of interest; however, its utility remains investigational. The methods to analyze androgen receptor expression by IHC vary between pathology laboratories, and there is no universally accepted cutpoint for androgen receptor–positivity. In TNBC, despite lower pathologic complete response (pCR) rates with neoadjuvant chemotherapy,[131] patients with luminal androgen receptor molecular subtype (by gene expression analysis) were found to have a better prognosis than those who did not.[132] Early-phase clinical trials with androgen receptor antagonists have yielded encouraging results for this molecular subtype of TNBC. [133]

HER2

HER2 is a member of the epidermal growth factor receptor (EGFR) tyrosine kinase family, which includes four transmembrane receptor proteins: EGFR-1, HER2, HER3, and HER4. Receptor activation, either through ligand binding or ligand-independent effects, results in homo- or heterodimerization of the receptor proteins, which stimulates cellular growth, cell survival, migration, and angiogenesis. Overexpression of the HER2 185-kd protein is a consequence of gene amplification, which occurs in approximately 20% of all breast cancers. HER2 status is defined by ASCO/CAP guidelines, which were updated in 2013.[134] Protein expression can be determined by IHC analysis using anti-HER2 antibody staining with 0 or 1+ categorized as negative, 2+ as equivocal, and 3+ as positive. Fluorescence in situ hybridization (FISH) evaluates for *HER2* gene expression and classifies tumors as HER2-positive (gene amplification) when the ratio of *HER2* gene copies to the centromeric portion of chromosome 17 (HER2:CEP17 ratio) is greater than or equal to 2.0 or when the single probe average *HER2* copy number is greater than or equal to 6.0 signals per cell. Up to 24% of breast cancers that are HER2 2+ by IHC have gene amplification and benefit from HER2-directed therapy; therefore, FISH analysis should be performed on all specimens that are equivocal (2+) on IHC analysis. The impact of soluble levels of the HER2 extracellular domain, detected in the serum, remains controversial.

HER2 overexpression or amplification is a strong predictive factor for response to HER2-directed therapy, including trastuzumab, a humanized monoclonal antibody directed at the extracellular domain of the 185-kd protein; pertuzumab, another humanized monoclonal antibody directed at the extracellular dimerization domain of HER2; ado-trastuzumab emtansine, an antibody-drug conjugate of trastuzumab and the microtubule inhibitor DM1; and lapatinib, an oral dual tyrosine kinase inhibitor of both HER2 and EGFR-1.

HER2 status is a modest prognostic indicator if a patient does not receive HER2-directed

therapy. It is correlated with a highly proliferative subtype of breast cancer, demonstrated by high-grade histology and lymph node involvement.[135] Independent of other prognostic indicators, including size, lymph node involvement, and hormone receptor status, HER2-positive disease that is not treated with anti-HER2 therapy is associated with a shorter DFS and breast cancer–specific survival. However, the degree of HER2 positivity is not associated with prognosis, and higher levels of HER2 do not predict increased efficacy from HER2-directed therapy.

Intrinsic Molecular Subtypes

The use of whole-genome analysis has transformed the understanding of breast cancer by identifying molecular ("intrinsic") subtypes, each with specific gene expression signatures and clinical characteristics. In addition to being prognostic for systemic disease recurrence, the intrinsic subtypes are now being established as prognostic indicators in terms of local disease recurrence following breast conservation or mastectomy.[136,137]

In general, the luminal subtypes includes the hormone receptor–positive breast cancers. It is the most common subtype, with an incidence of approximately 67%.[138] The luminal A subtype expresses more ER-related genes, is often low-grade, has a low incidence of *TP53* mutations, and is associated with the best overall prognosis in terms of DFS, OS, and locoregional disease relapse. Luminal B cancers express more proliferation and HER2-related genes and fewer ER-related genes, when compared with luminal A cancers. Luminal B cancers are often higher-grade and have a less favorable overall prognosis than luminal A cancers.

The HER2 intrinsic subtype does not express hormone receptors, but overexpresses genes within the *ERBB2* amplicon. These cancers are frequently HER2-positive, more often high-grade, and associated with more frequent *TP53* mutations (40 to 80%).

The basal-like subtype has a gene expression profile that mimics basal epithelial cells by not expressing hormone-related or HER2-related genes. This subtype expresses proliferation-related genes and basal cytokeratins 5, 6, and 17, and has a greater propensity to be high-grade and contain *TP53* mutations. Basal-like cancers are associated with the least favorable prognosis, with a high risk of systemic and local disease relapse and breast cancer-related death.[139] They are often classified as triple-negative because they are commonly negative for ER and PR expression, as well as HER2 overexpression. *BRCA1*-associated cancers are often basal-like, whereas *BRCA2* breast cancers include the entire spectrum of intrinsic subtypes, very much like sporadic cancers. The existence of a true fifth intrinsic subtype, "normal breast," is controversial.

Not only are the individual molecular subtypes associated with prognosis, but they also provide predictive information about the efficacy of specific therapies. Basal-like cancers are often more sensitive to DNA-damaging chemotherapy agents, such as cisplatin, whereas luminal A cancers are often treated effectively with endocrine therapy alone. Luminal B cancers often benefit from the addition of chemotherapy to endocrine treatment. The basal-like subtype is also associated with a greater probability of achieving a pCR following neoadjuvant chemotherapy, whereas the luminal A and B subtypes are less likely to do so.[140] Routine use of molecular subtyping for clinical purposes is not yet feasible; however, with the extensive development of targeted therapy in a field increasingly focused on personalized medicine, molecular subtyping may play a larger role in the treatment of breast cancer in the future.

MULTIFACTOR PROGNOSTIC INDICES

There are a number of indices that incorporate the multiple prognostic indicators into a cohesive

assessment. These models focus primarily on anatomic characteristics and include only the traditional molecular variables such as hormone receptor and HER2 status. The Nottingham Prognostic Index identifies three prognostic groups based on tumor size, lymph node status, and histologic grade.[141] Adjuvant! Online (www.adjuvantonline.com) has been a web-based prognostic calculator that utilizes the same indicators as the Nottingham Prognostic Index, plus patient age, comorbid conditions, lymph node status, and hormone receptor status. In addition to prognosis, Adjuvant! Online provided an estimate of the benefit of treatment with endocrine therapy and/or chemotherapy; however, it did not include HER2 status or information about the effects of trastuzumab therapy on HER2-positive disease.[142] Adjuvant! Online was deactivated in late 2015 for modification, and as of February 2017 it remains unavailable. It refers clients to another website, called “Predict” (http://www.predict.nhs.uk/predict.html), a tool that provides prognostic information based on patient and tumor characteristics.

These multifactor prognostic indices provide much better prognostic and predictive information than was available prior to their existence,[143] but additional prognostic and predictive information is provided by gene expression information.

Gene Expression Signatures

Differential gene expression profiling for breast cancer (a way of putting into practice some molecular prognostic and predictive factors discussed in the previous sections) has produced several validated tests to assess the risk of both local and systemic disease recurrence among breast cancers with a more favorable prognosis. They have not yet added substantial information about prognosis for the higher-risk subtypes, such as the HER2-positive or hormone receptor–negative breast cancers. The 70-gene signature MammaPrint (Agendia BV, Amsterdam, the Netherlands) was developed while studying a group of women younger than age 55 with node-negative disease and tumor sizes smaller than 5 cm. The signature was subsequently validated in a group of women (younger than age 53) with lymph node–positive or –negative disease.[144] Among the group with the poor prognostic signature, there was a 5-fold increase in the risk of systemic recurrence at 10 years compared with the group with the good prognostic signature. MammaPrint has been independently validated by the TRANSBIG consortium, which included women younger than age 60 with lymph node–negative disease.[145] Prospective validation of the 70-gene signature is ongoing in the MINDACT trial.[146] In this phase III study 6693 women with early-stage breast cancer were enrolled and their genomic risk (by 70-gene signature) and clinical risk (by a modified version of Adjuvant! Online) were determined. Women at low clinical and genomic risk (2745 [41.0%]) did not receive adjuvant chemotherapy, and those at high clinical and genomic risk (1806 [27.0%]) did receive chemotherapy. Patients with discordant clinical and genomic risk results were randomly assigned to either their genomic or clinical risk profile for determination of the use of chemotherapy. A total of 1550 patients (23.2%) were found to have high clinical and low genomic risk. At 5 years, the distant DFS rate among those who did not receive adjuvant chemotherapy was 94.7% (95% CI; 92.5, 96.2). The primary endpoint was met in that the lower boundary of the 95% CI for the 5-year distant DFS rate was ≥ 92% (i.e., the noninferiority boundary), supporting that chemotherapy was not very beneficial for patients with low genomic risk, despite higher clinical risk. In terms of absolute numbers, in a planned secondary analysis, the difference in the distant DFS rate between these patients and those who received chemotherapy was 1.5% in favor of the latter group.

The 21-gene expression assay known as Oncotype DX (Genomic Health, Redwood City,

California) was developed and validated through analysis of tumor biospecimens from patients enrolled in the NSABP B-14 clinical trial, which randomly assigned patients with ER-positive, node-negative disease to tamoxifen adjuvant therapy or placebo.[147] This is the most widely used prognostic test in the United States. The recurrence score is used as a continuous function and assesses residual risk of systemic recurrence among women with ER-positive breast cancer treated with tamoxifen. The risk of recurrence is classified as low, intermediate, and high. The prognostic value of this model has also been validated among patients treated with AIs and combination chemotherapy for node-negative and node-positive disease. The ongoing validation RxPONDER trial will better illustrate whether women with low recurrence scores can safely avoid chemotherapy in the setting of node-positive disease.[148]

The 21-gene expression assay has established utility in predicting the benefit of chemotherapy when added to tamoxifen as adjuvant treatment. Patients with low-risk disease (i.e., low recurrence score) do not appear to benefit from chemotherapy when given in addition to tamoxifen in the setting of lymph node–negative disease, regardless of menopausal status; similar findings are observed in the setting of postmenopausal lymph node–positive disease.[149,150] The 21-gene expression assay has also been shown to predict risk of local disease recurrence (ipsilateral breast, chest wall, and regional nodal), regardless of the administration of tamoxifen or chemotherapy.[151]

The prospective TAILORx trial was designed to clinically validate the prognostic and predictive value of the 21-gene expression assay in hormone receptor–positive, HER2-negative, lymph node–negative breast cancer. Initial results indeed confirm that patients with a low risk recurrence score of 0 to 10 (1626 [15.9%]) have a very favorable prognosis when treated with adjuvant endocrine therapy alone (no chemotherapy). Their 5-year rate of invasive disease–free survival was 93.8% (95% CI; 92.4, 94.9), freedom from recurrence of breast cancer at a distant site 99.3% (95% CI; 98.7, 99.6), and OS 98.0% (95% CI; 97.1, 98.6).[152] In this trial, patients with an intermediate recurrence score (defined as scores of 11 to 25) were randomly assigned to either receive or not receive adjuvant chemotherapy; those patients remain in follow-up and outcomes are eagerly anticipated.[153]

In 2016, ASCO published clinical practice guidelines on the use of biomarkers to guide adjuvant systemic therapy for early-stage invasive breast cancer.[126] Consistent with NCCN guidelines, the ASCO panel supported the use of the 21-gene assay (Oncotype DX) for adjuvant systemic therapy clinical decision-making in patients with lymph node–negative disease. The panel also provided recommendations on the clinical utility of biomarker and multifactor indices, including MammaPrint, EndoPredict, PAM50, Breast Cancer Index, Mammostrat, IHC4, urokinase plasminogen activator, and plasminogen activator inhibitor type 1.

INITIAL EVALUATION FOR OPERABLE BREAST CANCER

The initial evaluation of patients diagnosed with operable breast cancer includes a physical examination and breast imaging with diagnostic mammography with or without ultrasound. Additional diagnostic testing should be individualized, especially the use of breast MRI (see the Diagnosis section above). Baseline laboratory tests such as a complete blood count, hepatic transaminases, and alkaline phosphatase can be obtained for women who will need chemotherapy and/or for those in whom clinical symptoms or signs are suggestive of metastatic disease. Positron-emission tomography (PET)/CT has not been shown to be beneficial in evaluating local disease (i.e., the primary breast cancer or axilla); however, it can be a useful

tool for problem solving, such as determining the extent of locoregional disease when stage III disease is present.[154] In the absence of symptoms, systemic imaging studies to evaluate for metastases are not recommended for patients with stage 0, I, or II disease. Patients with stage III disease, however, should be considered for systemic staging by a CT of the chest and abdomen (with or without a CT of the pelvis) and a bone scan. PET/CT is another option, but this has not been shown to be superior to CT and bone scan for staging purposes.

There are several consultative services to be considered for patients with a new diagnosis of breast cancer. Genetic counseling should be provided for patients with a positive family history of cancer or other characteristics that may suggest an inherited predisposition, as outlined in the Risk Factor section of this chapter. Premenopausal women who use a hormonal method of contraception should be maintained on this form of contraception until an effective nonhormonal alternative can be implemented to replace it. In such cases, referral to a gynecologist or a women's health specialist is indicated. Per ASCO guidelines,[155] all patients of reproductive age should be counseled regarding the risks of infertility (due to chemotherapy) and/or delayed child-bearing (due to adjuvant endocrine therapy). Consultation with a reproductive specialist should be obtained for those interested in fertility preservation. Oocyte, sperm, and embryo cryopreservation are established methods for fertility preservation. Several trials have evaluated suppression of ovarian function with gonadotropin-releasing hormone (GnRH) agonists administered concurrently with chemotherapy as a method of fertility preservation. These trials yielded mixed results, and the primary outcome was commonly the recovery of ovarian function (menses) as opposed to a true measure of fertility, a successful pregnancy. A recent meta-analysis of 7 trials with 856 randomly assigned and evaluable patients demonstrated that the use of GnRH agonists was associated with a higher rate of recovery of regular menses after 6 months (odds ratio [OR], 2.41; 95% CI; 1.40, 4.15) and at least 12 months (OR, 1.85; 95% CI; 1.33, 2.59) after the last chemotherapy cycle. The use of GnRH agonists was also associated with a higher number of pregnancies (OR, 1.85; 95% CI; 1.02, 3.36).[156]

KEY POINTS

- Pathologic features associated with favorable prognosis include small tumor size, negative lymph node status, low tumor grade, absence of lymphovascular invasion, and positive hormone receptor status.
- The degree of estrogen receptor expression is positively correlated with response to endocrine therapy.
- HER2-positive status is predictive of benefit from HER2-directed therapy; it also is a modest negative prognostic indicator for patients who do not receive HER2-directed therapy.
- Several molecular biomarkers and gene expression signatures provide prognostic information; however, only the 21-gene recurrence score and 70-gene signature have done so with prospective data.
- The 21-gene expression assay was the first to be validated to predict the benefit of adjuvant chemotherapy, and early data support that the 70-gene signature provides similar information.

TREATMENT OF EARLY-STAGE DISEASE: STAGES 0, I, II, AND III

STAGE 0: DUCTAL CARCINOMA IN SITU (TisN0M0)

An appropriate definition of DCIS was accepted by the U.S. National Cancer Institute (NCI) during a State-of-the-Science conference and can be described as a “complete replacement of normal ductal cells with a spectrum of abnormal cells confined to the ducts without invasion.”[157] With the acceptance of mammographic screening in 1980, the incidence of DCIS has increased more than 7-fold, most commonly among women older than age 50, accounting for about 20% of all breast cancers in the United States. Important features of DCIS include size, histologic subtype (comedo, micropapillary or papillary, cribriform, and solid), cytologic or nuclear grade (low, intermediate, or high), presence of central necrosis, and ER status. A multigene assay, the Oncotype DX DCIS, has been validated as a prediction tool for recurrence risk among patients with DCIS treated with breast-conserving surgery without whole-breast radiotherapy; however, its utility in clinical practice has yet to be defined.[158]

An estimated 15 to 50% of DCIS will ultimately progress to invasive disease if left intact, either by direct transformation or by developing in parallel from a single progenitor cell.[159] The exact biologic mechanism is not known, nor can we distinguish which subset of DCIS will progress to invasive breast cancer. Therefore, by definition, we generally overtreat a proportion of women with DCIS in order to achieve the goal of decreasing subsequent development of ipsilateral invasive breast cancer. The risk of local recurrence of DCIS or development of invasive cancer following simple mastectomy without ALND is approximately 1%; however, breast-conserving therapy and mastectomy provide equivalent long-term disease-specific survival. In an analysis of individual patient data from 3729 patients treated during four randomized controlled trials that began before 1995 demonstrated that radiotherapy reduced the 10-year risk of recurrent DCIS or invasive breast cancer following breast-conserving surgery from 28% to 12% ($p < 0.00001$).[160] Local recurrence rates with breast-conserving therapy for a significant proportion of favorable DCIS diagnosed in modern practice with screening mammography is lower. In the Radiation Therapy Oncology Group (RTOG) 9804 study, patients with mammographically detected low- or intermediate-grade DCIS measuring less than 2.5 cm and a final margin width of 3 mm or more were randomly assigned to observation or whole-breast radiotherapy. The 7-year local failure rate was 0.9% in the radiotherapy arm, versus 7% with observation.[161] Both conventional (5 to 6 weeks) and hypofractionated (3 to 4 weeks) whole-breast radiotherapy are appropriate adjuvant radiotherapy options for DCIS. Accelerated partial-breast irradiation, commonly administered over 5 days, is under investigation for patients with DCIS and early-stage breast cancer. For example, a large randomized trial supported by the NCI (NSABP B-39) comparing this therapy with conventional WBI following breast-conserving surgery has completed accrual and long-term follow-up is awaited.The American Society for Therapeutic Radiation Oncology (ASTRO),[162] practice guidelines endorse accelerated partial-breast irradiation as a suitable option for patients with favorable DCIS who meet eligibility criteria for the RTOG 9804 study. Sentinel lymph node surgery is not necessary when breast conservation is performed for DCIS; however, this procedure may be considered with mastectomy because of the possibility of finding occult invasive disease within the breast, since a sentinel biopsy is not possible after the mastectomy has been performed.[163]

Approximately 50% of local recurrences following a diagnosis of DCIS are invasive. Overall, there is no difference in mortality between the local therapies, with 10-year breast cancer

survival following a diagnosis of DCIS being about 96 to 98%. Although ipsilateral development of invasive cancer is associated with a 2-fold greater mortality risk, this risk is not associated with a recurrence of DCIS alone.[164] The addition of tamoxifen (20 mg daily for 5 years) to breast conservation plus whole-breast radiotherapy (breast-conservation therapy [BCT]), contributes an additional 32% relative reduction in the risk of local recurrence and a 53% relative reduction in the risk of contralateral disease over the course of 15 years after diagnosis; however, the benefit of tamoxifen is seen only with ER-positive DCIS and has not yet been associated with improved OS.[165] The NSABP B-35 trial was designed to compare the efficacy of adjuvant tamoxifen with anastrozole in postmenopausal women who undergo BCT for ER-positive DCIS. These data demonstrated that anastrozole substantially decreased recurrences, especially in women ages 50 to 60, and in women older than age 60, recurrence rates were similar.[166] OS did not differ significantly according to hormonal therapy received. Tamoxifen and anastrozole are good options, and considerations regarding toxicities should influence drug choices for individual women. Further evaluation to define the role of systemic therapy in addition to BCT is pending the analysis of NSABP B-43, which compared two cycles of trastuzumab with placebo in HER2-positive DCIS.

KEY POINTS

- Diagnostic mammography with or without breast ultrasound is recommended for all women with a new diagnosis of operable (stages 0 through III) breast cancer.
- Additional diagnostics (e.g., laboratory tests, breast MRI, axillary ultrasound, chest x-ray, CT, PET/CT, or bone scan) should be individualized based on symptoms, exam findings, and clinical staging.
- DCIS (stage 0) accounts for approximately 20% of breast cancers in the United States.
- DCIS treated by mastectomy or BCT results in equivalent breast cancer–related 5-year survival rates, which, on average, approach 98%.
- For women with ER-positive DCIS who elect to undergo BCT, adjuvant tamoxifen reduces the risk of ipsilateral and contralateral recurrence with no established survival benefit.
- Adjuvant tamoxifen and anastrozole are appropriate options for decreasing subsequent invasive breast cancers in postmenopausal women with ER-positive DCIS treated with BCT.

STAGES I AND II DISEASE

For operable breast cancer, the treatment approach focuses both on local (breast and regional lymph nodes) and systemic disease control. These therapies complement each other and are not mutually exclusive—systemic treatment adds benefit to local disease control and local therapies will reduce the risk of systemic recurrence.[167] A meta-analysis from the EBCTCG reviewed 15-year survival data from 25,000 women and found that the addition of WBI following breast-conservation surgery also resulted in an approximate 5% reduction in breast cancer mortality.[168] Systemic therapy with tamoxifen reduces the relative incidence of ipsilateral breast recurrences by 50% in ER-positive disease, whereas chemotherapy reduces the relative

local recurrence rate by 33%, regardless of hormone receptor status. Both endocrine therapy and trastuzumab can safely be given concurrently with radiotherapy; however, chemotherapy is usually completed prior to starting radiation therapy. The choices for both local and systemic therapies are based on the prognostic indicators described previously, and treatment options have been outlined by several organizations to help guide decision-making.[169-171]

Local Disease Control

Breast-Conservation Therapy. The Fisher hypothesis of breast cancer describes invasive breast cancer as a systemic disease at its inception. This theory differed from the Halstedian philosophy of direct nodal extension of disease beginning in the breast. To test the Fisher hypothesis, pivotal trials were designed to limit the extent of surgery for the treatment of early-stage breast cancer. The NSABP B-04 found that, after 25 years, there was no difference in OS between radical mastectomy and simple mastectomy. These results were extended to NSABP B-06, which also demonstrated no significant difference in OS between total mastectomy and BCT.[172] A comparable survival outcome between mastectomy and BCT is also supported by several larger randomized trials. In general, radiation to the conserved breast reduces the relative risk of any first recurrence (locoregional or distant) by approximately 50%.[173] A meta-analysis of individual patient data for 10,801 women in 17 randomized trials demonstrated that 16% absolute reduction in any first recurrence and a 4% reduction in 15-year risk of breast cancer death with the addition of radiotherapy following breast-conserving surgery. Although the individual risk of ipsilateral breast cancer recurrence appears to be intrinsically subtype-specific,[137] modern systemic therapy has contributed to improved local control following BCT across all tumor types. Randomized controlled trials have demonstrated 10-year local recurrence risks of just 2 to 7% in patients with early-stage breast cancer.[174-176] Based on these results, options for local disease control in patients with operable (stages I and II) disease include total mastectomy or breast-conserving surgery (lumpectomy) and WBI, with BCT being the preferred procedure. Sentinel lymph node surgery is performed in both settings in clinically node-negative disease.

Optimal characteristics for breast conservation include the ability to resect the entire tumor with adequate negative surgical margins. Acceptable cosmetic outcome is important, and therefore the ability to adequately remove the cancer depends on the size of the cancer and the size of the breast (see the Neoadjuvant Systemic Therapy section). The definition of *adequate negative surgical margins* is no ink on tumor for invasive breast cancer and a 2 mm margin is recommended for DCIS.[177] The presence of an extensive intraductal component (defined as DCIS occupying at least 25% of an invasive carcinoma or a lesion that is predominantly DCIS with one or more foci of invasive disease) is not a contraindication to BCT, as long as negative margins are obtained. There are a few relative contraindications to breast conservation for operable disease, such as multicentric disease, prior radiation therapy, and some connective-tissue diseases involving the skin (e.g., scleroderma), which restrict the ability to safely give radiation.

For many years, patients with stage I or II invasive disease undergoing BCT have commonly been treated with tangential WBI over a course of 5 to 6 weeks (25 fractions).[178] Often, an additional 10- to 16-Gy boost to the tumor bed is given over 1 week, so that the breast receives 45 to 50 Gy of radiation and the tumor bed receives a total of 60 Gy. The boost has been shown to reduce the risk of local recurrence, specifically among women younger than age 50 and among those with high-grade invasive cancer.[179] Hypofractionated whole breast

radiotherapy in which the breast receives 40 to 42.5 Gy over 3 weeks (15 to 16 fractions) is now an established option for the majority of women with early stage breast cancer based on randomized trials demonstrating equivalent local control and comparably favorable toxicity compared with the more traditional 25 fraction approach.[174,176] In the UK Standardisation of Breast Radiotherpapy B (START-B) randomized controlled trial, the locoregional relapse rate was 4.3% at 10 years with hypofractionated (40 Gy in 15 fractions with or without a 10-Gy boost), compared with 5.5% in the conventionally fractionated arm (50 Gy in 25 fractions with or without a 10-Gy boost). Late effects such as breast shrinkage, telangiectasia, and breast edema all favored the 40 Gy arm. In patients who undergo breast-conserving surgery without adjuvant radiotherapy, the majority of ipsilateral recurrences develop in or near the tumor bed. Recurrences in other parts of the affected breast are rare (3 to 4%) and are believed to be new cancers rather than recurrences of the original cancer. This phenomenon has led to the concept of limiting radiation to the breast by using accelerated partial-breast irradiation, which, as discussed in the section on Stage 0, is emerging as a standard treatment option for carefully selected women with favorable invasive and noninvasive breast cancer.[180]

The potential morbidity associated with complete levels I and II ALND is substantial, translating into a risk of upper-extremity lymphedema of 20 to 30%. SLN surgery is associated with fewer complications and a lower lymphedema rate (6 to 7%) and is the procedure of choice for the surgical evaluation of the clinically negative axilla. The SLNs are the first lymph nodes to receive lymphatic drainage from the breast tumor and are the most likely site to contain metastatic involvement. SLNs are identified by lymphatic mapping using vital blue dye and/or radiolabeled colloid. The average number of SLNs is two to three nodes per patient. The *sentinel* lymph nodes are then dissected and intensively examined at two step-section levels of paraffin-embedded tissue that are stained with hematoxylin and eosin. Routine IHC staining for cytokeratins is not recommended, and most therapeutic decisions should be based on assessment with hematoxylin and eosin.[181,182] Based on a review of 69 studies involving 8059 patients comparing ALND with SLN surgery, the false-negative rate of SLN surgery is approximately 8%, and is comparable when used during breast conservation or mastectomy.[183]

If an SLN cannot be identified or if the axilla is clinically positive, a complete level I and II ALND is usually performed. Up to 48% of patients with a positive SLN have further axillary lymph node involvement, which supported the ASCO recommendation for completing an ALND when the SLN is positive.[183] The ACOSOG trial Z0011, however, found that patients with one to two positive axillary lymph nodes who are treated with breast conservation and tangential whole-breast radiotherapy may achieve adequate disease control of the axilla without undergoing an ALND or receiving more extensive axillary radiotherapy.[117] In this study, 891 eligible patients with clinical T1 or T2 tumors, a clinically negative axilla (N0), and only one or two positive sentinel lymph nodes following SLN biopsy were randomly assigned to receive or not to receive ALND. There was no difference in axillary recurrence rate, DFS, or OS between the two groups; therefore, consideration can be made to avoid a complete ALND in the setting of one or two positive SLNs, when these criteria are present.[184] This approach has not been evaluated among patients having a mastectomy, receiving neoadjuvant therapy, or opting for breast conservation but not receiving whole-breast radiotherapy. In these individuals, completion ALND is still often recommended after finding a positive SLN. However, recent data provide more support for using SLN surgery following neoadjuvant chemotherapy (see the section on Locoregional Therapy under Stage III Disease).

The ipsilateral axillary apex, infraclavicular and supraclavicular areas, along with the internal mammary lymph nodes should be irradiated (i.e., regional nodal irradiation) when four or more

axillary lymph nodes are positive. In addition, regional nodal irradiation should be considered when one to three axillary lymph nodes are involved.[185,186] The NCIC-CTG MA.20 clinical trial randomly assigned 1832 women to either WBI or WBI with regional lymph nodal irradiation.[185] Patients who received WBI and regional lymph nodal irradiation attained a significant improvement in locoregional and distant DFS with a nonsignificant trend toward an improved OS. This improvement in disease control was obtained at a cost of increased toxicity due to pneumonitis and lymphedema. The ultimate decision to add radiation fields to WBI should be based on individual risks and benefits.

There are special circumstances in which the addition of radiation therapy following breast conservation may be avoided. Older women with favorable tumor characteristics may undergo breast conservation surgery alone, as long as they receive adequate endocrine therapy. This determination is based on findings from a randomized trial of 636 women older than age 70 with ER-positive, pathologic T1 (≤ 2 cm), clinically N0 disease, who received breast conservation surgery and tamoxifen with or without whole-breast radiation therapy.[175] At 10 years, the locoregional recurrence rate was 2% with radiation and 10% without radiation; however, only 6% of the overall deaths were related to breast cancer, and there was no difference in DFS or OS. Partial breast irradiation is another reasonable option in patients with favorable disease.

Although mastectomy is the preferred approach for the majority of women with *BRCA*-associated breast cancer in order to reduce the risk of second cancers, BCT remains an acceptable means of local therapy if the patient prefers this approach. A multi-institutional study of 655 women with *BRCA1* and *BRCA2* mutations treated with either BCT or mastectomy demonstrated a higher local recurrence rate with BCT; however, the majority of the ipsilateral breast recurrences were second cancers.[187] Systemic therapy reduced the incidence of local recurrences among those treated with BCT. There was no difference in breast cancer–specific survival or OS between patients treated with BCT and those treated with mastectomy.

Total Mastectomy and Postmastectomy Radiotherapy (PMRT). Patients with a clinically negative axilla who are not candidates for BCT should undergo a total mastectomy and SLN biopsy, with completion ALND if the SLN biopsy is positive. An EBCTCG analysis of 1314 women who had axillary dissection and one to three positive nodes demonstrated that postmastectomy radiotherapy reduced the 10-year absolute risk of any first recurrence (both locoregional and distant) by 11.5% and reduced the 20-year absolute risk of breast cancer mortality by 7.9%. For the 1772 women with four or more positive nodes, postmastectomy radiotherapy reduced the 10-year absolute risk of any first recurrence by 8.8% and 20-year breast cancer mortality by 9.3%.[188] For this reason, PMRT should be considered following the completion of adjuvant chemotherapy when one or more axillary lymph nodes are involved; when there is clinical evidence of infraclavicular, supraclavicular, or internal mammary lymph node involvement; or when surgical margins are positive. There remains some controversy about the absolute benefits of PMRT in some subsets of patients with one to three axillary lymph nodes. Because of stage migration and improvements in systemic therapy and other aspects of multidisciplinary breast cancer care, recurrence rates may be low enough for some patients with favorable disease features that the risks of PMRT outweigh the potential benefits. Recommendations for treatment should be individualized and based on other adverse characteristics, such as lymphovascular involvement, triple-negative tumor status, young age, or close surgical margins (< 1 mm), as well as the potential risks of radiotherapy in a particular patient.[189] Radiation can safely be given concurrently with endocrine therapy or trastuzumab. Radiation concurrent with chemotherapy is not recommended. PMRT is also beneficial in the

treatment of locally advanced disease (e.g., tumor invading the chest wall or skin involvement). The optimal sequence of treatment in this setting is usually systemic therapy followed by surgery then radiation (see the section on Neoadjuvant Systemic Therapy under Stage III Disease). The use of modern treatment planning has improved targeting of areas at risk and resulted in less toxicity to the heart, great vessels, and lungs.

Adjuvant Systemic Therapy. The decision to add systemic therapy to the local treatment of breast cancer is based on the risk of distant metastasis and the benefit of therapies to reduce that risk. The features described in the section on Prognostic Indicators are utilized to determine risk of distant recurrence. In addition, age is an independent prognostic feature in that women younger than 35 years of age have a worse 5-year OS compared with women ages 35 to 69 (74.7% vs. 83.8–88.3%).[190] The threshold for offering adjuvant therapy is often reduced in this setting. Increased breast cancer mortality has also been observed in elderly patients (> age 65) based on results of several population-based studies and randomized trials. This finding is attributed to a later stage at diagnosis, higher comorbidity, and treatment discrepancies.[191] Relatively few clinical trials have included a substantial number of women older than age 70. In this patient population, the decision to administer adjuvant therapy is highly dependent on treatment-associated toxicity and the presence of comorbid conditions.

In general, breast cancer with a tumor larger than 0.5 cm and N0 has a high enough risk of systemic recurrence to warrant consideration of adjuvant treatment (Fig. 7-2). Tumors that are 0.5 cm or smaller and N0 may not necessarily gain a clinically significant benefit from systemic chemotherapy or HER2-directed therapy from the standpoint of reducing the risk of distant disease; however, if the cancer is hormone receptor–positive, adjuvant endocrine therapy is often considered, to reduce the risk of both systemic and local disease recurrence, given its favorable safety profile. Aside from these generalizations as to who would benefit from adjuvant therapy, the specific choice of treatment is based on the molecular profile of the cancer, namely the hormone receptor (ER/PR) and HER2 status. Collaborative meta-analyses of adjuvant therapy in early-stage breast cancer have been performed every 5 years by the EBCTCG since 1985.[74,127] These overview analyses lend support to current adjuvant therapy recommendations; however, the specific treatments should be based on individual clinical trial outcomes.

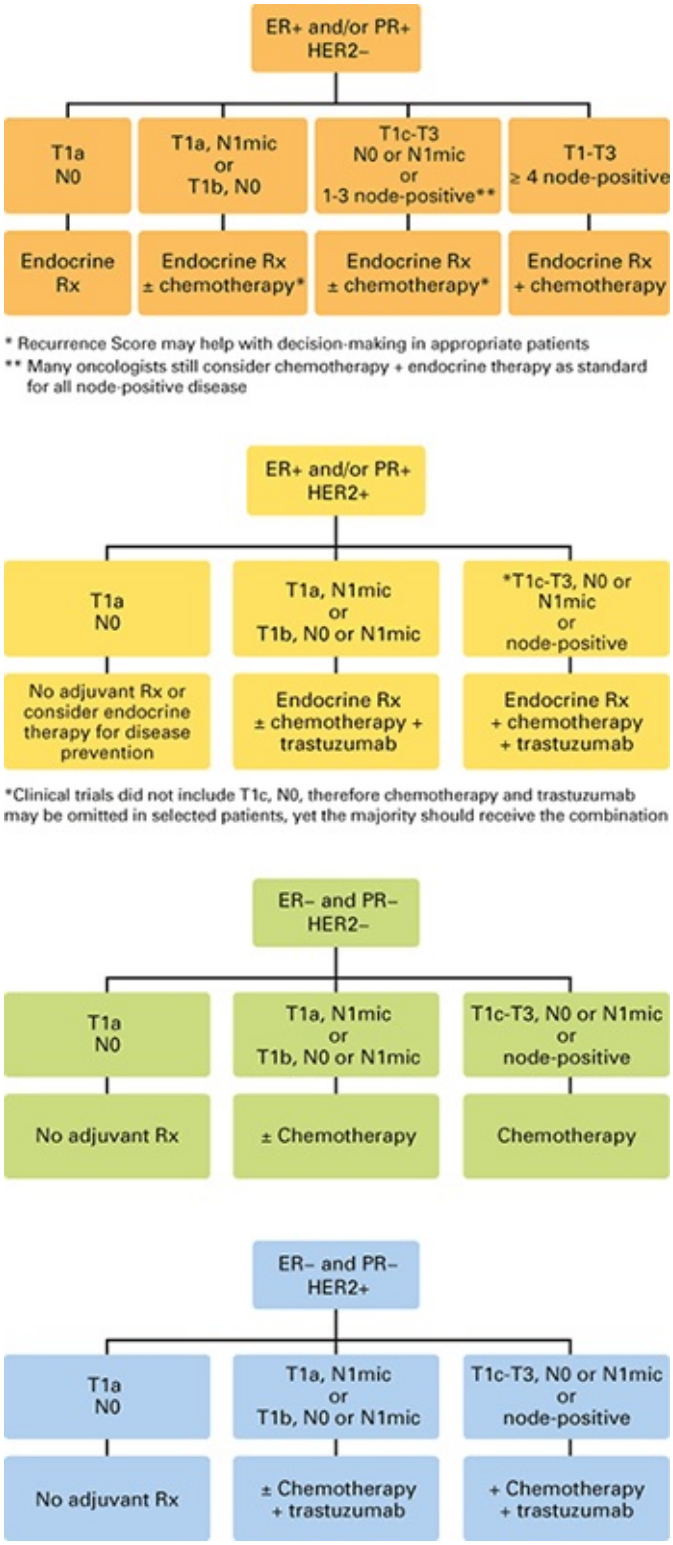

Fig.7-2 Guidelines for adjuvant systemic therapy.

Guidelines for adjuvant systemic therapy for (A) hormone receptor-positive, HER2-negative disease, (B) hormone receptor-positive, HER2-positive disease, (C) hormone receptor–negative, HER2-negative, and (D) hormone receptor–negative, HER2-positive disease. Abbreviations: ER, estrogen receptor; PR, progesterone receptor.

HORMONE RECEPTOR–POSITIVE DISEASE

Endocrine Therapy

Endocrine therapy reduces the risk of systemic recurrence and increases OS among women with hormone receptor–positive (ER and/or PR) breast cancer, regardless of age, menopausal status, nodal involvement, tumor size, HER2 status, or use of chemotherapy. For this reason, endocrine therapy should be considered as adjuvant therapy for almost all women with

hormone receptor–positive disease.[192,193] An exception to this involves older women with favorable breast cancer prognoses, especially with comorbid medical conditions. A commonly used adjuvant endocrine therapy is tamoxifen, which is effective in both pre- and postmenopausal women when given for 5 years. The EBCTCG meta-analysis showed that 5 years of tamoxifen reduced the relative risk of distant recurrence by approximately 41% and of dying by 34% (Table 7-6).[74]

Table 7-6 Benefit of Adjuvant Endocrine Therapy in Hormone Receptor–Positive Disease

Study	Endocrine Therapy/Duration	RR Recurrence (95% CI)	RR Mortality (95% CI)
Primary therapy			
EBCTCG[74]	Tamoxifen (5 yr)	0.61 (0.57, 0.65)	0.70 (0.64, 0.75)
ATAC[201]	Anastrozole vs. tamoxifen (5 yr)	0.90 (0.82, 0.99)	1.00 (0.89, 1.12)
BIG 1-98[202]	Letrozole vs. tamoxifen (5 yr)	0.88 (0.78, 0.99)	0.81 (0.69, 0.94)
Sequential therapy			
BIG 1-98[202]	Tamoxifen/letrozole vs. letrozole	1.05 (0.84, 1.32)	1.13 (0.83, 1.53)
	Letrozole/tamoxifen vs.letrozole	0.96 (0.76, 1.21)	0.90 (0.65, 1.24)
Extended therapy			
NCIC CTG MA.17[218]	Tamoxifen (5 yr) followed by letrozole (5 yr)	0.68 (0.55, 0.83)	0.98 (0.78, 1.22)
ATLAS[194]	Tamoxifen (10 yr)	0.84 (0.76, 0.94)*	0.93 (0.86, 1.00)*

Abbreviations: RR, relative risk.
*Comparing 5 years with 10 years of tamoxifen use.

Some studies support longer duration of tamoxifen for adjuvant treatment. The ATLAS trial randomly assigned 12,894 women with ER-positive disease to continued tamoxifen use for an additional 5 years (10 years total) or to discontinue tamoxifen after 5 years of treatment.[194] Continued tamoxifen use reduced the rate of recurrence and improved OS, with the benefits being more robust during the later years. The absolute mortality reduction was 2.8% at 15 years following diagnosis, which was 10 years after starting the second 5-year period of treatment. These results are supported by the aTTom trial, which randomly assigned 6953 women with ER-positive early-stage breast cancer to an additional 5 years of tamoxifen or discontinuation of tamoxifen after 5 years of treatment.[195] This trial also demonstrated an improved breast cancer recurrence rate and OS, specifically seen after 10 years of treatment. Prolonged tamoxifen use was associated with an increased incidence in pulmonary embolism (HR, 1.87) and endometrial cancer (HR, 1.74), with a 3.1% cumulative risk of endometrial cancer after 5 years of tamoxifen therapy, translating into an absolute increase in endometrial cancer mortality equaling 0.2%.[194] Though these data support increased efficacy of prolonged tamoxifen use, the decision must be weighed against potential adverse outcomes on an individual basis. For patients with early-stage disease (e.g., stage I) who are at low risk of disease recurrence, the potential toxicities may outweigh the benefits.

Substantial efforts have been made to determine the mechanisms of tamoxifen resistance in hormone receptor–positive disease. Tamoxifen undergoes extensive hepatic metabolism to metabolites (4-hydroxy-tamoxifen and endoxifen) that are known to be pharmacologically more active than tamoxifen, in terms of ER binding affinity and ability to suppress estradiol-stimulated cell proliferation.[196] Although serum concentrations of 4-hydroxy-tamoxifen are consistently low,

endoxifen concentrations are highly variable.[197,198] Cytochrome P450 2D6 (CYP2D6) is the primary hepatic enzyme responsible for tamoxifen metabolism.[199] Secondary analyses of prospective adjuvant tamoxifen studies (NCCTG 89-30-52,[200] ATAC,[201] BIG 1-98,[202] and ABCSG 8[203]), have reached discrepant conclusions on the importance of *CYP2D6* genetic variation and its association with DFS. In separate secondary analyses of NCCTG 89-30-52 and ABCSG 8, as compared with CYP2D6 extensive metabolizers, CYP2D6 poor metabolizers had a significantly higher rate of recurrence and death in patients treated with tamoxifen monotherapy. This was not observed in those treated with anastrozole, a drug not metabolized by CYP2D6.[203] Although the ATAC trial reported no association between *CYP2D6* genotype and clinical outcomes, less than 19% of the patients receiving tamoxifen were analyzed for this and conclusions could not be generated. Methods to analyze this association in the BIG 1-98 trial have been controversial.[204,205] Additional studies have demonstrated that endoxifen concentrations (but not 4-hydroxy-tamoxifen or tamoxifen) were associated with the risk of recurrence.[206,207] Although results of prospective studies are awaited, the development of endoxifen as a therapy is ongoing; early results demonstrate promising antitumor activity in patients with prior progression while taking tamoxifen.[208] Currently, ASCO guidelines do not recommend the use of CYP2D6 polymorphisms to guide selection of adjuvant endocrine therapy.[125]

Data from the EBCTCG meta-analysis that evaluated women younger than age 50 found that ovarian ablation alone improved DFS by 11% and improved OS by approximately 5%; however, this benefit was not significant when chemotherapy was administered, likely because of chemotherapy-induced amenorrhea. There did appear to be a greater effect among women younger than age 40.[74] A meta-analysis of 16 trials involving 11,906 premenopausal women using luteinizing hormone–releasing hormone (LHRH) agonists to induce ovarian suppression did not demonstrate a significant benefit when used alone; however, the addition of an LHRH agonist to chemotherapy, with or without tamoxifen, resulted in a 13% (95% CI; 2.4, 21.9; p = 0.02) reduction in risk of recurrence and a 15% (95% CI; 1.8, 26.7; p = 0.03) reduction in risk of dying—both of borderline significance.[209] Because of the variability in study design and consequent outcomes, tamoxifen became the standard endocrine therapy for premenopausal women.[210]

In 2014, the long-awaited results of the SOFT and the TEXT have challenged the paradigm for adjuvant endocrine therapy in premenopausal women.[211,212] In TEXT, women were randomly assigned to receive 5 years of tamoxifen or exemestane with concurrent ovarian function suppression (OFS). In SOFT, women were randomly assigned to receive 5 years of tamoxifen, tamoxifen plus OFS, or exemestane plus OFS. As a result of a low number of DFS events, the statistical analysis was amended to allow for a joint analysis of the exemestane plus OFS and tamoxifen plus OFS groups from both trials (total of 4690 patients). After a median follow-up of 68 months, the DFS was 91% for exemestane plus OFS and 87% for tamoxifen plus OFS (HR, 0.72; 95% CI; 0.60, 0.85). There was no significant difference in OS.

These results are contradictory to those from ABCSG-12, a trial in which premenopausal women were randomly assigned to receive tamoxifen plus OFS (alone or combined with zoledronate) or anastrozole plus OFS (alone or combined with zoledronate).[213] In this trial, women overall had a more favorable prognosis (no adjuvant chemotherapy was allowed) and absolute differences in clinical outcomes were small; however, after a median follow-up of 94 months, there was no difference in DFS between arms, and anastrozole plus OFS was associated with a 63% increase in the risk of death, compared with tamoxifen plus OFS (HR, 1.63; 95% CI; 1.05, 1.45; p = 0.03).

For the primary analysis in SOFT comparing tamoxifen and tamoxifen plus OFS after a median follow-up of 67 months, the addition of OFS to tamoxifen did not significantly improve DFS in the primary analysis; however, exemestane plus OFS did result in significant gains in DFS compared with tamoxifen (HR, 0.70; 95% CI; 0.53, 0.92). There was no significant change in any of the clinical endpoints among patients who did not receive chemotherapy. In those who did receive adjuvant chemotherapy (53% of 1084 patients) and retained premenopausal status after chemotherapy (typically younger women with higher grade and larger tumors), the DFS was 77% with tamoxifen, 81% with tamoxifen plus OFS, and 84% with exemestane plus OFS. The data from these trials support the consideration of OFS with exemestane for adjuvant endocrine therapy in premenopausal patients at high risk of breast cancer recurrence (e.g., age 35 or younger, or for whom adjuvant chemotherapy is recommended). Tamoxifen monotherapy appears to be sufficient for lower-risk women who do not require adjuvant chemotherapy.

Although tamoxifen retains its efficacy in postmenopausal women, AIs (i.e., inhibitors of the enzyme that converts androgens to estrogens) should be considered for the treatment of postmenopausal women, either following 5 years of tamoxifen, following 2 to 3 years of tamoxifen, or as initial therapy for 5 years. Tamoxifen remains an option for women who are not candidates for, or who cannot tolerate, AIs. When administered as monotherapy, AIs are not effective in pre- or perimenopausal women, and thus should not be used for adjuvant therapy in this group of patients in the absence of concurrent OFS. It is important to remember that chemotherapy-induced amenorrhea can be transient, and therefore endocrine therapy should, generally, be based on the menopausal status prior to treatment. There are three third-generation AIs: anastrozole and letrozole (nonsteroidal inhibitors) and exemestane (a steroidal inhibitor). Despite the fact that letrozole suppresses estradiol levels the most, they all appear to be comparable in efficacy[214,215] and to have similar side effects, including arthralgias, myalgias, and a reduction in bone density. Osteorporosis/osteopenia, hypertriglyceridemia, and hypercholesterolemia were less frequent with exemestane as compared with anastrozole.

An analysis of 12 trials that evaluated the efficacy of AIs used as adjuvant therapy can be divided into three cohorts: 5 years of primary therapy, switching to an AI after 2 to 3 years of tamoxifen, and extended therapy with an AI following 5 years of tamoxifen.[192] Compared with 5 years of tamoxifen, the use of an AI as primary therapy was associated with a 29% proportional reduction in risk of recurrence, whereas switching from 2 to 3 years of tamoxifen to an AI resulted in a 40% proportional reduction in risk of recurrence.[216] This translated into a 5% absolute reduction in disease recurrence with the use of an AI compared with tamoxifen alone.

Three studies demonstrated a modest benefit in risk of disease relapse, all utilizing a switch to an AI following tamoxifen; two studies switched to an AI after 2 to 3 years of tamoxifen, and one study switched following 5 years of tamoxifen. In longer follow-up, one trial, the Intergroup Exemestane Study, demonstrated a small improvement in OS.[217] Three trials of extended endocrine therapy (i.e., an AI for 3 to 5 years following 5 years of tamoxifen) also demonstrated additional reduction in disease recurrence; however, only one (NCIC CTG MA.17[218]) demonstrated a modest improvement in OS. It has been stated by some breast cancer experts that postmenopausal women should receive treatment with an AI during their first 5 years of adjuvant therapy, with the optimal strategy being either initially using an AI as primary endocrine therapy or switching from tamoxifen after 2 years to an AI for an additional 3 years. However, when the survival benefit from antiestrogen therapy is low to modest, some women will reasonably choose tamoxifien over an AI, given the different side-effect profiles.[219] Women who are intolerant of an AI after 2 years of treatment may switch to tamoxifen for the

remaining 3 years without compromising their outcomes.

Data are now available from several clinical trials evaluating extended duration of AI treatment beyond 5 years. In the MA.17R trial, 1918 postmenopausal patients completing 5 years of adjuvant AI were randomly assigned to continue their AI for an additional 5 years or to switch to placebo.[220] The majority of these patients had also received tamoxifen for some duration prior to initiation of their AI, with the median time from breast cancer diagnosis to registration being 10.6 years. The 5-year DFS rate was 95% with letrozole and 91% with placebo (HR, 0.66; p = 0.01). There was no difference in 5-year OS (93% with letrozole and 94% with placebo). There was a significant reduction in the annual incidence rate of contralateral breast cancer (0.21% with letrozole and 0.49% with placebo; HR, 0.42; p = 0.007). While there were no differences in quality-of-life measures, bone-related toxicities (bone pain, fractures, and new-onset osteoporosis) were more frequent among those taking letrozole.

In the DATA trial, 1912 postmenopausal patients were randomly assigned to 3 or 6 years of adjuvant AI after an initial 2 to 3 years of tamoxifen.[221] The study was negative for its primary endpoint of DFS. Adapted 3-year DFS was 83.1% and 79.4%, respectively, for those receiving an AI for 6 years or 3 years (HR, 0.79; p = 0.07). The difference was significant in the subgroup of patients with ER- and PR-positive, lymph node–positive disease who received adjuvant chemotherapy.

In NSABP B-42, 3966 postmenopausal patients completing 5 years of adjuvant endocrine therapy (either 5 years of AI or 2 to 3 years of tamoxifen followed by AI) were randomly assigned to receive either an AI for an additional 5 years or a placebo. At a median follow-up of 6.9 years, the DFS rate was 84.7% for those receiving 5 additional years of AI compared with 81.3% in those receiving placebo (HR, 0.85; p = 0.048); however, these results were not statistically significant, because the level for statistical significance was set at p = 0.0418 (after adjustments from interim analyses). Additionally, there was not a significant difference in OS.[222] Differences in the cumulative incidence of a breast cancer–free interval (6.7% with letrozole and 10.0% with placebo; HR, 0.71; p = 0.003) and distant recurrence (3.9% with letrozole and 5.8% with placebo; HR, 0.72; p = 0.03) were significant. When comparing the discordant DFS outcomes for the MA 17.R and B-42 trials, it is important to note that different definitions for qualifying DFS events were used in the two trials. In fact, when DFS in MA.17R was defined by adding deaths from any cause to recurrence and contralateral breast cancer, its hazard ratio was 0.80 (p = 0.06), similar to the 0.85 in B-42 (P = 0.048).

These studies suggest that an extended duration of adjuvant AI therapy may be associated with a small reduction in breast cancer recurrence and second primary breast cancer events, but these gains did not translate into a significant OS benefit. Many breast cancer experts suggest that extended AI use should not be recommended for all patients. Rather, this approach should be considered in patients at higher risk of recurrence (e.g., multiple positive lymph nodes) who have tolerated their previous adjuvant AI therapy.

Chemotherapy

Adjuvant chemotherapy reduces the risk of relapse early in the disease course (within the first 5 years) and can benefit[223] HR-positive disease in many cases. Over the past several years there has been a decrease in the use of chemotherapy for hormone receptor–positive/HER2-negative disease, stemming from recognition that, on average, chemotherapy is less beneficial in this large patient subgroup than in those with HER2-positive or triple-negative disease.

Nevertheless, there certainly are patients with HR-positive disease who obtain a sizable benefit from the administration of chemotherapy in addition to endocrine therapy. Chemotherapy can be considered when the tumor size is larger than 0.5 cm regardless of nodal status or when there is lymph node involvement regardless of tumor size. Factors that prompt the use of chemotherapy are a high histologic grade, a moderate to large disease burden, and a high 21-gene expression assay determined by Oncotype DX.[150] When both chemotherapy and endocrine therapy are recommended, chemotherapy is given first, then endocrine therapy.

While the role of the Oncotype DX 21-gene expression assay in assessing the benefit of adding chemotherapy to endocrine therapy in lymph node-positive disease is not as well established, a single retrospective analysis of a prospective trial and other indirect evidence in postmenopausal patients support that it may be helpful in determining chemotherapy benefit for patients with positive lymph nodes.[151] The ongoing RxPONDER trial is further exploring the value of the 21-gene expression assay in this clinical scenario. Despite the pending results of this trial, recent data support that Oncotype DX testing is done relatively frequently in patients with node-positive disease, and results of this testing influences clinical decision-making.[224]

There are several appropriate chemotherapy regimens used for adjuvant treatment in HER2-negative disease; the regimens used in adjuvant therapy for HER2-positive disease are discussed in the section on HER2-Positive Disease. Some principles for administering adjuvant chemotherapy are as follows[74]:

- Administer full-dose chemotherapy based on actual height and weight;
- Base chemotherapy administration in elderly patients on individual risk:benefit ratios, as most studies involved patients younger than age 70;
- Dose escalation adds no benefit to standard-dose chemotherapy in adjuvant treatment; and
- Combination chemotherapy is preferred and has greater benefits in women with node-positive and/or hormone receptor–negative disease.

In general, multidrug regimens containing anthracyclines and taxanes are appropriate for higher-risk disease, whereas shorter and less complex regimens can be used for node-negative tumors and selected node-positive tumors with more favorable disease biology (Table 7-7). The choice of regimen is dependent on the overall risk of disease recurrence and the relative reduction of risk with the administration of chemotherapy, balanced by the toxicity of the drugs, patient comorbidities, and patient preference. In hormone receptor–positive disease, anthracycline-containing chemotherapy reduces the relative risk of recurrence by 36% and reduces the relative risk of death by 35% when administered sequentially with tamoxifen.[75] In hormone receptor–positive breast cancer, the addition of taxanes to anthracycline-based regimens reduces the relative recurrence risk by an additional 12% and reduces the relative mortality risk by an additional 11%.[233] Chemotherapy regimens that are appropriate for use as adjuvant therapy in both hormone receptor–positive and hormone receptor–negative disease are outlined as follows.

Table 7-7 Adjuvant or Neoadjuvant Chemotherapy Options	
HER2-Negative Disease	Doxorubicin/cyclophosphamide × 4 cycles[225]
	Docetaxel/cyclophosphamide × 4 cycles*[226]
	Cyclophosphamide/methotrexate/5-fluorouracil × 6 cycles[225]
	Dose-dense doxorubicin/cyclophosphamide × 4 cycles followed by dose-dense paclitaxel × 4 cycles*[244]
	Doxorubicin/cyclophosphamide × 4 cycles followed by 12 weeks of paclitaxel*[228]
	Docetaxel/doxorubicin/cyclophosphamide × 6 cycles[244]
HER2-Positive Disease	Doxorubicin/cyclophosphamide × 4 cycles followed by 12 weeks of paclitaxel and trastuzumab with or without pertuzumab followed by trastuzumab with or without pertuzumab (over a 40-week duration)*[248]
	Docetaxel/carboplatin/trastuzumab +/- pertuzumab × 6 cycles followed by trastuzumab +/- pertuzumab (over a 34-week duration)*[255]
	Paclitaxel and trastuzumab weekly × 12 weeks followed by trastuzumab × 40-week duration[260]
	Pertuzumab, trastuzumab, and taxane (either paclitaxel or docetaxel) × 12 weeks total followed by doxorubicin/cyclophosphamide × 4 followed by trastuzumab with or without pertuzumab (over a 40-week duration)[291]

*Preferred regimen, per 2017 NCCN guidelines.

TRIPLE-NEGATIVE DISEASE

Adjuvant endocrine therapies are not effective, without the presence of their target, in hormone receptor–negative disease. In addition, trastuzumab, the humanized monoclonal antibody against the HER2 protein, has not been shown to be effective in HER2-negative disease. For this reason, chemotherapy is the mainstay of adjuvant treatment for TNBC, a subtype of breast cancer that lacks a positively identified therapeutic target. TNBC accounts for only approximately 10 to 15% of all breast cancers, is more common among young and/or black women, and is classically associated with high-grade cancers. Unlike other subtypes of breast cancer, the biology of TNBC is such that its prognosis does not correlate as closely with tumor size or nodal involvement.[234] For example, one study suggested that once one axillary lymph node is involved, additional axillary nodal involvement does not affect the poor prognosis already associated with node-positive TNBC. In addition, node-negative TNBC with a tumor size greater than 0.5 cm (T1b or higher) has a high enough risk of disease recurrence and death to warrant a discussion of adjuvant chemotherapy.[235]

As stated previously, the efficacy of chemotherapy is greater in TNBC, in which the risk of systemic recurrence is greatest within the first 2 to 3 years, and unlike hormone receptor–positive disease, the risk of recurrence is negligible after 5 to 10 years.

The comparison of anthracycline-containing to methotrexate-containing regimens in adjuvant therapy improved the proportional reduction in risk of recurrence by 12% and death by 15%.[74] These data support the use of anthracyclines for adjuvant treatment—the most commonly used combination regimen being doxorubicin and cyclophosphamide (AC) for four cycles. A relatively small randomized trial compared four cycles of AC with four cycles of another two-drug regimen, docetaxel and cyclophosphamide (TC), among women with stages I to III breast cancer.[226] After a 7-year follow-up, there was a 6% improvement in DFS and a 5% improvement in OS with the TC regimen. Although the trial was relatively small, these data suggest that the two regimens are comparable. TC was associated with less cardiotoxicity and

a lower risk of treatment-induced leukemia compared with AC, but both of these toxicities are relatively rare.

The question of duration of therapy was addressed by CALGB 40101, which evaluated 3171 patients with primarily lymph node–negative disease (94% node negative) and randomly assigned them to either four or six cycles of AC or single-agent paclitaxel.[236] Both regimens were administered every 2 weeks, with no difference in outcome (relapse-free survival or OS) between four or six cycles of treatment.

Based on a meta-analysis of 13 randomized trials involving 22,453 women, the addition of taxanes to anthracycline-containing regimens resulted in a 17% reduction in the relative risk of relapse and a 18% reduction in the relative risk of death at 5 years. This translates into a 5% absolute improvement in DFS and a 3% improvement in OS.[237] This relative benefit is constant, regardless of the type of taxane used (paclitaxel or docetaxel), patient age, or number of lymph nodes involved. It has been suggested that the addition of a taxane in sequence may offer a greater advantage compared with regimens in which the taxane is combined with the anthracycline; however, only a small number of trials provide evidence for this suggestion.

Initial adjuvant taxane studies demonstrated superior DFS and OS when four cycles of paclitaxel were administered following four cycles of AC, compared with four cycles of AC alone (CALGB 9344).[238] Similar results were seen when three cycles of docetaxel were given following three cycles of 5-fluorouracil, epirubicin, cytoxan (FEC), compared with six cycles of FEC (FNCLCC PACS 01 trial).[239] Two concurrent studies compared six cycles of 5-fluorouracil, doxorubicin, cyclophosphamide (FAC) with six cycles of docetaxel, doxorubicin, cyclophosphamide (TAC) in both node-positive breast cancer (BCIRG 001) and high-risk node-negative disease (GEICAM 9805).[240] Both studies demonstrated the superiority of TAC in reducing the relative risk of recurrence by 30%, but only the node-positive study found a relative reduction in risk of death, by about 30%.

Comparing the two strategies of adding taxanes to anthracycline-containing regimens, BCIRG 005 did not demonstrate a difference between six cycles of TAC and four cycles of AC followed by four cycles of docetaxel. NSABP B30, however, showed a superior DFS and OS with four cycles of AC followed by four cycles of docetaxel compared with four cycles of TAC or four cycles of docetaxel, doxorubicin.[241,242] Neutropenia is associated with the combination regimens more frequently, whereas neuropathy and nail changes are more common with the sequential therapies that include docetaxel. NSABP B-38 expanded this concept by comparing six cycles of TAC with two regimens: either four cycles of AC followed by four cycles of paclitaxel given every 2 weeks, or with this regimen with gemcitabine added to the paclitaxel arm.[243] The additional chemotherapy (gemcitabine) did not add benefit; however, six cycles of TAC was comparable in DFS and OS with four cycles of AC followed by four cycles of paclitaxel. Again, the toxicity profile differed between the two regimens, with neutropenic fever and diarrhea being more prevalent with TAC chemotherapy.

In an attempt to determine the optimal taxane and the best schedule for adjuvant therapy use, the ECOG 1199 study compared docetaxel with paclitaxel, both given either weekly for 12 weeks or every 3 weeks for four cycles, after completing four cycles of AC (given every 3 weeks) in node-positive and high-risk node-negative disease.[228] Data from this trial and other trials support that paclitaxel, administered weekly for 12 weeks, is better than the three other options of taxane administration. In an exploratory subset analysis of the ECOG 1199 trial, weekly paclitaxel increased 10-year DFS to 69% for TNBC, compared with about 59% in the other three arms. Overall 10-year survivals were 75%, compared with about 66%.

A dose-dense, every-2-week, chemotherapy schedule with growth factor support has been

associated with improved clinical outcomes compared with chemotherapy administration on a conventional every-3-week schedule. This was supported by CALGB 9741, in which 2005 women with lymph node–positive disease were randomly assigned to receive similar doses of AC for four cycles followed by paclitaxel for four cycles, given by dose-dense or conventional schedule.[244] The dose-dense regimen (every-2-week administration with filgrastim support) resulted in a 26% reduction in relative risk of recurrence and a 31% reduction in relative risk of death. As expected, within the group receiving the superior dose-dense regimen, patients with TNBC fared better as compared with patients with hormone receptor–positive disease in terms of improved reduction in risk of recurrence (32% vs. 19%); however, this was not significant. A meta-analysis of randomized trials that evaluated dose-dense adjuvant therapy confirmed the CALGB 9741 findings of a 15% relative reduction in risk of recurrence and a 10% relative reduction in risk of dying.[245] Patients with TNBC again obtained greater benefit compared with those with hormone receptor–positive disease.

HER2-POSITIVE DISEASE

HER2 is an important therapeutic target for the 15 to 20% of breast cancers that are classified as HER2-positive either by overexpressing the HER2 protein (3+ by immunohistochemistry) or by *HER2* gene amplification (FISH dual probe ratio ≥ 2.0 or single-probe average copy number ≥ 6 signals per cell). HER2 is an adverse independent prognostic indicator and predicts benefit with trastuzumab, the humanized monoclonal antibody against the extracellular domain of HER2. Trastuzumab has limited efficacy as a single agent in metastatic disease and has been studied in combination with chemotherapy only in the adjuvant setting. Patients with HER2-positive cancer that is node-positive regardless of tumor size or node-negative with tumor size greater than or equal to 1.0 cm (T1c or higher) should be offered a combination of chemotherapy and trastuzumab for adjuvant treatment. There have been several attempts at delineating the smallest tumor size in lymph node–negative, HER2-positive disease that will benefit from chemotherapy and trastuzumab. Several studies have demonstrated that T1a and T1b, HER2-positive, node-negative breast cancer has a substantial risk of recurrence and death.[246,247] Several other studies support the recommendation that HER2-positive, node-negative, T1b tumors be considered for trastuzumab-based therapy if other adverse characteristics are present (e.g., high grade, young age). The role of trastuzumab-based therapy in patients with T1aN0 disease remains unknown.

When added to chemotherapy, trastuzumab substantially improves DFS and OS compared with chemotherapy alone in HER2-positive disease. A meta-analysis of five adjuvant therapy studies that involved 9748 patients demonstrated a 38% reduction in the relative risk of recurrence and a 34% reduction in the relative risk of dying from any cause.[248] The largest individual analysis combined two U.S. studies: the three-arm NCCTG N9831 and the NSABP B-31. The NCCTG N9831 randomly assigned 1944 patients to chemotherapy alone (AC every 3 weeks for four cycles followed by weekly paclitaxel for 12 weeks), chemotherapy followed by 1 year of trastuzumab (sequential arm), or chemotherapy with 1 year of trastuzumab beginning with the paclitaxel (concurrent arm). The NSABP B-31 randomly assigned 2101 patients to chemotherapy (AC every 3 weeks for four cycles followed by paclitaxel every 3 weeks for four cycles) or chemotherapy and trastuzumab beginning with the paclitaxel.[229] Regardless of other patient or tumor characteristics, the addition of trastuzumab to chemotherapy resulted in a 48% relative improvement in DFS and a 39% relative improvement in OS.

The HERA trial evaluated combination chemotherapy followed by observation or 1 or 2 years

of adjuvant trastuzumab.[249-251] At an 11-year median follow-up, the HERA trial demonstrated that 1 year of trastuzumab significantly reduced the risk of a DFS event (HR, 0.76; 95% CI; 0.68, 0.86) and death (HR, 0.74; 95% CI; 0.64, 0.86), compared with observation. Two years of adjuvant trastuzumab did not improve DFS outcomes compared with 1 year of this drug. Estimates of 10-year DFS were 63% for observation, 69% for 1 year of trastuzumab, and 69% for 2 years of trastuzumab.[251] The results of the aforementioned studies suggest an interaction between chemotherapy and trastuzumab wherein concurrent administration may be of greater benefit as compared with sequential treatment. This concept was supported by an analysis of the NCCTG N9831 study that compared chemotherapy (AC every 3 weeks for four cycles followed by weekly paclitaxel for 12 weeks) followed by 1 year of trastuzumab (sequential arm) or chemotherapy with 1 year of trastuzumab beginning with the paclitaxel (concurrent arm).[252] The concurrent administration of trastuzumab with paclitaxel was associated with a 23% reduction in risk of an event as compared with sequential trastuzumab administration, suggesting that combined chemotherapy and trastuzumab is more beneficial than chemotherapy followed by trastuzumab.

The currently accepted duration of adjuvant trastuzumab is 1 year. The HERA trial randomly assigned patients receiving trastuzumab to 1 or 2 years of treatment, and showed no difference in progression-free survival (PFS) or OS after an 11-year follow-up.[253] Cardiac toxicity was greater with the 2-year duration. In contrast, the Finnish Breast Cancer Group's FinHer trial evaluated the benefit of 9 weeks of trastuzumab added to three cycles of docetaxel or vinorelbine followed by three cycles of FEC (without trastuzumab).[254] Patients who received trastuzumab experienced a 35% improvement in distant DFS; however, this was not significant. A large phase III trial that involved 3380 women (PHARE) failed to demonstrate noninferiority with a 6-month as compared with 12-month duration of trastuzumab.[230] The recommended duration of adjuvant trastuzumab is 1 year, given concurrently with a taxane; it should be given concurrently with endocrine therapy for hormone receptor–positive disease.

In the adult heart, HER2 functions to modify cardiac muscle response to stress. In theory, trastuzumab can interfere with the ability of the heart to adjust to stress, resulting in cardiac damage. The addition of trastuzumab in the adjuvant studies resulted in less than a 4% difference in congestive heart failure or death between the treatment arms, which was less than the early stopping rules required. However, 5% of patients experienced asymptomatic decreases in ejection fraction that required discontinuation of trastuzumab. Risk of cardiac compromise was associated with advanced age, hypertension, and initial ventricular function.

Concern about cardiac toxicity prompted investigation into a non–anthracycline-containing trastuzumab regimen: Taxotere (docetaxel), carboplatin, Herceptin (trastuzumab) (TCH), administered every 3 weeks for six cycles. BCIRG 006 compared this regimen with four cycles of AC every 3 weeks followed by four cycles of docetaxel alone or with 1 year of trastuzumab beginning with docetaxel.[242,255] BCIRG 006 confirmed a benefit with the addition of trastuzumab to chemotherapy; there was a 3% absolute difference in DFS and a 1% difference in OS at 5 years favoring the AC plus docetaxel and trastuzumab arm over the TCH arm. It should be noted, however, that the study was not designed to compare the two trastuzumab-containing arms and any conclusions about the benefits of one regimen over another should be considered exploratory. TCH was associated with less cardiac toxicity and risk of secondary leukemia compared with the AC plus docetaxel and trastuzumab regimen, making it an acceptable treatment alternative.

Thus, AC for four cycles followed by 12 weekly doses of paclitaxel with concurrent trastuzumab (TH), and then trastuzumab to complete a year, is commonly chosen as treatment

for a patient who is at substantial risk of disease recurrence and does not have significant risk factors for cardiac toxicity.[223] For patients at lower risk of disease recurrence or with significant cardiac risk factors, TCH represents a reasonable alternative. Although the standard doxorubicin, cyclophosphamide, paclitaxel, trastuzumab regimen prescribes AC administered every 3 weeks, there are safety data to support administering AC every 2 weeks for four cycles (dose-dense) rather than every 3 weeks prior to 12 weeks of TH.[256] When trastuzumab is used as a single agent following chemotherapy, it is commonly given every 3 weeks.[257] Cardiac monitoring with echocardiography or nuclear ventriculography is recommended every 3 months during adjuvant trastuzumab treatment.

ALTTO trial data failed to demonstrate any significant benefit for the addition of adjuvant lapatinib to trastuzumab compared with trastuzumab alone.[258] This was seen despite that, in the neoadjuvant setting (NeoALTTO), the addition of lapatinib to trastuzumab substantially increased pCR rates.[231] This finding raises concern regarding the value of new drug development in the neoadjuvant setting; however, the patient populations and drug regimens in NeoALTTO and ALTTO differed, potentially explaining the discordant trial results.

Results of another phase III study that evaluated dual HER2-directed therapy, the APHINITY trial, were presented at ASCO 2017.[259] The APHINITY trial randomly assigned 4805 patients with HER2-positive node-positive or high-risk node-negative breast cancer to adjuvant chemotherapy with trastuzumab and placebo/pertuzumab. With a median follow-up of 45.4 months, the addition of pertuzumab to chemotherapy and trastuzumab was associated with a 3-year invasive DFS rate of 94.1% as compared with the placebo arm rate of 93.2%. Pertuzumab reduced the relative risk of an invasive DFS event by 19% compared with placebo (HR, 0.81; 95% CI; 0.66, 1.00; p = 0.045). Treatment was effective in all subgroups; however, those with node-positive and/or hormone receptor–negative disease appeared to derive the most benefit. Diarrhea was increased in the pertuzumab arm, predominantly during chemotherapy and with the TCH regimen. Cardiac toxicity was low and not different between the two arms. The role of adjuvant pertuzumab in guidelines and clinical practice remains to be defined.

Retrospective data suggest that small, node-negative, HER2-positive breast cancers have a small but real risk of distant recurrence. Most patients with these cancers were not eligible for enrollment in the pivotal adjuvant trastuzumab clinical trials, and the use of any of the standard adjuvant regimens seemed excessive to many clinicians. Given this setting, investigators at the Dana–Farber Cancer Institute and a number of other major cancer centers sought to explore the efficacy of a trastuzumab-containing adjuvant therapy regimen that included a minimal amount of chemotherapy. The phase II Adjuvant Paclitaxel Trastuzumab (APT) trial involved 406 patients with node-negative, HER2-positive breast cancers that measured less than 3 cm; more than 90% had tumors less than 2 cm.[260] In this single-arm, multi-institutional study, patients received 12 weeks of paclitaxel (80 mg/m^2) and concurrent trastuzumab, followed by 9 months of single-agent trastuzumab therapy. The 7-year DFS was 93.3% and the 7-year recurrence-free interval was 97.5% at a median follow-up of 6.5 years, with only 4 (1%) of DFS events being distant metastasis. The regimen was well tolerated, with minimal neuropathy and cardiac compromise, and it is included as a regimen option in NCCN guidelines. These results are being further explored in the ATEMPT trial, which involves patients with stage I HER2-positive breast cancer, randomly assigned to 12 weeks of TH followed by trastuzumab for 9 months or 12 months of the antibody-drug conjugate, trastuzumab emtansine (TDM-1).

Neratinib is an oral tyrosine kinase inhibitor (TKI) that targets HER2 and HER1, and it differs from lapatinib in that it is an irreversible TKI and further targets HER4. While 2 years of

adjuvant trastuzumab did not improve clinical outcomes in the HERA trial, it was thought that extended HER2-directed therapy with a different mechanism of action could result in better disease control, especially for those with high-risk disease. This served as the rationale for the ExteNET trial, a phase III randomized, double-blind, placebo-controlled study of neratinib following adjuvant trastuzumab treatment.[261] Participants included 2840 patients with early-stage HER2-positive breast cancer who were within 2 years of completing adjuvant trastuzumab therapy. While the sponsor changed twice over the course of the study, the primary endpoint of invasive DFS remained constant for the intention-to-treat analysis. Two amendments were made over the course of the study, related to eligibility criteria to (1) mandate node-positive disease, and (2) reduce the interval of time from trastuzumab completion to registration from 2 years to 1 year. One year of adjuvant neratinib was associated with a 2-year invasive DFS rate of 94.2%, compared with a rate of 91.9% in those receiving placebo (HR, 0.66; 95% CI; 0.49, 0.90, p = 0.008). The most common adverse events were diarrhea, other gastrointestinal toxicities, fatigue, rash, and stomatitis. Treatment discontinuation due to diarrhea was 16.8%. These results led to the FDA approval of neratinib in 2017. Concurrent administration of antidiarrheal prophylaxis is recommended with initiation of neratinib per the FDA label. The role of adjuvant neratinib in guidelines and clinical practice remains to be defined.

KEY POINTS

- Stages I and II breast cancer treated by mastectomy or breast-conservation therapy (BCT) results in equivalent survival.
- Both WBI after BCT and postmastectomy radiation therapy are associated with a reduction in locoregional recurrence. Meta-analyses have also shown a small benefit in breast cancer mortality from adjuvant radiation therapy.
- Adjuvant tamoxifen remains standard adjuvant endocrine treatment for premenopausal women with hormone receptor–positive disease. Ovarian function suppression adds benefit to DFS (but not OS) when combined with 5 years of adjuvant tamoxifen or exemestane in premenopausal women with high risk disease.
- As compared with 5 years, 10 years of adjuvant tamoxifen has demonstrated a small improvement in DFS, and extended-duration tamoxifen can be considered an option in high risk pre- or postmenopausal patients.
- The AIs should be considered for the treatment of hormone receptor–positive disease in postmenopausal women. Administering AIs for 5 years was shown to have similar outcomes as initial AI for 2 to 3 years, followed by tamoxifen for 2 to 3 years. Extended-duration AIs have not consistently shown benefit beyond 5 years.
- Anthracycline- and/or taxane-based adjuvant chemotherapy is standard care for women with triple-negative breast cancer. Similar regimens can be used for patients with high-risk, hormone receptor–positive disease and in combination with HER2-directed therapy for HER2-positive disease.
- One year of adjuvant trastuzumab is recommended for HER2-positive breast cancer, given concurrently for 12 weeks with taxane-based chemotherapy followed by

monotherapy to complete 1 year.

- The addition of 1 year of adjuvant pertuzumab to trastuzumab provided a small absolute reduction in the risk of an invasive DFS event, and its use can be considered for high-risk patients.

STAGE III DISEASE

Stage III disease is often classified as locally advanced disease and can be grouped into two general categories: patients with large tumors or multiple positive lymph nodes but who clearly have operable disease that can be primarily resected, and patients with inoperable disease by virtue of skin involvement, disease attachment to the chest wall, or extensive nodal involvement that precludes initial surgical resection (e.g., matted axillary lymph nodes or supraclavicular lymph node involvement). The initial diagnostic evaluation and treatment of patients with operable stage III disease can be conducted in the same manner as for patients with stage II disease; however, often the preferred method is to administer systemic therapy first (primary systemic therapy, preoperative, neoadjuvant) followed by surgery and radiation. Often this sequence is performed to improve surgical options by allowing the possibility of breast conservation or sentinel node biopsy without ALND. The sequence of treatment using neoadjuvant systemic therapy is required for the treatment of inoperable stage III disease in order to allow definitive local therapy, determine disease response to systemic therapy, and improve survival.

Locoregional Therapy

A meta-analysis of nine randomized trials that involved 3946 patients (including patients with stage II cancer) evaluated outcomes when the same systemic therapy was administered to patients with operable breast cancer, preoperatively (neoadjuvant) versus postoperatively (adjuvant), revealing no difference in mortality or distant disease recurrence.[262] Neoadjuvant systemic therapy is associated with considerable tumor shrinkage, thus allowing for a greater proportion of patients to achieve breast conservation.[263]

A greater risk of locoregional disease recurrence was found among patients who received radiation alone as local therapy, following neoadjuvant systemic therapy, excluding surgery. Even in the setting of a complete clinical disease response to neoadjuvant systemic therapy, resecting the region of the primary tumor site with appropriate breast surgery is currently recommended for optimal local disease control, although this is being evaluated in ongoing clinical trials.[263,264]

Breast-conservation surgery after neoadjuvant systemic therapy has classically been followed by radiation therapy; however, the criteria for PMRT in this setting have been less well defined, until recently. In 2016, the ASCO/ASTRO/SSO guidelines recommended PMRT for patients with positive lymph nodes following neoadjuvant systemic therapy.[265] There is currently insufficient evidence to recommend whether PMRT should be administered or can be routinely omitted in those with clinically negative nodes who receive neoadjuvant systemic therapy or in those with a complete response in the lymph nodes with neoadjuvant systemic therapy. The recommendation of the panel is to enter eligible patients into clinical trials designed to address these clinical scenarios (NSABP B-51 and A11202).

The optimal surgical management of the axilla in the setting of neoadjuvant chemotherapy remains complex and is an area under investigation. Patients with a clinically negative axilla (by

physical examination and axillary ultrasound) at the time of presentation can undergo SLN surgery after completion of chemotherapy. SLN surgery post–neoadjuvant systemic therapy is acceptable and has a similar SLN identification and false-negative rate as seen prior to systemic therapy.[266] If the SLNs are negative, then no further axillary surgery is indicated. If any of the SLNs is positive, then completion ALND is recommended.

Patients with a positive axillary lymph node confirmed by FNA biopsy or core needle biopsy at the time of diagnosis usually undergo complete axillary lymph node dissection following neoadjuvant chemotherapy; however, SLN surgery is increasingly used to evaluate for residual nodal disease. Neoadjuvant systemic therapy has been shown to convert 40 to 75% of positive lymph nodes to negative lymph nodes. Several recent multicenter clinical trials[267-269] show false-negative rates with SLN surgery in this setting that are similar to rates in patients with clinically node-negative breast cancer treated with neoadjuvant chemotherapy.

Current clinical trials are further exploring the optimal locoregional management of the axillae. Alliance A011202 is randomly assigning patients with a positive SLN after neoadjuvant chemotherapy to axillary dissection or axillary radiation to evaluate which modality provides the best local control and survival. NSABP B-51 is asking whether adjuvant nodal radiation is required in women who convert from biopsy-proven node-positive disease to pathologically node-negative disease (by SLN surgery or ALND) after neoadjuvant chemotherapy, by randomly assigning these women to nodal radiation or no radiation.

Neoadjuvant Systemic Therapy

Chemotherapy. A pCR has variable definitions in the literature; however, the consensus definition is absence of invasive carcinoma in the breast and axillary lymph nodes.[263] A pCR with neoadjuvant systemic therapy is associated with a more favorable outcome, compared with patients who have residual disease in the breast and/or axilla.[270] NSABP B-18 and NSABP B-27 compared neoadjuvant chemotherapy to adjuvant chemotherapy using chemotherapy regimens of AC alone or AC followed by docetaxel.[271] Both studies demonstrated superior DFS and OS among the patients who achieved pCR compared with those who did not, although the pCR rate was only 13 to 26%. In the final analysis, however, there remained no difference in overall DFS or OS when the chemotherapy was administered in the neoadjuvant versus the adjuvant setting.

Although TNBC is associated with a less favorable overall prognosis, this subtype of breast cancer is more chemosensitive and has a greater propensity of achieving a pCR to neoadjuvant chemotherapy, compared with hormone receptor–positive disease.[272] Patients with TNBC who achieve a pCR have a favorable OS, that is similar to patients with non-TNBC who achieve a pCR.[273] Residual disease following neoadjuvant chemotherapy in TNBC and HER2-positive disease is associated with a worse DFS compared with other subtypes of breast cancer treated similarly.[274] In this way, neoadjuvant chemotherapy can be used as a mechanism of evaluating tumor biology, disease resistance, and, ultimately, prognosis.[2754] When neoadjuvant chemotherapy is used, the regimen selected should be the same as what would be administered in the adjuvant setting, typically consisting of an anthracycline and a taxane.[263,276]

Given the relationship between pCR and OS, several neoadjuvant clinical trials have been designed to evaluate novel chemotherapy regimens, some including targeted agents, with an overarching goal of improving on existing pCR rates associated with standard therapy. In CALGB 40603, the addition of neoadjuvant carboplatin to anthracycline- and taxane-based chemotherapy was evaluated in patients with clinical stages II and III TNBC. Rates of pCR in

the breast and axilla were 41% for standard chemotherapy and 54% when carboplatin was added to the regimen (p = 0.0029).[277] This significant improvement in pCR was also achieved when carboplatin was added to a more complex neoadjuvant anthracycline- and taxane-based regimen that included bevacizumab in patients with TNBC (absolute increase of 16.3%) participating in the GeparSixto trial.[278] Despite encouraging results in a population in need of better therapies, the 3-year event free survival (EFS) results for these trials yielded different conclusions. In CALGB 40603, there was an absolute gain in EFS of 4.9%; however, this was not statistically significant.[279] In GeparSixto, there was an absolute gain in EFS of 9.7% that was statistically significant.[280] Notably, patients in GeparSixto had a better overall prognosis (more T1 and N0 disease), a larger incremental benefit from carboplatin, as well as a larger cumulative dose and longer overall duration of anthracycline and taxane chemotherapy, as compared with patients in CALGB 40603. Thus, recognizing that the platinum agents can be toxic and that these trials lack long-term safety data, as well as the discrepant EFS outcomes between these trials, many experts still consider the use of carboplatin in TNBC to be investigational. Biomarkers predictive of carboplatin benefit are needed to help guide patient selection. Optimal dosing and schedule for carboplatin, which also varied in these two trials, remains to be determined.

There is no clearly established role for adjuvant chemotherapy once neoadjuvant chemotherapy is completed, even if pCR is not attained, assuming a complete course of therapy was administered as neoadjuvant systemic therapy. There has been a single report of a pre-planned interim analysis of a phase III trial that a 24-week course of capecitabine may improve clinical outcomes for those without pCR after contemporary neoadjuvant anthracycline and taxane-based chemotherapy, leading some oncologists to utilize this approach in clinical practice.[281]

Endocrine Therapy. Neoadjuvant endocrine therapy is an acceptable treatment for postmenopausal women with hormone receptor-positive disease, although the pCR rate of 1 to 8% is lower than with chemotherapy.[264] At least five randomized trials (including patients with stage II disease) have demonstrated superiority with neoadjuvant AI treatment compared with tamoxifen.[282] The IMPACT trial compared neoadjuvant anastrozole, tamoxifen, and the combination of anastrozole and tamoxifen, and found a greater ability to achieve BCT with anastrozole compared with tamoxifen (46% vs. 22%).[283] A comparison of neoadjuvant letrozole with tamoxifen, performed by the Letrozole Neoadjuvant Breast Cancer Study Group, demonstrated a superior clinical response with letrozole (55% vs. 36%, respectively) and superior frequency of BCT (45% vs. 35%, respectively), but no difference in the low pCR rates.[284]

For post-menopausal women, all three third-generation AIs (anastrozole, letrozole, and exemestane) appear to be equally effective when administered in the neoadjuvant setting in terms of clinical response and surgical outcomes.[285] Despite low pCR rates associated with neoadjuvant endocrine therapy, surrogate markers of response can offer prognostic information about long-term clinical outcomes, including the hormone receptor status of residual disease (ER-negative is less favorable) and the Ki67 expression in residual tumor (low value is more favorable).[286] Prospective validation of these biomarkers is ongoing. Patients who have a clinical response to neoadjuvant endocrine therapy should continue on endocrine therapy postsurgery, as per adjuvant treatment recommendations (see the Stage I and II Disease, Hormone Receptor Positive Disease, and Endocrine Therapy sections). Those who do not have a clinical response should be considered for adjuvant chemotherapy to be followed by adjuvant endocrine therapy. Neoadjuvant endocrine therapy in pre-menopausal women and men remains

investigational.

HER2-Directed Therapy. Like TNBC, HER2-positive breast cancer is associated with a high probability of tumor response to neoadjuvant chemotherapy, and this response rate is increased substantially with the addition of HER2-directed treatment. Two studies evaluated neoadjuvant trastuzumab-containing regimens administering the trastuzumab with an anthracycline. A meta-analysis of these two randomized trials compared neoadjuvant chemotherapy with and without trastuzumab for HER2-positive disease.[287] Both studies demonstrated a significant benefit with added trastuzumab in the pCR rate (20 to 40% actual improvement), and a 33% relative reduction in risk of recurrence and death. The cardiac event rate was 11%. Two additional studies, using epirubicin plus cyclophosphamide (EC) every 3 weeks followed by a taxane with or without capecitabine, also initiated trastuzumab with the anthracycline and observed favorable pCR rates of 32 to 39%, with a less than 4% incidence of cardiac toxicity.[288,289] These studies provide short-term safety data for the combination of anthracycline chemotherapy and neoadjuvant trastuzumab. A recent randomized study failed to demonstrate an improvement in pCR rate with the concurrent administration of trastuzumab with anthracycline and taxane-based chemotherapy over the previously established standard to administer anthracycline-based chemotherapy alone followed by taxane-based chemotherapy with trastuzumab. Given this result and the lack of long-term safety and efficacy data, it appears best to administer trastuzumab sequentially with anthracycline-based chemotherapy, as opposed to concurrently.[290]

In an attempt to add to the efficacy of trastuzumab administered pre-operatively, two phase III trials evaluated the role of lapatinib in this setting. GeparQuinto compared four cycles of EC followed by four cycles of docetaxel concurrent with either lapatinib or trastuzumab. Among the 620 randomly assigned patients, the pCR rate was significantly higher with trastuzumab compared with lapatinib (30.3% vs. 22.7%, respectively, $p = 0.04$).[232] No difference in pCR rate was demonstrated between the lapatinib alone and trastuzumab alone arms (24.7% vs. 29.5%) in a second complex trial involving 455 patients randomly assigned to receive 6 weeks of lapatinib alone, trastuzumab alone, or lapatinib combined with trastuzumab prior to continuing HER2-directed therapy with 12 weeks of paclitaxel (NeoALTTO).[231] Combination lapatinib and trastuzumab with paclitaxel resulted in a superior pCR rate, 51.3%.

The benefit seen with dual HER2-directed therapy prompted an evaluation of pertuzumab in the neoadjuvant setting. The NeoSphere trial was an open-label, phase II study that randomly assigned 417 patients to receive four cycles of docetaxel combined with either trastuzumab, pertuzumab, or both agents versus combination pertuzumab and trastuzumab without docetaxel (a nonchemotherapy arm).[291] The combination pertuzumab and trastuzumab with docetaxel achieved the highest pCR rate of 39.3%, compared with the other groups. This trial, as well as the TRYPHAENA study,[292] combined with the survival advantage seen with pertuzumab in the metastatic setting, led the FDA to provide accelerated approval of this combination for neoadjuvant treatment of HER2-positive breast cancer. All patients in the NeoSphere trial also received adjuvant treatment with three cycles of FEC chemotherapy concomitant with trastuzumab followed by completion of 1 year of trastuzumab therapy.

Based on these results, a promising option for neoadjuvant systemic therapy of HER2-positive disease is a combination of trastuzumab and pertuzumab with a taxane-based chemotherapy. This is either preceded by or followed with an anthracycline-based regimen. Trastuzumab should be administered for a total of 1 year. The optimal chemotherapy regimen used in neoadjuvant systemic therapy with trastuzumab and pertuzumab is still unknown. Notation in the most recent NCCN guidelines allows for the use of pertuzumab in the adjuvant

setting if it was not received in the neoadjuvant setting; results of the APHINITY trial support this.

INFLAMMATORY BREAST CANCER

Inflammatory breast cancer (IBC) is an uncommon virulent subset of disease that now accounts for up to 2% of all breast cancers in the United States. IBC (T4d) is a clinical diagnosis in the setting of documented invasive breast cancer and is characterized by a rapid onset of clinical changes in the breast—skin erythema, warmth, edema (peau d'orange), breast enlargement, and pain—usually occurring within a 3-month time frame, but not present for longer than 6 months. This type of breast cancer is designated as inflammatory because the clinical signs mimic mastitis; an empiric treatment with antibiotics often delays the diagnosis of cancer. These clinical criteria differentiate IBC from a neglected locally advanced breast cancer with secondary inflammatory characteristics, which is associated with a more favorable prognosis. A discrete mass may be absent in patients with IBC, and pathologically, tumor emboli are seen within dermal lymphatics in 75% of cases.[293] The classic physical findings of the breast are due to damage of the dermal lymphatics caused by tumor emboli, and the corresponding palpable finding is known as "ridging." Patients with IBC are often younger at the age at diagnosis, are more often black, and by definition, present with inoperable disease.[294] Breast imaging with mammography usually finds asymmetrical increased density throughout the affected breast, associated with skin thickening and axillary adenopathy. MRI is more sensitive and specific in finding breast masses and confirming disease response to neoadjuvant chemotherapy, compared with mammography.[295]

Although the complete spectrum of intrinsic subtypes is seen in IBC, there is a propensity for the disease to segregate into the more proliferative HER2-positive and triple-negative molecular subtypes. Patients with IBC have as high as a 2-fold increased risk of dying of disease as patients diagnosed with noninflammatory locally advanced breast cancer, with OS rates being consistently less than 50%. Approximately 20 to 40% of patients with IBC have evident metastatic disease at the time of presentation.[296] Given the high risk of developing metastatic disease, a trimodality approach to treatment is appropriate: neoadjuvant chemotherapy followed by mastectomy with ALND and PMRT with comprehensive regional nodal irradiation. Hormone receptor–positive IBC is treated similarly to noninflammatory breast cancer, with endocrine therapy given following chemotherapy. The primary goal of this treatment sequence is to optimize conditions for a surgical intervention; the secondary goal is that it allows for real-time assessment of the primary systemic therapy's antitumor efficacy through evaluation of the pathologic disease response at the time of mastectomy.

Although the optimal neoadjuvant chemotherapy regimen for IBC has not been defined, the type of neoadjuvant systemic therapy should be selected from those regimens outlined previously for noninflammatory breast cancer. Both prospective and retrospective studies support the use of combination anthracycline- and taxane-based regimens. The addition of taxanes to anthracycline regimens has resulted in an improved pCR rate and improved OS.[297] The prognosis of HER2-positive IBC has greatly improved in the era of HER2-directed therapy. HER2-positive IBC should be treated with a dual HER2-targeted neoadjuvant regimen with trastuzumab and pertuzumab, as previously described.

IBC appears to have a unique molecular profile characterized by overexpression of the epithelial adhesion protein E-cadherin, overexpression of the *RhoC* oncogene, and a high frequency of *TP53* gene mutations, in addition to a loss of expression of *WISP3,* which has

growth and angiogenesis inhibitory functions.[298] A greater understanding of the molecular biology of IBC may help to decipher the pathophysiology of the disease and to develop rationally designed and more effective therapies.

There is a direct correlation between systemic disease control and local disease control with IBC. The goal of neoadjuvant chemotherapy is to render the breast operable. Breast conservation is contraindicated, as is SLN biopsy. A total mastectomy with levels I and II ALND improves surgical control, compared to lesser surgeries. Radiation therapy follows, although the optimal radiation dose and sequence is not well established. The chest wall and regional lymph nodes (supraclavicular, infraclavicular, internal mammary) are included in the treatment field, and the cumulative radiation dose is 50 to 66 cGy. Reconstruction of the breast is best deferred, in order to avoid delays in delivering optimal local therapy for IBC. If neoadjuvant chemotherapy results in an inadequate response in the breast, radiation can be administered prior to mastectomy.[299]

KEY POINTS

- For patients with stage II or III breast cancer, neoadjuvant chemotherapy is associated with a reduction in the need for mastectomy and/or ALND.
- For stage II or III breast cancer, survival is equivalent whether the same chemotherapy regimen is administered in the neoadjuvant or the adjuvant setting.
- Neoadjuvant endocrine therapy is an acceptable treatment approach for postmenopausal women with stage II or III hormone receptor–positive breast cancer. It can result in higher breast-conservation rates, but it infrequently results in pCR.
- Residual disease following neoadjuvant chemotherapy for TNBC and HER2-positive disease is associated with worse DFS, compared to those who achieve a pCR.
- Pertuzumab, when administered with trastuzumab and taxane-based chemotherapy, is associated with a significantly increased pCR rate; this led to its accelerated FDA approval for management of stages II and III HER2-positive breast cancer.
- Inflammatory breast cancer (IBC) is managed by neoadjuvant chemotherapy followed by mastectomy with ALND, postmastectomy radiation therapy, and adjuvant endocrine therapy, when indicated. Despite optimal multimodality care, DFS is worse compared with noninflammatory breast cancer, even for patients who achieve a pCR.

RECURRENT OR METASTATIC DISEASE

LOCOREGIONAL RELAPSE

Locoregional disease relapse can be defined as cancer recurrence in the ipsilateral breast, chest wall, or regional lymph nodes. Isolated locoregional recurrences are treated with curative intent. Those that occur within the first 5 years after diagnosis are associated with a poorer prognosis than later recurrences. Recurrences that develop after 5 years usually represent de novo second primary tumors and have a more favorable outcome compared with earlier recurrences within the proximity of the original tumor, which usually represent disease that has been resistant to prior radiation and systemic therapy. The treatment of locoregional

recurrences requires a multidisciplinary approach.

Ipsilateral breast tumor recurrence (IBTR) following BCT has been associated with a 3- to 4-fold increase in the risk of systemic metastasis. The NSABP reviewed five of its more recent adjuvant studies that involved 2669 women treated with breast-conserving surgery, radiation therapy, and systemic treatment and found that patients who experienced an IBTR had a 2.72-fold greater risk of distant disease developing at 5 years and a 2.58-fold greater risk of death, compared with those who did not have disease recurrence.[300] Patients who experienced a chest wall recurrence following mastectomy fared worse, with a 6.68-fold greater risk of distant recurrence at 5 years and a 5.85-fold greater risk of death. IBTRs are usually treated with total mastectomy, since repeat radiation treatment is contraindicated. In cases without prior radiation, BCT can be considered. Small series have evaluated repeat lumpectomy and accelerated partial-breast irradiation in the setting of prior lumpectomy and radiation and have shown low toxicity, although long-term outcome data is awaited. Regarding management of the axilla, the axilla should be evaluated with physical examination and ultrasound. If clinically negative, SLN surgery can be attempted, however it has a lower SLN identification rate.[301] ALND should be considered in cases in which SLNs have not been identified. In cases with clinically positive nodes or positive SLN(s), an ALND should be performed.

As in IBTR, chest wall recurrences after mastectomy occur most frequently within the first 5 years posttreatment and rarely occur after 10 years. The majority of chest wall recurrences develop in the proximity of the mastectomy incision, whereas fewer recurrences develop in the regional lymph node areas (in order of decreasing frequency: supraclavicular, axillary, internal mammary). A review of 11,452 women treated with standard locoregional therapy for early-stage breast cancer at the European Institute of Oncology demonstrated a shorter subsequent DFS and OS among patients in whom regional lymph node recurrences developed, compared with the DFS and OS associated with an IBTR or a nonnodal chest wall recurrence.[302] The risk of subsequent distant disease and consequent adverse effects on OS decreased with time after the initial nonnodal chest wall recurrence, whereas patients with regional lymph node recurrences remain at high risk for the development of distant disease and a shortened OS for a long time. The treatment of an isolated chest wall recurrence requires a surgical excision, if feasible, with the goal of obtaining negative margins. The chest wall and supraclavicular lymph nodes should then receive standard radiation therapy, if not given previously.

Because of the high rate of distant disease in patients who have a locoregional breast cancer recurrence, staging studies are usually performed at the time of the recurrence to evaluate for the presence of metastatic disease. On the basis of data supporting its efficacy, systemic therapy is often administered after completion of local treatment for a locoregional recurrence. The international CALOR (BIG 1-02/IBCSG 27-02/NSABP B-37) trial enrolled 162 out of a planned 977 patients with invasive breast cancer in whom an isolated local and/or regional ipsilateral recurrence developed after mastectomy or BCT.[303] Patients received radiation therapy, endocrine therapy, or trastuzumab as appropriate, and were also randomly assigned to receive chemotherapy or not. The chemotherapy regimen selection and duration of treatment was per physician choice. The 5-year DFS was improved with chemotherapy (69%) compared with no chemotherapy (57%). The benefit was primarily seen in TNBC (67% with chemotherapy vs. 35% without chemotherapy). The 5-year OS was comparable between the two groups—numerically, but not significantly, higher in the chemotherapy group (88% with chemotherapy vs. 76% without chemotherapy). Although this is a highly underpowered study, it does support consideration of chemotherapy following local or regional disease recurrence in select circumstances.

KEY POINTS

- Disease recurrence in a previously irradiated breast commonly requires a mastectomy for local disease control.
- The addition of chemotherapy after a locoregional recurrence may benefit some patients, especially those with triple-negative disease.

STAGE IV (METASTATIC) DISEASE

Metastatic breast cancer is an extremely heterogeneous entity. Treatment options depend on location of metastasis and number of sites involved, presence or absence of hormone receptor expression and HER2 overexpression, an assessment of disease responsiveness to systemic therapy based on characteristics such as disease-free interval, and an estimation of the need for rapid disease response to therapy. Given the diverse presentation of metastatic disease and the wide range of therapeutic possibilities, the goal of this section is to provide a guide for approaching treatment options rather than providing specific treatment recommendations. As with adjuvant therapy of early-stage disease, there are options for treatment outlined by different organizations to help guide decision-making.[169,304,305]

The overall goals of treating metastatic breast cancer are to slow the progression of disease, improve quality of life, and prolong survival while minimizing treatment-associated toxicity. Metastatic breast cancer is a chronic disease; sequential, single-agent therapy is a mainstay of treatment. The incorporation of new therapies over recent decades has resulted in a gradual improvement in OS by 1 to 2% per year.[306] The benefits of individual regimens are often comparable in first-line or subsequent treatment; therefore, the optimal sequence of therapies has not yet been determined.[307]

Once metastatic disease is diagnosed, its extent should be determined by radiographic imaging. The most common initial sites of metastasis include bone, liver, and lung, which can be imaged by conventional CT and bone scan. PET imaging can complement these studies, especially in the setting of lytic bone metastases, which may be underestimated on bone scanning. Central nervous system disease is less likely to be present at the initial presentation of metastatic disease; MRI of the brain can be deferred until symptoms arise. The molecular subtypes of breast cancer have a predilection for metastasizing to specific sites, which may affect the decision to image these areas. HER2-positive disease and TNBC are associated with a higher frequency of brain metastasis (in about a quarter to a third of patients in some reports) compared with the HR-positive subtype (10%).[308] Bone metastases are more common among the hormone receptor–positive subtype (68%), whereas TNBC is associated with a high frequency of metastasis to the lungs (40%). Discordance of hormone receptor and HER2 status between the primary tumor and the metastatic disease can occur in approximately 10 to 15% of cases. A biopsy of the initial metastatic site is often warranted to determine receptor status and to confirm the presence of metastatic breast cancer rather than another malignancy, either primary or metastatic. Additionally, serial biopsies along the metastatic course at the time of progression may be useful, as acquired resistance to therapies can be the result of changes in gene and protein function.

The measurement of the circulating extracellular domain of HER2 as a surrogate marker for HER2 status of the tumor has not yet been established and should be relegated to clinical

trials.[309] Other serum markers, such as the MUC-1 assays, CA 27.29 or CA 15-3, and the carcinoembryonic antigen levels, have not been shown to impact survival in nonmetastatic settings, but can complement the interpretation of imaging studies in metastatic disease. Changes in these assays, by themselves, usually should not dictate changes in therapy. The application of circulating tumor cells in the interpretation of disease response and management of therapy for metastatic disease remains investigational.

Endocrine Therapy

In the setting of hormone receptor–positive metastases that are not associated with rapidly progressing disease or visceral crisis, endocrine therapy should generally be the initial treatment approach. Objective response rates to endocrine therapy are comparable to those of single-agent chemotherapy for first-line treatment; however, the onset of action is slower for endocrine therapy, given the differing antitumor mechanisms of action. Sequential treatment with endocrine therapy regimens is appropriate; however, the likelihood of disease response and duration of response generally becomes smaller/shorter with each change in regimen. At the time of cancer progression, a switch to chemotherapy is always an option. Virtually all patients with metastatic hormone receptor–positive breast cancer ultimately receive chemotherapy. The decision to switch to chemotherapy is based on a low likelihood of a response to additional endocrine therapy, as well as on the other considerations outlined above. Chemotherapy and consideration for combination therapy should be given if the disease is rapidly progressing or in the setting of visceral crisis.

The choice of initial endocrine therapy is dependent on the menopausal status of the patient, the type of prior endocrine therapy used for adjuvant treatment, and the duration between adjuvant endocrine therapy and disease recurrence. There is an association between response to endocrine therapy and the strength of ER and PR expression. In the setting of hormone receptor–positive metastatic disease, disease response is important, but clinical benefit (defined as the percentage of complete and partial disease responses plus stable disease exceeding 6 months) may supersede disease response.

Historically, OFS has been effective in premenopausal women with hormone receptor–positive metastatic disease. The use of a GnRH agonist in the metastatic setting has resulted in outcomes similar to those for surgical ovarian ablation. Tamoxifen has also been found to be equally as effective as ovarian ablation, regardless of the degree of circulating estrogen levels. A meta-analysis of four randomized trials that involved 506 premenopausal women compared a GnRH agonist alone or combined with tamoxifen and found a 22% reduction in the risk of death and a 30% reduction in the risk of disease progression/death with the combination.[310] Patients whose disease initially responds to combination OFS and tamoxifen can subsequently be treated similarly to postmenopausal women. In this scenario, medical OFS should continue throughout the duration of such endocrine therapy; a bilateral oophorectomy may be pursued as an alternative.

In postmenopausal women, third-generation AIs (letrozole, anastrozole, and exemestane) have been shown to be superior to tamoxifen as first-line therapy for hormone-responsive metastatic disease in a meta-analysis and are associated with an 11% reduction in the risk of death.[311,312] On an individual basis, selective AIs were found to be superior to tamoxifen in terms of overall disease response rate, time to treatment failure, and clinical benefit. Unless disease progression occurred on or soon after the completion of adjuvant AI therapy, the AIs historically (before 2015) were the recommended choice for first-line endocrine therapy for

postmenopausal women.[312-314] For patients who experienced progression while taking an AI, tamoxifen or fulvestrant were often used as first-line therapy. Data also demonstrate that switching from a nonsteroidal AI (letrozole or anastrozole) to a steroidal AI (exemestane) could result in a modest disease response, suggesting a component of non–cross-reactivity.[315] Studies presented/published in 2015–2016, however, challenged the role of single-agent AI as recommended first-line therapy.

An important pathway for facilitating disease responses with endocrine therapy involves cyclin-dependent kinases (CDKs) 4 and 6. In February 2015, the FDA granted accelerated approval for palbociclib, a CDK4/6 inhibitor that blocks progression of the cell cycle from G1 to S phase. This approval was based on the results of a randomized phase II trial (PALOMA-1) of palbociclib plus letrozole versus letrozole alone as first-line therapy in 165 postmenopausal patients with ER-positive metastatic breast cancer.[316] Investigator-assessed PFS essentially doubled for patients who received palbociclib (HR, 0.49; 95% CI; 0.31, 0.74). Response rates were also increased. The final OS results were presented at ASCO 2017.[317] Median OS was 37.5 months (95% CI; 31.4, 47.8) for combination therapy, compared with 34.5 months (95% CI; 27.4, 42.6) for letrozole alone (HR, 0.897; 95% CI; 0.623, 1.294; p = 0.281). The phase III PALOMA-2 trial confirmed these findings with an improvement in median PFS from 14.5 months with letrozole alone to 24.8 months for the combination therapy (HR for disease progression or death, 0.58; 95% CI; 0.46, 0.72; p < 0.001).[318] Confirmed ORRs were also higher for the combination therapy (55%) as compared with letrozole alone (35%). OS data were immature at the time of the initial publication. As compared to letrozole alone, the combination therapy was associated with higher levels of neutropenia (rate of grade 3 or 4 events, 65%), febrile neutropenia (1.8%), thrombocytopenia, anemia, and alopecia. Dose reductions for palbociclib occurred in 36% of patients. The PALOMA-2 results led to full FDA approval of palbociclib in combination with an AI as first-line therapy. Given the outcomes of the PALOMA-1 and PALOMA-2 trials, the combination of letrozole and palbociclib has been recognized as an option for first-line endocrine therapy.[319]

The phase III MONALEESA-2 trial evaluated letrozole with placebo or in combination with a different CDK4/6 inhibitor, ribociclib, as first-line therapy in postmenopausal, hormone receptor–positive, HER2-negative advanced breast cancer.[320] A preplanned interim efficacy analysis demonstrated an improvement in PFS, with a HR of 0.556 (95% CI; 0.429, 0.720; p < 0.0001). The estimated median PFS had not been reached in the ribociclib-containing arm and was 14.7 months in the placebo-containing arm. The ORR in patients with measurable disease was 52.7% (95% CI; 46.6, 58.9) in the ribociclib plus letrozole arm versus 37.1% (95% CI; 31.1, 43.2) in the placebo plus letrozole arm. OS data are immature. These findings supported the 2017 FDA approval of ribociclib in combination with an AI as first-line therapy in this patient population. A third CDK4/6 inhibitor, abemaciclib, has been granted Breakthrough Therapy designation by the FDA by demonstrating significant clinical activity as a single agent and in combination with fulvestrant in early-phase clinical trials among patients with prior progression on endocrine therapy.[321] The results of a phase III registration trial, MONARCH 3, evaluating abemaciclib or placebo in combination with letrozole or anastrozole, are anticipated soon.

Also challenging AI monotherapy for consideration in first-line management is fulvestrant, an analog of 17-beta estradiol, which causes ER disruption and degradation when it binds to the ER, leading to inhibition of estrogen signaling and consequent cellular growth. Unlike other endocrine therapies, fulvestrant is given by monthly intramuscular injection. The CONFIRM trial demonstrated the need to use a loading dose in order to obtain steady-state drug concentrations within the first month of administration; a dose relationship was illustrated with

fulvestrant on PFS as well as OS.[322,323] The phase II FIRST study, which utilized the current standard fulvestrant dose (500 mg), demonstrated a superior time to tumor progression and OS compared with anastrozole in the first-line setting, although the clinical benefit and overall response were comparable.[324] A subsequent phase III FALCON trial confirmed an improvement in PFS with fulvestrant (16.6 months) as first-line treatment compared with anastrozole (13.8 months; p = 0.0488).[324] As a result of these studies, NCCN lists fulvestrant as one of the first-line options.

Fulvestrant has been studied in the PALOMA-3 trial, alone and in combination with palbociclib, after prior progression on endocrine therapy.[325] Notably, premenopausal patients were eligible to participate in this trial and comprised 21% of the overall study population. These patients received OFS concurrently with their assigned therapy. Median PFS was 9.5 months for the combination therapy and 4.6 months for fulvestrant alone (HR, 0.46; p < 0.0001). The safety profile was comparable to that observed in the first-line therapy trials. Hormone receptor expression levels, as well as *PIK3CA* and *ESR1* mutation status, were not associated with treatment response with palbociclib. Current ASCO guidelines support fulvestrant alone or in combination with palbociclib in the second-line clinical setting.[319]

Three studies in postmenopausal women investigated the combination of an AI with fulvestrant as endocrine therapy for recurrent hormone receptor–positive breast cancer. As these trials were initiated prior to the findings from CONFIRM, all studies used the lower dosing regimen for fulvestrant (250 mg per dose). SWOG 0226 randomly assigned patients to first-line therapy with anastrozole alone or combined with fulvestrant.[326] Approximately 60% of the patients enrolled had not been exposed to prior adjuvant endocrine therapy. With a 35-month median follow-up, PFS was longer in those receiving combination endocrine therapy compared with those receiving AI alone (15 months vs. 13.5 months; p = 0.007), as was OS (47.7 months vs. 41.3 months; p = 0.049). These data contrast with the FACT trial, which also randomly assigned patients to first-line therapy with anastrozole alone or combined with fulvestrant.[327] In SWOG 0226, two-thirds of the enrolled patients had received adjuvant tamoxifen. No difference was seen in the primary endpoint of time to progression or with median OS. The phase III SoFEA trial examined patients with disease progression while taking a nonsteroidal AI and randomly assigned them to fulvestrant plus placebo, fulvestrant plus anastrozole, or exemestane.[328] There were no differences in PFS or OS among the three groups. In total, the role of combined AI and fulvestrant is not well established because of the discrepancies previously noted and the availability of newer targeted agents.

A major signaling pathway involved in the development of endocrine resistance is the phosphoinositide-3 kinase (PI3 kinase)–Akt–mTOR pathway.[329] Inhibition of this pathway can occur by targeting mTOR with the rapamycin analogues, everolimus and temsirolimus. The efficacy of adding mTOR inhibitors to endocrine therapy is thought to be due to reversal of endocrine resistance, as evidenced by two trials in metastatic breast cancer, TAMRAD and BOLERO-2. TAMRAD was a phase II trial that involved 111 postmenopausal women whose disease was previously treated with an AI in the adjuvant (41%) and/or metastatic (67%) setting.[330] The primary endpoint of clinical benefit rate—defined as all patients with either a complete (CR), partial disease response (PR), or stable disease at 6 months—was achieved in 61% of patients who received combination everolimus and tamoxifen, compared with 42% who were treated with tamoxifen alone (exploratory p = 0.045). A greater difference in benefit from combination therapy was seen among patients with secondary (acquired) endocrine resistance (74% with combination therapy vs. 48% with tamoxifen alone), which was defined as disease relapse after 6 months of completing adjuvant AI or responding to AI treatment for metastatic

disease for 6 months or longer, compared with patients with primary (de novo) resistance (46% with combination vs. 36% with tamoxifen alone), which was defined as disease relapse during or within 6 months after completing adjuvant or metastatic AI therapy.

The results of the phase III BOLERO-2 trial further supported the hypothesis that everolimus is effective in overcoming endocrine resistance. In this trial, 724 postmenopausal women whose disease progressed or recurred while receiving a nonsteroidal AI were randomly assigned 2:1 to receive either combination everolimus and exemestane or exemestane alone.[331] The median PFS was improved with combination therapy from 4.1 to 10.6 months (HR, 0.36; $p < 0.001$). The added toxicity from everolimus includes a relatively common risk of stomatitis and a low, but potentially serious, risk of pneumonitis. This study led to the 2012 FDA approval of everolimus in combination with exemestane for the treatment of ER-positive, HER2-negative metastatic breast cancer following disease progression during treatment with a nonsteroidal AI.

Other endocrine therapy options for later lines of treatment include megestrol acetate (progestins), fluoxymesterone (androgens), or relatively high doses of estrogen.

Chemotherapy

Chemotherapy is the mainstay of treatment for metastatic hormone receptor–negative breast cancer. It is also indicated in hormone receptor–positive breast cancer in the setting of rapidly progressing or symptomatic disease, disease associated with visceral crisis, and endocrine resistance despite targeted therapeutic drugs (Table 7-8). Sequential use of single-agent chemotherapy is recommended instead of combination chemotherapy regimens, given that the latter are associated with more toxicity without a clear survival benefit. The exception to this rule is in the setting of visceral crisis or rapidly progressive disease that requires prompt cytoreduction[332]; in this setting, the increase in tumor response rates associated with combination chemotherapy may outweigh the added toxicity associated with these regimens.

Table 7-8 **Metastatic Chemotherapy Options**[170,171]		
HER2-Negative Disease	Single Agent	Paclitaxel weekly
		Doxorubicin or pegylated liposomal doxorubicin
		Docetaxel every 21 days
		Nab-paclitaxel (weekly or every 21 days)
		Capecitabine
		Gemcitabine
		Vinorelbine
		Eribulin
		Ixabepilone
		Carboplatin
		Cisplatin
	Combination	Ixabepilone/ capecitabine
		Gemcitabine/ paclitaxel
		Docetaxel/ capecitabine
		Metronomic low-dose cyclophosphamide and methotrexate
HER2-Positive Disease	Pertuzumab, trastuzumab, and taxane	
	T-DM1	
	Paclitaxel weekly and trastuzumab	
	Vinorelbine and trastuzumab	
	Gemcitabine and trastuzumab	
	Capecitabine and lapatinib	

Anthracyclines and taxanes are considered the most active chemotherapies for metastatic breast cancer, although the increased use of both drugs in adjuvant treatment has prompted the development of other non–cross-reacting agents. Single-agent anthracyclines such as doxorubicin and pegylated liposomal doxorubicin are associated with about a 35 to 40% response rate for first-line therapy, the latter being associated with a safer cardiac profile.[333]

Among the taxanes, the most commonly used single-agent drugs include paclitaxel, docetaxel, and nab-paclitaxel, which are associated with an approximately 40% response rate for anthracycline-resistant disease treated in the first-line setting. The optimal schedule varies by taxane, with preference for paclitaxel to be administered weekly and docetaxel every 3 weeks, whereas nab-paclitaxel appears equally effective either weekly or every 3 weeks.[334] A randomized trial that involved 799 patients compared the PFS of first-line therapy with weekly

paclitaxel, nab-paclitaxel, or ixabepilone.[335] The PFS for ixabepilone (7.4 months) was inferior to that for paclitaxel (11.0 months), while the PFS for nab-paclitaxel (9.3 months) was not superior to that for paclitaxel. The safety profile of nab-paclitaxel revealed more hematologic and nonhematologic toxicity, including peripheral neuropathy, when compared with paclitaxel.

Taxane resistance is increasingly common with the general use of taxanes in the adjuvant setting. Several mechanisms of resistance exist, including overexpression and increased activity of the P-glycoprotein drug efflux pump, the development of mutations in the tubulin genes, and alterations in tubulin expression. Several chemotherapeutic agents have been developed in an attempt to overcome these various mechanisms of resistance. Other microtubule-targeting agents, such as the epothilones (e.g., ixabepilone), or the halichondrin B analog, eribulin, have demonstrated antitumor efficacy as second-line or more distant therapies in the setting of both anthracycline- and taxane-resistant disease.[336] In the EMBRACE trial, 762 women who had received between two and five prior chemotherapeutic regimens for metastatic disease, including anthracyclines and taxanes,[337] were randomly assigned to receive single-agent eribulin or the treatment of the attending physician's choice. Patients treated with eribulin achieved a significant improvement in OS (median, 13.1 months vs. 10.6 months).

Other effective single-agent chemotherapies available for the treatment of patients pretreated with anthracyclines and taxanes result in response rates of about 30% and include antimetabolites such as capecitabine (a 5-fluorouracil analog), the nucleoside analog gemcitabine, or the vinca alkaloid vinorelbine. The platinum salts, such as cisplatin and carboplatin, are DNA-damaging agents that appear to be more effective for the treatment of TNBC, particularly *BRCA*-mutant disease.

The anthracyclines contribute to cardiac toxicity on the basis of cumulative dosing and should be avoided in the setting of hyperbilirubinemia. Vinorelbine, ixabepilone, and taxanes increase peripheral neuropathy, with the duration and severity of symptoms dependent on individual risks (e.g., diabetes mellitus) and choice of drug. Caution must be used when capecitabine or platinum agents are administered in the setting of renal dysfunction, and ixabepilone should be avoided in patients with hepatic dysfunction.

The optimal duration of chemotherapy administration for metastatic disease remains unknown. Multiple studies investigating this issue have used regimens that are considered obsolete by today's standards. In general, the continuation of chemotherapy may result in prolonged DFS, especially in the first-line setting, but this has not yet translated into a significant improvement in OS. For this reason, the duration of treatment must be tailored to each individual patient, taking into account the toxicity of treatment, control of disease-related symptoms, and quality of life.[338] Patients whose disease is responding well to chemotherapy without significant toxicity do not need to stop after a prescribed number of cycles, whereas chemotherapy "holidays" are appropriate for patients who require time to recover from toxicity and whose disease may still be responsive to less-toxic targeted therapy, such as endocrine therapy or HER2-directed therapy. Patients with hormone receptor–positive or HER2-positive disease who achieve an adequate response can reasonably discontinue chemotherapy and begin or continue a targeted treatment, such as endocrine therapy or HER2-directed therapies, allowing for a break from chemotherapy-related toxicity.

The phase III OlympiAD trial evaluated the PARP inhibitor olaparib as monotherapy compared with chemotherapy in patients with germline *BRCA*-mutant, HER2-negative advanced breast cancer.[339] All 302 patients had received prior anthracycline- and taxane-based chemotherapy and none were allowed to have had progression on prior platinum chemotherapy. They were randomly assigned 2:1 to olaparib or single-agent chemotherapy of physician choice

(capecitabine, eribulin, or vinorelbine). Olaparib was associated with an ORR of 60% and a superior median PFS of 7.0 months compared with an ORR of 29% and a median PFS of 4.2 months for patients receiving conventional chemotherapy (HR; 0.58; p = 0.0009). There were more low-grade adverse events in those receiving olaparib (primarily nausea and vomiting), whereas there were more high-grade adverse events in those receiving chemotherapy (primarily neutropenia).

HER2-Directed Therapy

Pertuzumab and trastuzumab both target the extracellular domain of HER2; trastuzumab binds to subdomain IV and disrupts ligand-independent downstream signaling, whereas pertuzumab binds to subdomain II, which blocks dimerization of HER2 and subsequent ligand-dependent signaling. The CLEOPATRA trial assessed the added benefit of pertuzumab to combination docetaxel and trastuzumab for first-line treatment of metastatic, HER2-positive breast cancer.[340] This phase III trial randomly assigned 808 patients to receive pertuzumab, trastuzumab, and docetaxel (PTD) compared with trastuzumab and docetaxel with placebo (TD). The primary endpoint of PFS was significantly improved among patients who received both HER2-targeting agents and docetaxel compared with TD (18.5 months vs. 12.5 months; HR, 0.62; p < 0.001). A 6-month improvement in PFS was also seen in the subgroup that had been exposed to adjuvant trastuzumab. The ORR was superior in the PTD arm compared with the TD arm (80.2% vs. 69.3%, p = 0.001), as was the OS, with a 34% reduction in the risk of death with PTD compared with TD (p = 0.0008).[341] In June 2012, the FDA approved combination pertuzumab, trastuzumab, and either docetaxel or paclitaxel as the taxane backbone for first-line therapy of HER2-positive metastatic breast cancer. The final survival analysis in this trial revealed that PTD was associated with a median OS of 56.5 months, which compared with TD translated to an impressive absolute gain in OS of 15.7 months (hazard ratio favoring the pertuzumab group, 0.68; 95% CI; 0.56, 0.84; p < 0.001).[342] The PTD regimen is considered optimal first-line therapy per ASCO guidelines.[305]

Single-agent trastuzumab administered in the metastatic setting provides an ORR of 15 to 26%. The addition of chemotherapy to trastuzumab for first-line treatment improves this rate to 60 to 70%, regardless of which of several types of chemotherapy is administered (e.g., vinorelbine, docetaxel, weekly paclitaxel, or combination taxane plus carboplatin). Early studies that evaluated the efficacy of early administration of combination trastuzumab and chemotherapy in metastatic disease demonstrated an improvement in OS, specifically 1-year OS. The dramatic disease response observed when trastuzumab was added to chemotherapy for the treatment of metastatic HER2-positive disease prompted oncologists to empirically continue trastuzumab when progressive disease dictated a change in chemotherapy. The GBG 26/BIG 3-05 study subsequently confirmed the benefit of continuing trastuzumab with alternative chemotherapy following disease progression with combination chemotherapy and trastuzumab.[343] In this trial, 156 patients were randomly assigned to receive capecitabine alone or capecitabine with continued trastuzumab following disease progression during treatment with first-line trastuzumab or trastuzumab plus chemotherapy. The continuation of trastuzumab with capecitabine resulted in an improvement in PFS, but not OS; however, in further evaluation, allowing for crossover and the effects of third-line therapy, OS was significantly improved in those who continued administration of trastuzumab compared with those who did not.

Lapatinib, a dual tyrosine kinase inhibitor of epidermal growth factor receptor 1 (EGFR-1) and HER2, is also effective in the treatment of HER2-positive metastatic breast cancer, when

administered either in combination with trastuzumab or in combination with capecitabine.[344,345] Combination lapatinib plus capecitabine following disease progression during treatment with trastuzumab resulted in a doubling of the time to tumor progression compared with capecitabine alone.

Trastuzumab emtansine, T-DM1, is an antibody-drug conjugate of trastuzumab and the chemotherapy agent, DM1, a derivative of maytansine, which causes microtubule inhibition. The EMILIA study evaluated the effect of T-DM1 on PFS and OS, compared with combination lapatinib and capecitabine, among 991 patients with HER2-positive metastatic breast cancer whose disease had progressed following treatment with trastuzumab and a taxane.[346] Treatment with T-DM1 resulted in a 12.8% improvement in ORR, a 3-month improvement in PFS (HR, 0.65; 95% CI; 0.55, 0.77; $p < 0.001$), and a 32% reduction in the risk of death (HR, 0.68; 95% CI; 0.55, 0.85; $p < 0.001$) compared with lapatinib and capecitabine; this resulted in FDA approval of T-DM1 in 2013. The differences in PFS and OS in favor of T-DM1 were both highly significant. T-DM1 was also less toxic than the combination of capecitabine and lapatinib. The MARIANNE trial demonstrated no improvement in PFS when pertuzumab was combined with T-DM1 as first-line therapy for HER2-positive metastatic breast cancer.[347] Furthermore, T-DM1 alone or combined with pertuzumab did not result in superior PFS as compared with taxane-based chemotherapy with trastuzumab. The T-DM1 regimens were, however, associated with no febrile neutropenia and less neuropathy, diarrhea, and alopecia. A third trial, the TH3RESA study, involved 602 patients with recurrent, HER2-positive breast cancer and were randomly assigned to T-DM1 or to the treatment of physician's choice.[348] Approximately 30% of the patients enrolled had received more than five prior regimens for recurrent disease. The primary endpoint was PFS and was in favor of T-DM1, with an HR of 0.53 ($p < 0.0001$). The superiority of T-DM1 was also seen among patients who had received prior trastuzumab. Based on the consistent results from the EMILIA and TH3RESA studies, T-DM1 offers an effective and tolerable option for the treatment of HER2-positive disease that has progressed following trastuzumab and taxane chemotherapy, and it is recommended as a second-line treatment per ASCO guidelines.[305]

Approximately 45% of HER2-positive breast cancer is also hormone receptor–positive, which allows targeted therapy for both to be incorporated into the treatment of metastatic disease. Cross-talk exists between HER2 and the ER, resulting in relative resistance to endocrine therapy alone. The addition of trastuzumab to anastrozole, and lapatinib to letrozole, significantly improved PFS and clinical benefit compared with endocrine treatment alone in patients with hormone receptor–positive, HER2-positive metastatic disease; however, an OS advantage was not seen, likely because of the crossover study designs.[349]

KEY POINTS

- Metastatic breast cancer is primarily incurable; therefore, the goal of treatment is to control disease progression and improve quality of life.
- The choice of systemic therapy is based on the hormone receptor and HER2 status, as well as on the extent of metastatic disease, effect of disease on the patient's quality of life (i.e., symptoms and performance status), and pace of the metastatic disease.
- Endocrine therapy is the preferred initial treatment for hormone receptor–positive, HER2-negative metastatic disease unless visceral crisis or extensive visceral involvement is

present.

- Sequential single-agent chemotherapy is preferable to combination chemotherapy unless a rapid disease response is required.
- Combination pertuzumab, trastuzumab, and taxane therapy is the recommended first-line treatment for HER2-positive metastatic disease.
- Trastuzumab emtansine, an antibody-drug conjugate, is effective treatment for recurrent HER2-positive disease after progression during treatment with trastuzumab.

Bone-Modifying Agents

Approximately 65 to 80% of patients with metastatic breast cancer will have disease manifestation in the bone, most commonly among the hormone receptor–positive cancer subtype. Although bone involvement is associated with a more favorable prognosis than visceral metastases, patients are at higher risk of skeletal-related events (SREs) or other complications occurring over time, such as pathologic fracture, cord compression, pain, hypercalcemia, and the need for surgical interventions. Breast cancer that metastasizes to bone is treated with appropriate systemic therapy. Palliative radiation therapy to specific sites of disease can reduce the morbidity associated with pain and fracture, as well as control disease that may compromise the spinal cord.

Breast cancer that metastasizes to bone can produce osteoblastic or osteolytic bone lesions, both of which are associated with activation of osteoclasts. Breast cancer cells involving the bone can also secrete cytokines that stimulate receptor activator of nuclear factor kappa B ligand (RANKL) secretion by osteoblasts, which mediates osteoclast survival. Bisphosphonates are pyrophosphate analogs that are internalized by osteoclasts, which disrupt their function and result in apoptosis. Clinically available bisphosphonates (e.g., pamidronate and zoledronate) have been shown to reduce the incidence of SREs, the time to the occurrence of SREs, and pain.[350] Denosumab, a humanized monoclonal antibody to RANKL, delayed the advent of SREs by 18% over zoledronic acid among 2046 women with metastatic breast cancer.[351] Zoledronic acid use was associated with renal compromise, whereas hypocalcemia was more common with denosumab. Calcium and vitamin D supplementation should be employed for patients receiving bone-modifying agents, while renal function should be monitored in patients receiving bisphosphonates. Both drugs are associated with a 2% incidence of osteonecrosis of the jaw; ideally, physicians should avoid administering these agents to patients, for an undefined period of time, before or after any invasive dental procedure that involves manipulation of the bone. These agents should be considered once lytic bone metastases are diagnosed (see Chapter 21 Symptom Management). The optimal dosing intervals were not well studied until recently, when dosing interval studies were reported for zoledronate. Although recommendations had been monthly for both agents, results from a randomized trial that evaluated the use of the second year of zoledronate, following a year of monthly dosing demonstrated that dosing zoledronate monthly was equivalent to dosing every 3 months.[352] A randomized trial that compared up-front zoledronate at monthly versus 3-monthly intervals for 2 years also demonstrated equivalence.[353] Similar data are not available for denosumab, and the different mechanisms of action for denosumab and zoledronate do not allow for one to assume that the data would be similar for these two drugs. The optimal duration of treatment with either a bisphosphonate or denosumab is unknown, since the

therapeutic intervals in published studies vary from 3 months to indefinitely. Two years may be a reasonable duration for this treatment.[353]

Multiple clinical trials have been conducted to determine the role of bisphosphonates given in the adjuvant setting in an attempt to reduce the development of metastatic disease. Conflicting data exist, as the AZURE trial exhibited no effect of zoledronic acid on DFS among 3360 patients with stages II and III disease treated with chemotherapy, whereas the ABCSG-12 study demonstrated a 36% reduction in risk of disease recurrence among 1803 premenopausal women with stages I and II disease treated with ovarian suppression and endocrine therapy alone.[354,355] A meta-analysis of 13 studies that investigated the role of adjuvant bisphosphonates showed no impact on DFS or OS; however, there was a trend of improved DFS and a reduction in risk of death among postmenopausal women.[356] A subsequent meta-analysis of 17 trials and data from more than 21,000 patients demonstrated a 3.5% absolute reduction in the risk of distant relapse, predominantly bone metastatic relapse, as well as a 2.3% absolute improvement in all-cause mortality (OS) among postmenopausal women who received adjuvant bisphosphonate treatment.[357] In 2017, Cancer Care Ontario and ASCO published evidence-based recommendations, based on a systematic review of the literature.[358] The review determined that adjuvant bisphosphonates (either zoledronic acid 4 mg IV every 6 months or clodronate 1600 mg once daily orally) reduce the risk of recurrence and improve survival in patients who are postmenopausal by natural menopause or by ovarian suppression or ablation. The review also noted that long-term survival data for adjuvant denosumab are still lacking. It is recommended that adjuvant bisphosphonates be considered as adjuvant therapy for postmenopausal patients who are deemed candidates for systemic therapy.

KEY POINTS

- Bisphosphonates or denosumab decrease SREs when bone metastases are present.
- Adjuvant bisphosphonates have been associated with a reduction in risk of recurrence and improvement in OS. They should be considered for postmenopausal patients who are candidates for adjuvant systemic therapy.
- Renal function should be monitored with bisphosphonate use.
- Calcium and vitamin D supplementation should be strongly considered for patients receiving bone-modifying agents.

SPECIAL CIRCUMSTANCES

MALE BREAST CANCER

Like female breast cancer, most male breast cancers are of ductal origin (85 to 95%). The rate of hormone receptor expression is in excess of 90%, higher than what is observed in female breast cancer.[359] Male patients with breast cancer are usually diagnosed at a later disease stage compared with female patients. Local therapy is often mastectomy because of anatomical constraints, although BCT can be offered if standard criteria for BCT are met (see the Local Disease Control section under Stages I and II Disease). Recommendations for local disease treatment should be governed by the same criteria outlined for breast cancer in women.

Adjuvant therapy also should be administered using the same criteria as those used for women because randomized clinical trial data that specifically inform the treatment of men are not available. Adjuvant chemotherapy may be beneficial only in men with higher-grade and higher-stage cancers. Tamoxifen, however, is the mainstay of endocrine therapy in hormone receptor–positive male breast cancer. Few data exist to support the use of AIs alone or combined with LHRH agonists for adjuvant treatment among men. AI use may be best administered with medical (LHRH agonist) or surgical orchiectomy. In the metastatic setting, there are case reports of responses with an AI alone and in combination with an LHRH agonist. Although most clinicians favor the combination in this setting, and this is supported by biologic data, it is acceptable to start with an AI alone and follow closely.

ELDERLY PATIENTS

There has been a dramatic increase in breast cancer in older adults in the United States, with an expected increase to 72 million adults older than age 65 by 2030. Since more than one-half of all breast cancer diagnoses occur among older women, there is an expectation that this population will become more prevalent in the realm of oncologic care. The current life expectancy of a 70-year-old woman is 17.5 years, which is sufficient time for a high-risk breast cancer to recur. An assessment of comorbidities is essential, since more than 50% of patients older than age 50 have at least one comorbidity, and this percentage increases to 66% among patients older than age 75. Comorbidities are independent predictors of worse survival; however, among healthy elderly women, newer chemotherapy regimens, given without dose reduction, impart the same relative benefit as in younger women.[360] Older women can be more susceptible to some toxicities associated with chemotherapy. Hematologic toxicity is more common, often leading to dose reductions of chemotherapy, which may compromise outcome. Women older than age 65 have a 26% higher risk of congestive heart failure associated with anthracycline use.[361] An adequate interpretation of chemotherapy benefit among high-risk elderly women is difficult to make given that women older than age 65 comprise 8% of enrollment in clinical trials. The CALGB 49907 trial randomly assigned 633 women older than age 65 to receive adjuvant therapy with capecitabine compared with AC or CMF.[362] Two-thirds of the women were older than age 70, and 5% were older than age 80. The standard regimens of AC and CMF were associated with a 50% lower risk of recurrence or death compared with the *less toxic* oral capecitabine regimen. These data continue to support the benefit of standard chemotherapy in healthy elderly women who do not have substantial comorbidities.

PHYLLODES TUMOR

Phyllodes tumors of the breast are similar to fibroadenomas in that they contain both stromal and epithelial components. They are classified as benign, borderline, or malignant. Their prognosis depends largely on the status of surgical margins after resection. The greatest risk of recurrence is local, although metastasis can occur, primarily to the lungs. The primary treatment of a phyllodes tumor is surgical—either with excision or mastectomy, with both requiring generous negative margins (> 1 cm). ALND is not indicated, neither is routine adjuvant systemic therapy or radiotherapy. Because this tumor acts primarily like a stromal malignancy, options for the treatment of metastatic disease can be based on therapies for soft-tissue sarcomas.

KEY POINTS

- The treatment of male breast cancer is extrapolated from information about female breast cancer, with tamoxifen as the preferred agent for adjuvant endocrine therapy.
- There are limited data supporting the use of AIs for the treatment of metastatic disease in men.
- Performance status and comorbidities, but not age, should be the deciding factors for adjuvant therapy recommendations for male breast cancer.

SURVEILLANCE AND SURVIVORSHIP

With the increasing ability to detect earlier-stage breast cancer and the greater efficacy of adjuvant therapy, more women with breast cancer are expected to live long and prosperous lives following their diagnosis and treatment. Consequently, surveillance plans and survivorship issues play a large role in ongoing patient care. The primary goal of surveillance after completion of adjuvant therapy is to detect a new and curable cancer at an early stage (Table 7-9). Routine history and physical examinations and annual mammographic screening are important features of follow-up. ASCO recommendations for surveillance include a history and physical exam every 3 to 6 months for the first 3 years, then every 6 months for the next 2 years, then annually.[363] When breast conservation is used for local therapy, mammographic imaging of the affected breast should occur about 6 months after the completion of radiation therapy (which is often approximately 1 year after diagnosis) and then continue annually once mammographic stability is observed. There are no good data to support supplementary breast imaging in most breast cancer survivors, with exceptions being in women with hereditary breast cancer syndromes or those who had significant medical radiation exposure.

Table 7-9 **ASCO Recommendations for Follow-up Care of Patients with Primary Breast Cancer**

Mode of Surveillance	Summary of Recommendations
Recommended breast cancer surveillance	
History/physical examination	Every 3 to 6 months for the first 3 years after primary therapy; every 6 to 12 months for years 4 and 5; then annually
Patient education regarding symptoms of recurrence	Physicians should counsel patients about the symptoms of recurrence, including new lumps, bone pain, chest pain, abdominal pain, dyspnea, or persistent headaches; helpful websites for patient education include www.cancer.net and www.cancer.org
Referral for genetic counseling	Criteria include Ashkenazi Jewish heritage; history of ovarian cancer at any age in the patient or any first- or second-degree relatives; any first-degree relative with a history of breast cancer diagnosed before age 50; two or more first- or second-degree relatives diagnosed with breast cancer at any age; patient or relative with diagnosis of bilateral breast cancer; and history of breast cancer in a male relative
Breast self-examination	All women should be counseled to perform monthly breast self-examination
Mammography	First posttreatment mammogram 1 year after the initial mammogram that leads to diagnosis but no earlier than 6 months after definitive radiation therapy; subsequent mammograms should be obtained as indicated for surveillance of abnormalities
Coordination of care	Continuity of care is encouraged and should be performed by a physician experienced in the surveillance of patients with cancer and in breast examination, including the examination of irradiated breasts; if follow-up is transferred to a primary care physician (PCP), the PCP and the patient should be informed of the long-term options regarding adjuvant hormone therapy for the particular patient; this may necessitate referral for oncology assessment at an interval consistent with guidelines for adjuvant hormone therapy
Pelvic examination	Regular gynecologic follow-up is recommended for all women; patients who receive tamoxifen should be advised to report any vaginal bleeding to their physicians
Breast cancer surveillance testing: not recommended	
Routine blood tests	Complete blood counts and liver-function tests are not recommended
Breast MRI	Breast MRI is not recommended for routine breast cancer surveillance; MRI may be considered on an individual basis for high-risk women
Systemic imaging studies	Chest x-ray, bone scans, liver ultrasound, computed tomography (CT) scans, and fluorodeoxyglucose positron-emission tomography (FDG-PET) scans are not recommended
Tumor markers	CA 15-3, CA 27-29, and carcinoembryonic antigen testing are not recommended

The use of nonbreast imaging, tumor markers, or laboratory tests among asymptomatic patients has not been found to be beneficial and has been shown to adversely affect quality of life and increase downstream healthcare utilization.[364] Despite this, these tests, unfortunately, are commonly utilized in clinical practice. Most breast cancer recurrences are often identified between office visits; therefore, it is crucial to focus on patient education concerning signs and symptoms of disease recurrence. Once symptoms occur, appropriate imaging should be performed. The surveillance time should also be used to ensure that appropriate referrals for genetic counseling are made. Screening for second primary cancers among patients with genetic risks should occur, as outlined in the previous section on Screening.

Clinical outcomes have been shown to be identical when patients continue their posttreatment surveillance with either their oncologist or primary care provider. This emphasizes the need to understand other women's health issues in addition to breast cancer. Understanding potential long-term complications of treatment is also important. Chemotherapy-

induced amenorrhea or ovarian suppression can result in the onset of menopausal symptoms at an earlier-than-expected age. Hot flashes can often be controlled with venlafaxine or gabapentin, whereas the use of intravaginal estrogens to improve vaginal dryness and sexual dysfunction requires ongoing discussions with patients. Intravaginal DHEA has recently been demonstrated to be another option for treating vaginal dryness/dyspareunia.[365] The use of AIs can adversely affect bone density, which should be closely monitored. Awareness of potential cardiac toxicity from anthracyclines and trastuzumab may require the involvement of cardiologists. Focusing on good health activities, such as exercise and maintaining a normal BMI, appear to favorably impact the risk of disease recurrence. Cognitive dysfunction associated with cancer therapy is a subject of ongoing investigation. The psychosocial ramifications following the diagnosis and treatment of breast cancer cannot be minimized and may require ongoing support and therapy. In 2016, ASCO and the American Cancer Society developed a comprehensive set of guidelines that extend beyond cancer surveillance recommendations to further address symptom management, surveillance and management of late toxicities of cancer therapy, and general wellness (weight management, nutrition, activity, etc.) recommendations.[366]

KEY POINTS

- A complete history and physical examination with annual mammography is the primary schedule of disease monitoring after the completion of therapy.
- Anthracyclines and trastuzumab are associated with a risk of cardiac toxicity.
- AIs are associated with decreased bone density.
- Chemotherapy can result in premature amenorrhea, resulting in menopausal symptoms such as hot flashes, vaginal dryness, and sexual dysfunction.

Acknowledgments

The following authors are acknowledged and graciously thanked for their contribution to prior versions of this chapter: Lisa A. Carey, MD; Beth Overmoyer, MD; and Eric Winer, MD. The authors recognize the contributions of colleagues who have provided thoughtful review and content for this chapter, including Judy Boughey, MD; Robert Mutter, MD; Kathryn Ruddy, MD; Matthew Goetz, MD; Deborah Rhodes, MD: and Amy Connors, MD. They furthermore recognize the reviewers for their effort and critical feedback to enhance the chapter, as well as Ms. Vicki Shea for her secretarial assistance in the preparation of the chapter.

LUNG CANCER

Jonathan W. Riess, MD, MS, and David R. Gandara, MD

Recent Updates

- Important advances in immunotherapy for lung cancer continue to occur. The U.S. Food and Drug Administration (FDA) approved the anti–programmed cell death 1 (PD-1) antibody pembrolizumab for the treatment of advanced non-small cell lung cancer (NSCLC) as first-line treatment for NSCLC that harbors PD-1 ligand (PD-L1) expression ≥ 50%. (Reck M, *N Engl J Med* 2016)
- The ALK inhibitor alectinib was approved, on the basis of high response rates and prolonged progression-free survival, for the treatment of advanced ALK-rearranged NSCLC after disease progressed while being treated with crizotinib. (Larkins E, *Clin Cancer Res* 2016)

OVERVIEW

An estimated 222,500 new cases of lung cancer were expected in 2017, leading to approximately 155,870 deaths.[1] Although lung cancer accounts for approximately 13% of all cancer diagnoses, it is responsible for about 26% of all cancer deaths. Thus, unlike with breast, colon, and prostate cancers, most patients (about 84%) who are diagnosed with lung cancer will die of the disease. Lung cancer is the leading cause of cancer deaths for both men and women.[2] More women die of lung cancer each year than of breast, cervical, and uterine cancers combined; indeed, nearly twice as many women in the United States die from lung cancer than from breast cancer. More men die annually of lung cancer than of colorectal and prostate cancers combined. The incidence and death rates from lung cancer have been decreasing for men, and these numbers were rising for women until about 2000 and have since been leveling off.

The major cause of lung cancer is smoking. Numerous epidemiologic and laboratory studies, as well as in vitro data, have tied the present pandemic of lung cancer to the carcinogenic effects of tobacco smoke. Some data suggest that women with lung cancer who smoke and who are undergoing hormone-replacement therapy experience a less favorable outcome than those who are not undergoing such therapy.[3]

The incidence of lung cancer, although declining for both white and black men, is approximately 20% higher for black men.[2] Race-related variances in lung cancer, however, are complicated by differences in socioeconomic status, which are associated with disparities in smoking rates, types of cigarettes smoked, and exposures to inhaled agents in the workplace. In the United States, the most common form of lung cancer was squamous cell cancer until approximately 1987, when it was supplanted by adenocarcinoma. Small cell lung cancer once accounted for approximately 20% of all lung cancers, but its incidence has been declining, as

has large cell histology.[4]

KEY POINTS

- Lung cancer is the most common cause of cancer-related deaths in the United States for both men and women, and most patients (approximately 84%) will die of the disease.
- The epidemiology of lung cancer in the United States is changing somewhat, with a decrease in the incidence among men but an increase in women over the past 25 years, which has been leveling off since 2000. There also is a decrease in large cell and small cell histologic subtypes with an increase in the proportion of adenocarcinoma for both men and women.

ETIOLOGY

Cigarette smoking is the most common cause of lung cancer and is responsible for approximately 85% of all cases. Other risk factors include occupational or environmental exposure to substances such as arsenic, chromium or nickel, radon, air pollution, radiation, and environmental (secondhand) tobacco smoke.

The risk of lung cancer among cigarette smokers increases with the number of cigarettes smoked and the duration of smoking history—the latter of which is a stronger risk factor than the number of cigarettes smoked per day. A tripling of the number of cigarettes smoked per day is estimated to triple the risk of lung cancer, whereas a tripling of the duration of smoking is estimated to increase the risk 100-fold.[5] Of note, moderate- to high-intensity smoking (defined as ≥ 10 cigarettes per day) has dramatically declined in the United States since the 1960s.[6] The risk of lung cancer decreases with smoking cessation, and it approaches that of the nonsmoking population after 10 to 15 years of abstinence. However, one study among women reported that even after 30 years, the risk was not as low as for the population who had never smoked.[7] It is estimated that approximately half of all lung cancers in the United States occur in former smokers. The risks associated with e-cigarettes and their role in controlling tobacco use still require clarification.[8]

Passive smoking also is a risk factor; the risk of lung cancer for nonsmoking spouses of cigarette smokers is approximately 20 to 30% higher than the risk for nonsmoking spouses of nonsmokers.[5] It has been estimated that approximately 25% of lung cancer cases among never-smokers are caused by exposure to environmental tobacco smoke.[5] Nevertheless, data on molecular profiling of cancers from never-smoking patients show a very different pattern of abnormalities from those associated with smoking (*p53* and certain *KRAS* mutations), with a high incidence of mutations in the epidermal growth factor receptor (EGFR) or anaplastic lymphoma kinase (ALK) fusions, as described in this chapter. These data suggest that the proportion of patients with lung cancer attributed to secondhand smoke may have been overestimated.[9]

Cigarette smoke contains thousands of constituents, many of which are carcinogenic. Two of the major classes of nicotine-related inhaled carcinogens include the polycyclic aromatic hydrocarbons and *N*-nitrosamines, which are metabolized to nitrosamine ketone and *N*′-nitrosonornicotine. Both compounds are activated by the cytochrome P450 enzyme system and exert carcinogenic effects through the formation of DNA adducts. The distribution of

benzo(a)pyrene diol epoxide adducts along the exons of the *TP53* gene occurs preferentially in codons 157, 248, and 273, which are the same mutational hot spots of *TP53.* Nitrosamine ketone has been postulated to be one factor that leads to the increased incidence of adenocarcinomas, because it predominantly induces these tumors in mice.[5]

Smoking causes each of the four major subtypes of lung cancer, although the dose–response relationship is steepest with small cell lung cancer. Indeed, small cell lung cancer is a disease that is found almost exclusively in smokers. Although adenocarcinoma in situ (AIS) is more likely to develop in nonsmokers than the other subtypes of lung cancer, smoking is still the major risk factor for this form of the disease.

Cigar smoking also is associated with an increased risk of lung cancer, although the risk is not as high as with cigarette smoking, most likely because cigar smokers do not inhale as deeply as do cigarette smokers. Similarly, risks related to pipe smoking also are lower because of differences in smoking frequency and depth of inhalation. Light cigarettes provide no benefit compared with other cigarettes; the lower tar and nicotine numbers on light cigarette packs and in advertisements are misleading because the low tar and nicotine levels recorded on smoking machines are artificial.[10]

Radon is a naturally occurring, chemically inert gas that is a decay product of uranium. The relative risk of lung cancer is increased for underground miners who are exposed to high levels of radon. For underground miners who smoke, the risk may exceed 10 times the risk for a nonsmoking miner. The relationship between indoor residential radon exposure and lung cancer risk is less well defined, although it is estimated that 2 to 10% of lung cancers may be caused by exposure to residential radon.[11] Exposure to asbestos combined with smoking acts to increase the risk of lung cancer. High doses of radiation also have been associated with an increased risk of lung cancer. For example, an increased risk has been observed for patients with breast cancer, as well as for long-term survivors of Hodgkin and non-Hodgkin lymphomas, particularly if patients continue to smoke after completing radiation therapy.

KEY POINTS

- Most cases of lung cancer (85%) are caused by carcinogens in tobacco smoke; a small percentage of cases are caused by passive smoking or exposure to radon, radiation, or other chemicals.
- Host differences may account for different susceptibilities to lung cancer.

HOST FACTORS

Genetic susceptibility to lung cancer has been postulated based on the fact that cigarette smoking causes lung cancer in a minority of people who smoke. Because many carcinogens in tobacco smoke are metabolized by the cytochrome P450 system—such as the polycyclic aromatic hydrocarbons—differences in subtypes or polymorphisms of these enzymes have been proposed as one mechanism of lung cancer risk. Other factors that may increase risk for some individuals include differences in glutathione *S*-transferase, an enzyme that detoxifies reactive metabolites of polycyclic aromatic hydrocarbons, and enzymes that modulate DNA repair capacity.

Epidemiologic studies have shown that a family history of lung cancer is a predictor of

increased risk. Familial aggregation of lung cancer has led to the hypothesis that there is a genetic susceptibility for lung cancer.[12] This may be related to inherited differences in carcinogen metabolism and activation and also to DNA repair capacity. For example, leukocyte DNA adduct levels have been associated with the risk of lung cancer, with an odds ratio (OR) of 1.86 (95% CI; 0.88, 3.93), particularly for never-smokers (OR, 4.04; 95% CI; 1.06, 15.42).[13] Germline polymorphisms in genes with products that activate (cytochrome P450 1A1 *[CYP1A1])* or detoxify (glutathione *S*-transferases M1 *[GSTM1]* and T1 *[GSTT1])* chemical carcinogens found in tobacco smoke have been associated with a risk of lung cancer from environmental tobacco smoke that is substantially greater than the risk for individuals who are heterozygous or homozygous carriers of the wild-type *GSTM1* allele.[14] However, some of the results from these studies are conflicting, suggesting that particular polymorphisms may predict increased risks in specific ethnic populations, limiting generalizability. Thus, germline polymorphisms should not be used to predict an individual person's lung cancer risk or for screening purposes. Genomewide association studies (GWAS) have identified the N allele of the D398N polymorphism of the nicotinic acid/acetylcholine receptor as well as polymorphisms in the reverse transcriptase component of telomerase (TERT) as potential increased risk factors for lung adenocarcinoma.[15] However, these results must also be interpreted with caution because the GWAS studies were not based on a functional hypothesis and therefore these alterations may not represent "drivers" of carcinogenesis.

The R331W missense mutation in *YAP1* was identified as a germline risk allele for lung adenocarcinoma, increasing the odds ratio of lung adenocarcinoma 5.9-fold. The *YAP1* oncogene plays an important role in the Hippo pathway, binding and activating many transcription factors that contribute to tumorigenesis.[16] The EGFR-T790M mutation, most frequently associated with resistance to EGFR–tyrosine kinase inhibitor (TKI), can also be present less frequently *de novo* and as a germline risk allele for lung cancer.[17] Detection of tumor EGFR-T790M before treatment with EGFR-TKI can be used to screen for familial EGFR-T790M and lead to suitable patients being referred for genetic counseling.[18]

Additional factors associated with increased lung cancer risk include previous lung damage, such as chronic obstructive pulmonary disease, and fibrotic disorders that restrict lung capacity, such as pneumoconiosis. Diets deficient in vitamins A and C and beta-carotene intake also have been associated with increased risk, whereas fruit and vegetable consumption may be weakly protective.

Preclinical evidence has suggested that higher dietary intake of retinol is associated with a decreased risk of lung cancer. Based on this evidence, three double-blind, placebo-controlled chemoprevention trials were conducted with beta-carotene, vitamin A, or one of their derivatives. A protective effect against lung cancer was not observed in any of the studies. Rather, beta-carotene supplementation was associated with an increased risk of lung cancer among high-risk populations of heavy smokers in two of the three trials.[19-21]

PATHOLOGY

More than 95% of lung cancers consist of one of the four major histologic types: squamous, adenocarcinoma, large cell, or small cell. Small cell lung cancer has scant cytoplasm, small hyperchromatic nuclei with a fine chromatin pattern, and indistinct nucleoli with diffuse sheets of cells, whereas non-small cell lung cancer (NSCLC) has abundant cytoplasm, pleomorphic nuclei with a coarse chromatin pattern, prominent nucleoli, and glandular or squamous architecture. Other subtypes, which are rare and therefore less well studied, include carcinoid, large cell

cancer with neuroendocrine features, and large cell neuroendocrine cancer.[22] Extremely rare primary tumors in the lung include sarcomas, cancers with sarcomatoid or sarcomatous elements (e.g., giant cell cancer, carcinosarcoma, pulmonary blastoma), and cancers of the salivary gland type (e.g., mucoepidermoid cancer, adenoid cystic cancer).

Adenocarcinoma, large cell cancer, and squamous cell cancer are collectively known as NSCLC. They exhibit differences in sensitivity to chemotherapy and radiation therapy when compared with small cell cancer, which is described in detail later in this chapter. Other clinical differences between small cell cancer and non-small cell cancer include the more rapid clinical course of small cell lung cancer and the enhanced association of small cell lung cancer with paraneoplastic syndromes and neuroendocrine features on pathologic examination. Adenocarcinoma in situ (AIS; discussed in the following section) is a subtype of adenocarcinoma that has received considerable attention because of its tendency to occur in women and in never-smokers.

PREINVASIVE LESIONS

Squamous Dysplasia

Squamous dysplasia may be mild, moderate, or severe, depending on the severity of the atypia and the thickness of the abnormality within the bronchial epithelium. There is increasing interest in using squamous dysplasia as an indicator of heightened risk when identifying patients for participation in chemoprevention studies.

Atypical Adenomatous Hyperplasia

Atypical adenomatous hyperplasia is considered a precursor to adenocarcinoma and is usually identified incidentally, often at the time of resection. The lesions are typically small (a few millimeters) and consist of discrete but ill-defined bronchoalveolar proliferation in which the alveoli are lined by monotonous, slightly atypical cuboidal to low-columnar epithelial cells. Their prognostic significance is unclear.

NON-SMALL CELL LUNG CANCER

Although the natural history of the subtypes of NSCLC differs somewhat when assessed on a stage-by-stage basis, histologic subtype is not a significant prognostic indicator. However, histologic subtype now has an influence on treatment selection, based on different chemosensitivity and safety profiles of squamous and nonsquamous tumors. Immunohistochemical (IHC) staining can help differentiate histology.

Adenocarcinoma

Adenocarcinoma is the most common histologic subtype in the United States and appears to be on the rise, although the reason for this is unknown. It accounts for more than 50% of all NSCLCs, has been associated with scarring, is more likely to be peripherally located than squamous cell or small cell cancer, and tends to metastasize frequently. It consists of four subtypes: acinar, papillary, AIS, and solid with mucus formation. Lung adenocarcinoma typically stains positive for cytokeratin 7 (CK7) and negative for cytokeratin 20 (CK20). The majority (but not all) of pulmonary adenocarcinomas also stain positive for thyroid transcription factor 1 (TTF-1).[23]

AIS (formerly known as “bronchioloalveolar cancer”) is defined as an adenocarcinoma of the

lung that grows in a lepidic fashion along alveolar septae. In the 1999 World Health Organization/International Association for the Study of Lung Cancer (WHO/IASLC) classification, the lack of invasive growth was added as an essential criterion because data suggested that surgical resection might cure disease in such patients. Histologically, pure AIS is rare; more common is adenocarcinoma, mixed subtype, with both AIS features and invasive components. The tumor typically presents in one of two forms: mucinous or nonmucinous. Mucin-producing tumors (30 to 40%) tend to be multicentric and TTF-1–negative and rarely harbor sensitizing *EGFR* mutations. Nonmucinous tumors (50 to 60%) tend to be solitary and TTF-1–positive and have high rates of *EGFR* mutations. This form of lung cancer develops in never-smokers more than the other subtypes. Although the prognosis is excellent for patients with small, solitary nonmucinous tumors, the prognosis for patients with advanced AIS is comparable with prognoses for other lung adenocarcinomas. Of note, small lesions discovered on screening computed tomographic (CT) scans, which are commonly found to have a “ground glass” appearance, are often AIS. The current staging classification is presented in Table 8-1.[24,25]

Table 8-1 **Definitions for Tumor-Node-Metastasis (TNM) Descriptors**[24]

T (Primary Tumor)	
TX	Primary tumor cannot be assessed, or tumor proven, by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma *in situ* Squamous cell carcinoma *in situ* (SCIS) Adenocarcinoma in situ (AIS): adenocarcinoma with pure lepidic pattern, ≤3 cm in greatest dimension
T1	Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1mi	Minimally invasive adenocarcinoma: adenocarcinoma (≤3 in greatest dimension) with a predominantly lepidic pattern and ≤5 mm invasion in greatest dimension
T1a	Tumor ≤1 cm in greatest dimension. A superficial, spreading tumor of any size whose invasive component is limited to the bronchial wall and may extend proximal to the main bronchus also is classified as T1a, but these tumors are uncommon.
T1b	Tumor >1 cm but ≤2 cm in greatest dimension
T1c	Tumor >2 cm but ≤3 cm in greatest dimension
T2	Tumor >3 cm but ≤5 cm or having any of the following features: • Involves the main bronchus regardless of distance to the carina, but without involvement of the carina • Invades visceral pleura (PL1 or PL2) • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung T2 tumors with these features are classified as T2a if ≤4 cm or if the size cannot be determined and T2b if >4 cm but ≤5 cm.
T2a	Tumor >3 cm but ≤4 cm in greatest dimension
T2b	Tumor >4 but ≤5 cm in greatest dimension
T3	Tumor >5 cm but ≤7 cm in greatest dimension or directly invading any of the following: parietal pleura (PL3), chest wall (including superior sulcus tumors), phrenic nerve, parietal pericardium; or separate tumor nodule(s) in the same lobe as the primary
T4	Tumor >7 cm or tumor of any size invading one or more of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; separate tumor nodule(s) in an ipsilateral lobe different from that of the primary
N (Regional Lymph Node)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M (Distant Metastasis)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial effusion. Most pleural (pericardial) effusions with lung cancer are a result of the tumor. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and not an exudate. If these elements and clinical judgement dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging descriptor.
M1b	Single extrathoracic metastasis in a single organ (including involvement of a single nonregional node)
M1c	Multiple extrathoracic metastases in a single organ or in multiple organs

Squamous Cell Cancer

Squamous cell cancers account for approximately 25% of all NSCLCs. These lesions tend to be located centrally and are more likely to cavitate than other histologic types. Squamous cell cancers, which most often arise in segmental bronchi and involve lobar and mainstem bronchi by extension, are recognized by the histologic features of intercellular bridging, squamous pearl formation, and individual cell keratinization. Squamous cell lung cancer often overexpresses squamous histology marker p63 and its isoform p40 as well as CK5/6.[26]

Large Cell Cancer

Large cell cancers account for approximately 10% of all lung cancers, and its incidence is

declining. These tumors are typically poorly differentiated and are composed of large cells with abundant cytoplasm and large nucleoli.

SMALL CELL LUNG CANCER

In the 1999 WHO/IASLC classification, small cell cancer is divided into two subtypes: so-called pure small cell lung cancer and combined histology lung cancer—the latter of which consists of elements of both non-small cell and small cell lung cancers. Histologically, the tumor is characterized by small cells with scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli. Nuclear molding and smearing of the nuclear chromatin may be present owing to crush artifact. Mitotic figures are common, and necrosis can be extensive. On electron microscopy, the cells may appear to have neuroendocrine granules. Neuroendocrine markers such as chromogranin and synaptophysin are frequently overexpressed.[27] Clinically, these tumors tend to be centrally located, are often found submucosally, and are more commonly associated with paraneoplastic syndromes. Because of the rapid growth and proliferation of these tumors, the clinical course tends to be more rapid than that of NSCLC. However, small cell lung cancers also are more responsive to both chemotherapy and radiation therapy, although resistance usually develops. Small cell lung cancer is on the spectrum of neuroendocrine cancers that consists of typical and atypical carcinoid, large cell, and small cell primary lung tumors.

OTHER PULMONARY NEUROENDOCRINE TUMORS

The normal lung contains neuroendocrine cells, although their significance is unclear. Neuroendocrine lung tumors represent a spectrum of pathologic entities, including typical carcinoid, atypical carcinoid, and large cell neuroendocrine cancer. Small cell lung cancer and large cell neuroendocrine cancer are high-grade neuroendocrine tumors, whereas typical carcinoid and atypical carcinoid are low and intermediate grades, respectively. Neurosecretory granules, particularly chromogranin A and synaptophysin, often are seen on electron microscopy. The presence of chromogranin, synaptophysin, and CD56 (neural cell adhesion molecule [NCAM]) may be detected by IHC. Approximately 20 to 40% of patients with both typical and atypical carcinoids are nonsmokers, whereas virtually all patients with small cell lung cancer and large cell neuroendocrine cancer are cigarette smokers.

Carcinoid Tumors

Carcinoid tumors are low-grade malignant neoplasms of neuroendocrine cells, which are divided into typical and atypical types, with the latter possessing more malignant histologic and clinical features. Surgery is the primary treatment for typical carcinoid tumors. The prognosis is excellent for patients with typical carcinoids.

Compared with typical carcinoids, atypical carcinoids tend to be larger, have a greater number of mitoses, and are associated with necrosis. Patients also are more likely to have distant metastases at presentation, and survival is significantly reduced.

Large Cell Neuroendocrine Cancer

Large cell neuroendocrine cancer is a high-grade, non-small cell neuroendocrine cancer. These tumors are characterized by histologic features similar to small cell cancer but are formed by larger cells. Large cell neuroendocrine cancer is defined as a tumor with neuroendocrine

morphologic characteristics, including organoid nesting, palisading, a trabecular pattern, and rosette-like structures. A mitotic count of 11 mitoses or more per 2 mm^2 is the main criterion for separating large cell neuroendocrine cancers and small cell lung cancers from atypical carcinoid tumors. The mitotic rates are usually high for both large cell neuroendocrine cancers and small cell lung cancers, with an average of 70 to 80 mitoses per 2 mm^2. Large cell neuroendocrine cancers are separated from small cell lung cancers by using the criteria listed in Table 8-2.[28]

Table 8-2 Characteristics of Large Cell Neuroendocrine Tumors That Distinguish Them from Small Cell Lung Cancers[28]

▪ Larger cell size
▪ Abundant cytoplasm
▪ Prominent nucleoli
▪ Vesicular or coarse chromatin
▪ Polygonal rather than fusiform shape
▪ Less prominent nuclear molding
▪ Less conspicuous DNA encrustation of blood vessel walls

Large cell cancers with neuroendocrine morphology are tumors that resemble large cell neuroendocrine tumors on light microscopy but lack proof of neuroendocrine differentiation on electron microscopy or IHC. The significance of this histology is unknown.

The prognosis for patients with large cell neuroendocrine cancer is worse than that for patients with atypical carcinoid and classic large cell cancer. Five-year survival is 21% for patients with large cell neuroendocrine cancer, 65% for atypical carcinoid, and 90% for typical carcinoid.[28]

KEY POINTS

- Preinvasive lung cancer lesions include squamous dysplasia and atypical adenomatous hyperplasia.
- Unlike other lung cancers, AIS occurs more commonly in never-smokers, is seen in men and women with the same frequency, and is associated more commonly with *EGFR* mutations than other types of lung cancer.
- Pulmonary neuroendocrine tumors represent a spectrum of neoplasms characterized by the presence of neurosecretory granules on electron microscopic evaluation and a distinct immunohistochemical phenotype.

BIOLOGY

Paradigm-changing studies have shifted the perspective on NSCLC from being considered a single disease or a few histology-based subgroups to the current concept of a large number of molecularly defined subtypes (Fig. 8-1) of variable prevalence.[29] Also, publications from The

Cancer Genome Atlas effort and other groups have revealed the impressive complexity of lung cancer, as demonstrated by both interpatient and intrapatient tumor heterogeneity.[30,31] Guidelines for molecular testing have been issued by multiple organizations, including the International Association for the Study of Lung Cancer, the American Society of Clinical Oncology, and the National Comprehensive Cancer Network (NCCN). All recommend concurrent testing for *EGFR* mutations, *ALK* translocations, and *ROS1* translocations in lung adenocarcinoma, large cell carcinoma, and NSCLC not otherwise specified (NSLC-NOS), with a turnaround time of less than 2 weeks. In addition, NCCN recommends broad molecular profiling to identify other molecular alterations that could be matched to potential targeted treatment either as an off-label use or as part of a clinical trial (Current NCCN Guidelines Reference).[32] Molecular testing including broad molecular profiling and testing for *EGFR* mutations, *ALK* translocations, and *ROS1* translocations should also be considered in squamous cell histology, particularly for patients who are never-smokers or light smokers, have small biopsy specimens, or have mixed histology.[33]

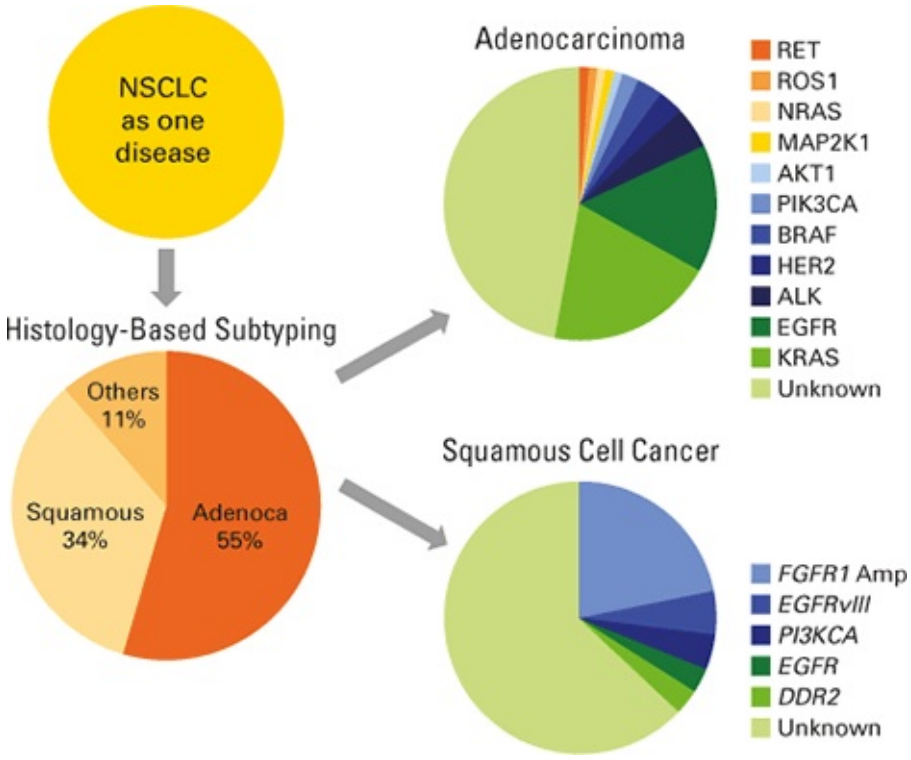

Fig. 8-1 Evolution of non-small cell lung cancer (NSCLC) subtyping from histologic- to molecular-based.[21]

Abbreviations: Adenoca, adenocarcinoma; EGFR, epidermal growth factor receptor; MAP2K1, mitogen- activated protein kinase kinase 1.

Adapted from Li T, Kung HJ, Mack PC, et al. Genotyping and genomic profiling of non-small-cell lung cancer: implications for current and future therapies. J Clin Oncol. *2013;31:1039–1049.*

The most common and clinically relevant molecularly defined subtypes found in non-squamous NSCLC are described in Fig. 8-1. Identifying actionable molecular drivers in squamous histology NSCLC is ongoing and is the subject of several clinical trials, including the Squamous Lung Master Protocol (LUNG-MAP).[34]

EPIDERMAL GROWTH FACTOR RECEPTOR

EGFR belongs to the HER/erbB family of growth factor receptors, which includes EGFR (HER1 or erbB1), HER2/neu (erbB2), HER3 (erbB3), and HER4 (erbB4). These cell-surface proteins

consist of an extracellular ligand-binding domain, a transmembrane structure, and an intracellular tyrosine kinase domain. The binding of ligand to receptor activates receptor dimerization and tyrosine kinase autophosphorylation, initiating a cascade of intracellular events and leading to increased cell proliferation, angiogenesis, metastasis, and a decrease in apoptosis. Inappropriate activation of this receptor-signal transduction pathway can be caused by ligand or receptor over expression, receptor mutation, binding of intracellular ligands, or dimerization with other receptors (heterodimerization or "receptor crosstalk") (Fig. 8-2).[35]

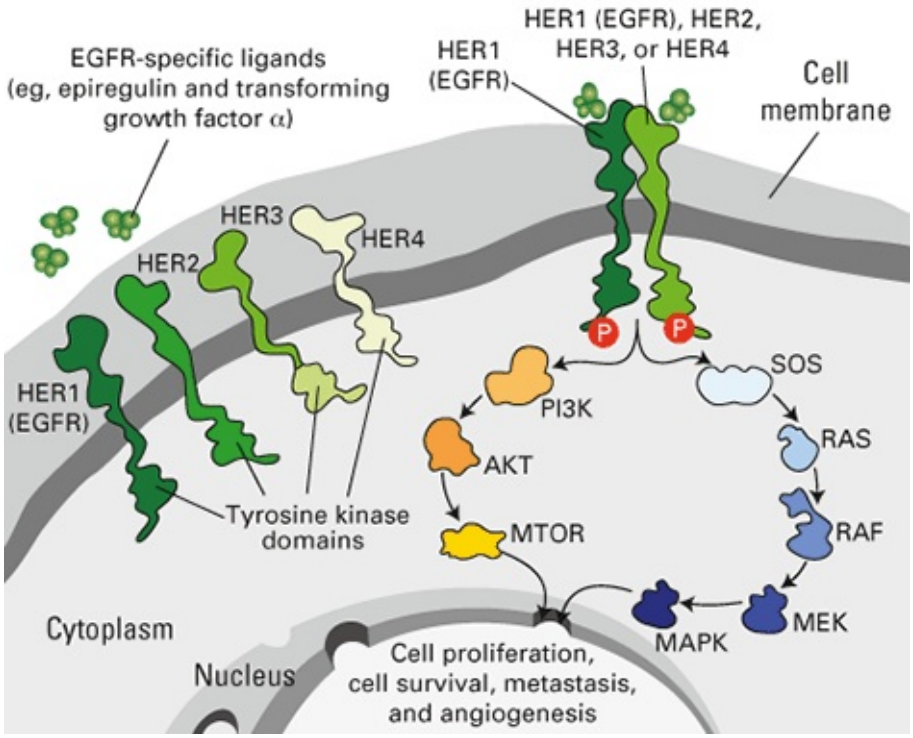

Fig. 8-2 Epidermal growth factor receptor (EGFR) signaling pathways.

Shown in the left portion of the figure are the four members of the ERBB (or HER) family of receptors. All four members of this family have tyrosine kinase domains in the cytoplasmic portion of the receptor. However, the tyrosine kinase domain of HER3 does not have catalytic activity. The right portion of the figure shows that binding of ligands to the HER family of receptors induces either homodimerization or heterodimerization of the receptors. Dimerization results in phosphorylation of the tyrosine residues of the EGFR kinase domain. The activated receptor may then phosphorylate a wide array of intracellular signaling cascades, such as the RAS–RAF–MEK–ERK and PI3K–AKT pathways, that induce cellular proliferation, angiogenesis, and metastases. EGFR amplification can obviate the requirement for ligand-induced dimerization.

Abbreviations: mTOR, mammalian target of rapamycin; P, phosphorylation; SOS, Son of Sevenless.

Overexpression of EGFR (which can be demonstrated by IHC) has been found in as many as 70% of NSCLCs and is an independent negative prognostic factor.[36] However, the most reliable biomarker to predict radiographic response to EGFR inhibitors is the presence of activating *EGFR* mutations. These mutations (detected by gene sequencing) hyperactivate the EGFR, rendering the cancer cell dependent on EGFR for survival and progression. These EGFR-mutant oncogene–addicted tumors are exquisitely sensitive to EGFR-TKIs. At diagnosis, these mutations appear mutually exclusive of *KRAS* and *ALK* aberrations and are associated with certain clinicopathologic features (i.e., females, East Asians, never-smokers or light smokers, and adenocarcinoma histology, especially nonmucinous AIS).

In NSCLC, activating mutations occur in the EGFR tyrosine kinase domain, centered around exons 18 to 21. Mutations in exons 19 and 21 (termed "classic" *EGFR* mutations) account for

approximately 90% of *EGFR* mutations. Exon 19 mutations are most commonly in-frame deletions of amino acids 747 to 750. Exon 21 mutations are characteristically L858R substitutions. The presence of *EGFR* mutations is both prognostic and predictive. Activating *EGFR* mutations are also associated with improved response to both conventional chemotherapy in general and EGFR-TKIs in particular. In NSCLC cases harboring classic *EGFR* mutations, EGFR-TKIs yield RRs over 60%—compared with RRs of approximately 10% in wild-type *EGFR* cases.

ANAPLASTIC LYMPHOMA KINASE

The *ALK* gene, which encodes a tyrosine kinase, was originally identified in a subset of anaplastic large cell lymphomas with a t(2;5)(p23;q35) translocation. In a rare subset (2 to 7%) of cases of NSCLC, chromosome 2p inversion results in fusion of the protein encoded by the echinoderm microtubule-associated protein-like 4 *(EML4)* gene with the intracellular signaling portion of the ALK receptor tyrosine kinase. Analogous to *EGFR* mutations, *EML4-ALK* fusions result in constitutive tyrosine kinase activity, dependence of the cancer cell on activated downstream mitogenic pathways, and sensitivity to ALK inhibition.[37]

Other genetic aberrations involving the *ALK* gene have been identified in anaplastic large cell lymphomas, inflammatory myofibroblastic tumors, and neuroblastomas. Efficacy of ALK inhibitors such as crizotinib or ceritinib for treatment of some of these other conditions highlights the increasing recognition that a tumor's molecular characteristics—and not anatomic site or histology—may ultimately guide treatment selection in oncology.[38]

The terms *"ALK* positivity," *"ALK* rearrangement," *"ALK* fusion," and *"ALK* translocation" are essentially synonymous and refer to the presence of the *EML4-ALK* translocation. Despite the rarity of this molecular aberration, because of the vast number of lung cancer cases worldwide, an estimated 40,000 such cases occur annually.[39] Similar to *EGFR* mutations, *EML4-ALK* translocations are associated with certain clinicopathologic features.[40,41] These include never or light smoking; adenocarcinoma histology (especially signet-ring subtype), and younger age. In contrast to *EGFR* mutations, *ALK* translocations do not appear to have a clear association with patient sex or race/ethnicity. *ALK* translocations are typically mutually exclusive of *EGFR* and *KRAS* mutations, though they sometimes can occur together, usually in the setting of acquired resistance to crizotinib.[42]

ALK rearrangements can be identified using IHC, fluorescence in situ hybridization (FISH), or polymerase chain reaction assay. Of these, FISH appears to be the most clinically applicable, although dual IHC and FISH may increase the detection of these cases, and IHC alone is being used more frequently.[41] *EML4-ALK* FISH employs differently labeled break-apart (split signal) probes on the 5′ and 3′ ends of the *ALK* gene. Normal *ALK* generates a fused (yellow) signal, while *ALK* rearrangements appear as separate red and green signals. The standard cutoff for a positive result is a split signal in more than 15% of cells examined.[43]

KRAS

RAS proteins are a family of guanine nucleotide–binding proteins that play an important role in the intracellular-signaling pathway. In response to the interaction between tyrosine kinase receptors and their ligands, RAS becomes activated in the triphosphate form, which leads to a cascade of downstream events responsible for the regulation of cell cycle and apoptosis, including the RAF-1/mitogen-activated protein kinase pathway and the RAC/RHO pathway. If mutated, the protein products of the mutated genes remain in an active state, resulting in a

continuous “on” signal that causes uncontrolled cell growth.

KRAS mutations, which occur primarily in exons 12, 13, and 61, are found mainly among patients with lung adenocarcinomas (approximately 25%) and in smokers. At diagnosis, they are typically mutually exclusive of *EGFR* mutations and *ALK* translocations. *KRAS* mutations have been associated with a poor prognosis and resistance to EGFR inhibitors.[44,45] Their effect on anti-EGFR monoclonal antibody therapy in NSCLC is not clear.

ROS1

ROS1 gene rearrangements are oncogenic drivers present in about 2% of NSCLC tumors.[46] ROS1 is an orphan tyrosine kinase of the insulin receptor family located on chromosome 6 and with sequence homology to *ALK.* Gene rearrangements of *ROS1* lead to constitutive activation of this tyrosine kinase. Like many oncogene-addicted lung cancers, *ROS1*-rearranged tumors commonly arise in young nonsmokers with lung adenocarcinoma histology. In addition to being an ALK and MET inhibitor, crizotinib is a potent inhibitor of ROS1 and has impressive activity in lung cancers with *ROS1* gene rearrangements, as evident from an exceptionally high overall RR (approximately 72%) and median progression-free survival (PFS) (19.2 months).[47]

RET

RET-gene fusions have been identified in 1 to 2% of NSCLCs.[48] Patients whose tumors harbor *RET* fusions can respond to RET inhibitors such as cabozantinib.[49] Clinical trials with *RET* inhibitors for patients with the *RET*-fusion gene are underway.

HER2

HER2 mutations have been described in about 1 to 2% of NSCLCs. *HER2* can be amplified in lung cancer as it is in breast cancer, but the *HER2* mutations found in NSCLC are distinct from *HER2* amplification and most commonly are insertions in exon 20.[50] Responses to afatinib among patients with HER2-mutated lung cancer have been documented.[51]

BRAF

BRAF mutations are present in 2 to 4% of lung adenocarcinomas. Unlike *EGFR* mutations and *ALK* rearrangements, *BRAF*-mutant lung adenocarcinoma is typically associated with patients who have been smokers.[52] Unlike melanoma, in which the majority of *BRAF* mutations are V600E, only about half of the *BRAF* mutations in NSCLC are V600E. Lung adenocarcinomas with *BRAF* V600E mutations can be sensitive to BRAF inhibitors either alone or in combination with downstream inhibition of MEK-ERK. In the phase II trial of the *BRAF V600E* inhibitor dabrafenib combined with the MEK inhibitor trametinib, the overall response rate (ORR) was 63% and the 12-week disease control rate (DCR) 88%.[53] Outcomes were better with combined *BRAF V600E* and MEK inhibition than inhibition of *BRAF V600E* with dabrafenib alone, which resulted in a lower, but still substantial, 32% ORR and 56% 12-week DCR.[54]

MET

MET exon 14 skipping mutations represent approximately 2.5% of NSCLCs and are higher in frequency in the rare sarcomatoid histology of NSCLC (~20 to 30% frequency). These juxtamembrane splice-site mutations lead to decreased MET degradation and appear to be

potent oncogenic drivers. Tumor responses to MET inhibitors such as crizotinib have been observed.

OTHER MUTATIONS

The paradigm of treatment of NSCLC has shifted over the past several years from a uniform chemotherapy approach to the identification and targeting of "actionable" driver mutations. This has led to the approval of EGFR tyrosine kinase inhibitors for first-line treatment of patients who have lung cancer with EGFR-activating mutations and of crizotinib for treatment of patients with *ALK and ROS1* rearrangements. Molecular profiling of 1000 patients with lung adenocarcinoma has identified other mutations that are being targeted in other clinical trials.[55] Mutations in *PIK3CA, Akt,* and others have also been documented. Research is ongoing to determine whether these mutations are oncogenic drivers and to match such mutations to effective targeted therapeutics.

LIQUID BIOPSIES FOR GENOMIC TESTING

Increasingly, liquid biopsies for genomic testing are being employed for molecular analyses of NSCLCs. Genomic testing is performed on blood using various nucleic acid sequencing methods examining a single gene of interest or an oncopanel of genes such as digital droplet polymerase chain reaction (ddPCR), BEAMing, real-time PCR, or next-generation sequencing of an oncopanel of genes. This examination of circulating tumor DNA (ctDNA) differs from examining whole circulating tumor cells because DNA shed in the blood is examined whether or not it is still contained in a tumor cell in the bloodstream.

The cobas real-time PCR test is approved by the U.S. Food and Drug Administration (FDA) in both tissue and plasma for the detection of the two most common EGFR-activating mutations (EGFR exon 19 and EGFR L858R) as well as EGFR-T790M (the most common resistance mutation to first- and second-generation EGFR-TKI (erlotinib, gefitinib, afatinib).

Broader genomic profiling of ctDNA using next-generation sequencing methods that examine multiple genes important in lung cancer (*EGFR, ALK, ROS1, BRAF,* etc.) is also sometimes used when tissue is insufficient or tissue biopsy for molecular testing is impractical.

A positive blood test is generally specific for the presence of the molecular aberration, and outcomes in EGFR-mutant NSCLCs have been shown to be similar whether the mutation was detected in tissue or plasma; however, a negative test should be interpreted with caution and followed by a tissue biopsy to more conclusively determine the presence or absence of the genomic aberration in question, particularly when there are approved therapies available such as osimertinib for acquired resistance to EGFR-TKI in the presence of an EGFR-T790M mutation.[56]

ANGIOGENESIS

Bevacizumab, a monoclonal antibody to vascular endothelial growth factor (VEGF), has been approved for the treatment of patients with nonsquamous histology in combination with carboplatin/paclitaxel for first-line treatment of NSCLC (see section on Non-Small Cell Lung Cancer Treatment).[57] Numerous previous randomized, phase III trials had not shown a benefit of VEGF receptor (VEGFR) TKIs when given in combination with chemotherapy.[58,59] However, one phase III trial showed improvement in overall survival (OS), PFS, and RR for patients with NSCLC treated with the VEGFR2 antibody ramucirumab when combined with docetaxel for

patients with progressive NSCLC during or after platinum-based chemotherapy.[60]

The major issues limiting the use and effect of antiangiogenic therapies are safety considerations and lack of predictive biomarkers. Bevacizumab and other antiangiogenic agents are associated with a distinct toxicity profile that reflects effects on normal vasculature and includes bleeding, clotting, hypertension, wound healing complications, gastrointestinal perforation, and proteinuria. The mechanisms of these adverse events are diverse and not fully understood. Bleeding may be a result of vascular endothelial cell apoptosis or tumor detachment from blood vessels in response to VEGF-directed therapy.[61,62] Hypertension is thought to arise from reduced nitric oxide production because of VEGF inhibition, which promotes vasoconstriction.[63] Proteinuria may be a result of disruption of glomerular endothelial integrity or by glomerular basement membrane damage caused by hypertension.[64]

The identification of markers predictive of benefit from anti-VEGF monoclonal antibodies and VEGFR-directed TKIs has proven elusive. Emerging but unproven biomarkers include tumor microvessel density, serum VEGF, soluble VEGFR2 and VEGFR3, intracellular adhesion molecule and other angiogenic and inflammatory markers, VEGF and VEGFR polymorphisms, circulating endothelial cells, noninvasive imaging of perfusion and oxygenation, and development of on-treatment hypertension.[65-69]

TUMOR SUPPRESSOR GENES

The *TP53* tumor suppressor is the most frequently mutated gene in cancer and is found in more than 50% of tumors. In lung cancer, loss of one *TP53* allele on chromosome 17p13 and mutational inactivation of the other allele occurs in more than 75% of small cell lung cancers and in 50% of NSCLCs. Although *TP53* mutations are common among patients with lung cancer, their prognostic significance is unclear.

LKB1 is another tumor suppressor inactivated or mutated in NSCLC. Inactivation of LKB1 is present in about 19% of cases of squamous cell lung cancer and 34% of lung adenocarcinoma. Inactivating mutations of *LKB1* contribute to lung cancer initiation, differentiation, and metastases.[70]

GENOMIC/PROTEOMIC PROFILING

Progress in the techniques for identifying proteins and genes over- and underexpressed in lung tumors has resulted in the ability to molecularly profile a tumor. For example, microarray techniques that profile the expression of thousands of genes can, in theory, simultaneously identify genetic signatures that may be able to identify patients with a favorable or unfavorable prognosis or patients likely to respond to a given therapy. A number of these genetic signatures have been described, but they have not been validated as predictive markers in prospective clinical trials.[71-75] It is also now possible to perform next-generation sequencing of hundreds of genes. This broad genomic profiling offers the opportunity to identify potential oncogenic drivers to treat with FDA-approved drugs or match to a clinical trial. Some current guidelines recommend broad genomic profiling beyond *EGFR* mutations; *ALK* and *ROS1* rearrangements are used to try to identify additional molecular alterations.[32] Caution must be exercised, in interpretation of this vast amount of genomic data. When “passenger” rather than “driver” mutations are targeted, treatment may be inferior to standard of care systemic therapy. Increasingly, institutions are adopting “Molecular Tumor Boards” to interpret this vast amount of data in a multidisciplinary fashion.

LUNG CANCER IMMUNOBIOLOGY

The past several years have seen a tremendous acceleration in our understanding of the immune microenvironment of lung cancer and translation of this understanding to the development of immunotherapies to treat advanced lung cancer. The most promising avenue of investigation has been the development of immune checkpoint inhibitors: monoclonal antibodies that overcome immune inhibition that tumors can exploit to prevent the immune system from attacking the tumor. See Chapter 4: Principles of Immuno-Oncology and Biologic Therapy for mechanistic details regarding the immune system and cancer.

KEY POINTS

- The most readily targeted molecular abnormalities associated with lung cancer are driver oncogenes, currently best represented by *EGFR* mutations and *ALK* and *ROS1* translocations. In contrast, targeting loss of tumor suppressor genes such as *p53* and *RB* has proven much more difficult. Although antiangiogenic therapy with bevacizumab and ramucirumab has proven active in NSCLC, at present these agents are employed in a "nontargeted" fashion, without the benefit of well-defined predictive biomarkers.
- Guidelines recommend concurrent testing for *EGFR* mutations and *ALK* and *ROS1* translocations, particularly in lung adenocarcinoma, large cell histology, and NSCLC not otherwise specified and with strong consideration for testing for never-smokers and light smokers with squamous cell histology, small biopsy samples, or mixed histology with a turnaround time of less than 2 weeks.
- Broad genomic profiling to identify molecular aberrations such as *HER2* insertions, *BRAF* mutations, and *RET* gene fusions among others that can be matched to clinical trials with targeted therapies should also be considered.

CLINICAL PRESENTATION

Most patients with lung cancer present with symptomatic disease (Table 8-3). The most common symptoms are anorexia, fatigue, weakness, and cough. Patients with AIS may have bronchorrhea (large quantities of foamy sputum) and shortness of breath out of proportion to radiographic findings.

Table 8-3 Symptoms Associated with Lung Cancer	
Typical	▪ Cough
	▪ Increased production of sputum
	▪ Shortness of breath
Common	▪ Fatigue
	▪ Weight loss
	▪ Anorexia
	▪ Low-grade fever
Less Common	▪ Chest pain (usually from a pleural-based lesion)
	▪ Hemoptysis
	▪ Hoarseness (secondary to laryngeal-nerve involvement)
	▪ Bone pain
	▪ Pleural effusion
Infrequent	▪ Signs and symptoms consistent with obstruction of the superior vena cava, superior sulcus, or Pancoast tumors
	▪ Pericardial tamponade
	▪ Paraneoplastic syndromes
	▪ Signs and symptoms consistent with brain metastases

Metastatic disease at presentation is common in small cell lung cancer (75%) and adenocarcinoma (50%), and many metastatic sites are possible, with brain, bone, liver, and adrenal gland being the most common sites of metastatic disease.[76] Liver and bone marrow metastases develop in approximately 20 to 30% of patients, and brain metastases occur in over 20%.[77,78]

Paraneoplastic syndromes are caused by humoral factors produced by cancer cells that act at a site distant from both the primary site and its metastases or by cross-reactivity between host antitumor antibodies and normal tissues.[79] For all paraneoplastic syndromes, treatment of the underlying cancer is recommended. Additionally, syndrome-specific therapies may be employed. The two most common paraneoplastic syndromes among patients with NSCLC are hypercalcemia and hypertrophic pulmonary osteoarthropathy. Although hypercalcemia is most often caused by diffuse skeletal metastases, it can be the result of ectopic production of a parathyroid hormone–related peptide or other humoral substances. Excessive production of corticotropin may result in Cushing syndrome with excess cortisol production, resulting in muscle weakness, weight loss, hypertension, hyperglycemia, and profound hypokalemia. This syndrome is most commonly found in small cell lung cancer. As a result of the rapid tumor growth, the classical physical stigmata of Cushing syndrome are often absent.

Small cell lung cancer also is associated with paraneoplastic neurologic abnormalities.

Central nervous system (CNS) paraneoplastic disorders include cerebellar degeneration, dementia, limbic encephalopathy, Lambert–Eaton syndrome, and visual paraneoplastic syndrome with optic neuritis and retinopathy.

Cerebellar degeneration is characterized by progressive cerebellar dysfunction with ataxia, dysarthria, hypotonia, and dementia. This syndrome is associated with four different antineuronal antibodies, the most common being an antibody against Purkinje cell proteins. Limbic encephalopathy is characterized by progressive dementia, hallucinations, depression, agitation, anxiety, or similar disturbances. Paraneoplastic sensory neuropathy often is caused by an anti-Hu antibody and is associated with subacute distal sensory loss and the absence of deep tendon reflexes with normal muscle strength. Anti-Hu is a circulating polyclonal immunoglobulin G that reacts with CNS neurons as well as the dorsal root and trigeminal ganglia. It can be associated with encephalopathy, autonomic neuropathy, and cerebellar degeneration.

Lambert–Eaton syndrome occurs in less than 1% of patients. It is caused by onconeural antibodies targeting presynaptic calcium channels and is characterized by proximal muscle weakness. Unlike with myasthenia gravis, muscle strength tends to improve with repeated activity.

KEY POINTS

- Common symptoms of lung cancer include local symptoms, such as cough and shortness of breath, and constitutional symptoms, such as fatigue, weakness, anorexia, and weight loss.
- The most common sites for metastatic disease in lung cancer are the lungs (both ipsilateral and contralateral), adrenal glands, liver, bone, and brain.
- Patients with lung cancer may present with a number of paraneoplastic syndromes.

SCREENING

Most patients with lung cancer present with advanced disease, raising a question about the role of screening to detect these tumors at an earlier and theoretically more curable stage (Fig. 8-3). The three screening interventions for lung cancer that have been explored include chest x-ray, cytologic analysis of sputum, and low-dose spiral CT. Although the role of screening patients at high risk for the development of early-stage disease was debated for many years, CT-based screening has been found to demonstrate a reduction in lung cancer mortality.

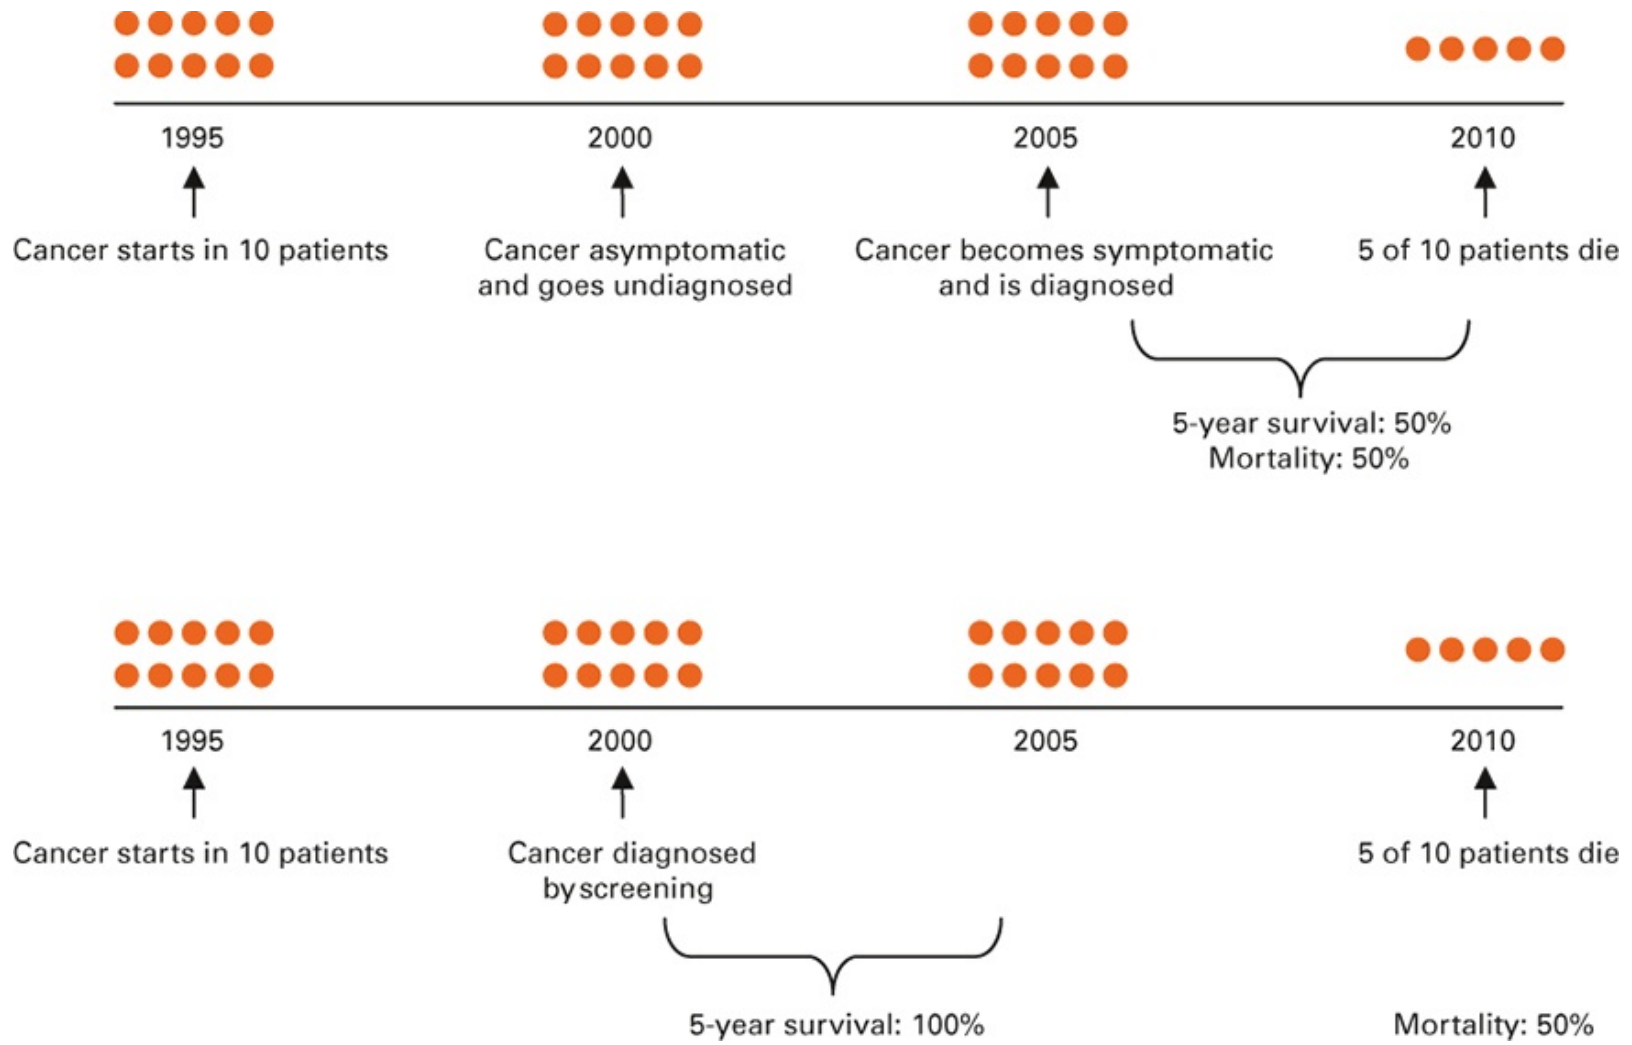

Fig. 8-3 Lead-time bias and its effects on survival and mortality rates.

Low-dose, noncontrast, thin-slice, helical or spiral CT is a scan in which only the pulmonary parenchyma is examined, negating the use of intravenous contrast medium and the necessity of a physician's presence. This type of scan can usually be done quickly (within one breath) and involves low doses of radiation. In a nonrandomized, controlled study from the Early Lung Cancer Action Project, low-dose CT was shown to be more sensitive than chest x-ray for detecting lung nodules and lung cancer in early stages.[80]

The National Lung Screening Trial (NLST) was a randomized multicenter study comparing low-dose helical CT scans with chest x-ray for the screening of older current and former heavy smokers for early detection of lung cancer.[81] From 2002 to 2004, more than 50,000 high-risk individuals from 33 U.S. centers were randomly assigned to three annual screenings with single-view posteroanterior chest x-ray or low-dose CT. The study enrolled individuals between ages 55 and 74 who had at least a 30 pack-year smoking history (former smokers needed to have quit within the previous 15 years). Individuals with a prior lung cancer diagnosis, hemoptysis, unexplained weight loss of more than 15 pounds, or chest CT within 18 months before enrollment were excluded. The rate of screening adherence exceeded 90%. The rate of positive screening tests was 24% with CT and 7% with chest x-ray. However, in both arms, there was a false-positive rate of 93 to 96%. There were 247 deaths from lung cancer per 100,000 person-years in the CT group and 309 deaths per 100,000 person-years in the chest x-ray group, corresponding to a 20% relative reduction in lung cancer mortality ($p = 0.004$). CT was also associated with a 6.7% reduction in all-cause mortality ($p = 0.02$). Based on these data from the NLST trial, the U.S. Preventive Services Task Force issued recommendations for

lung cancer screening with low-dose CT for patients ages 55 to 80 who had a smoking habit of 30 pack-years or more and who are currently smoking or had quit within the past 15 years. Although the NLST showed for the first time that CT-based screening reduced lung cancer mortality, numerous questions regarding implementation, cost, associated biomarkers to identify patients with high-risk disease and management of false-positive test results remain and will be important topics for future studies (Table 8-4).[82]

KEY POINTS

- Interpretation of screening studies requires an understanding of length-time bias, lead-time bias, overdiagnosis, and the distinction between survival and mortality.
- The NLST, which randomly assigned individuals with high-risk disease to three annual helical CT scans or chest x-rays, was the first study to demonstrate a 20% relative reduction in lung cancer mortality and a 6.7% relative reduction in all-cause mortality.
- In the NLST, there was a 24% rate of positive screening tests with helical CT, of which 96% were non–lung cancer diagnoses. The optimal means by which to implement screening and evaluate positive screening tests are not yet known.

Table 8-4 **Points about Screening for Lung Cancer to Share with Patients**[81,82]
▪ Results from observational studies of CT screening among patients at high risk (i.e., those with a history of heavy smoking) indicate a high rate of diagnosis of lung cancer in stage I (a relatively curable stage).
▪ CT screening reveals many noncalcified nodules, only a small fraction of which will be found to be lung cancer. The patient must be prepared to live with this uncertainty and must be able to commit to frequent follow-up scans.
▪ Costly invasive procedures that are associated with serious risks may be required to evaluate some nodules.
▪ Despite these considerations, the National Lung Screening Trial, which randomly assigned approximately 50,000 high-risk individuals to annual chest x-ray or low-dose spiral CT scan for 3 years, demonstrated a 20% reduction in lung cancer mortality with CT-based screening.
▪ A diagnostic workup should be done by physicians who are experienced in such evaluation.
▪ The selection of a facility with physicians who are experienced and credentialed in multidisciplinary fields (including thoracic surgery, pathology, and pulmonology) is critical to an optimal outcome.
▪ The most effective way for smokers to improve their health is to stop smoking.

PROGNOSTIC FACTORS

Prognostic factors predict a patient's outcome independently of treatment. Favorable prognostic factors for both NSCLCs and small cell cancers include stage, performance status (PS), lack of substantial weight loss (loss of < 5%), and female sex. Age is not an independent prognostic factor; fit older patients tend to fare as well as their younger counterparts. Further, older patients with good PS generally fare better than younger patients with poor PS. Histologic subtype also is not an independent prognostic factor for NSCLC, although adenocarcinoma is more likely to metastasize earlier than squamous cell carcinoma. However, once metastasized, these two histologies have similar prognoses.

PREDICTIVE FACTORS

Predictive factors forecast how a patient will fare with treatment. In lung cancer, *EGFR* mutation status is useful for predicting which patients are likely to derive the most benefit from EGFR-TKIs, particularly responses and improved time to progression.[83]

PREOPERATIVE EVALUATION FOR NSCLC

The suitability of a patient for a definitive resection depends on two factors: the stage of the

lesion and the ability of the patient to withstand surgery. A detailed discussion of the preoperative evaluation and comorbid conditions are beyond the scope of this chapter; however, assessment of pulmonary reserve is discussed here.

MEDICAL ASSESSMENT OF PULMONARY RESERVE

Preoperative evaluation for a thoracotomy starts with spirometry. General guidelines are described here, although it should be emphasized that a certified general thoracic surgeon, working as part of a multidisciplinary thoracic oncology team, is best qualified to determine whether a patient is a surgical candidate. The forced vital capacity is the value that has been used most commonly to assess suitability for surgery; a predicted postoperative forced vital capacity of less than 1 L or a preoperative value of less than 2 L for a pneumonectomy or less than 1.5 L for a lobectomy usually suggests that the patient is at risk for perioperative complications. Diffusion capacity should be measured if there is concern that the forced vital capacity may not be adequate or that the patient has signs or symptoms of interstitial lung disease. A low diffusion capacity (< 50% of predicted) suggests an increased risk of postoperative morbidity or mortality.

Pulmonary status should be optimized as much as possible before surgery. Treatment of bronchitis with antibiotics, bronchodilators, and/or oral corticosteroids is helpful. The patient should quit smoking, if applicable, and preoperative training with incentive spirometry and weight reduction should be considered when appropriate.

KEY POINTS

- Prognostic factors predict how a patient is likely to fare, regardless of which treatment is used. Positive clinical prognostic factors for lung cancer include stage of disease, PS, lack of substantial weight loss, and female sex.
- Predictive factors forecast how a patient is likely to fare with a specific treatment. For instance, *EGFR* mutations predict for higher RR and longer PFS with EGFR-TKIs.

NON-SMALL CELL LUNG CANCER

STAGING

The current (8th edition) tumor–node–metastasis (TNM) staging system of the American Joint Committee on Cancer (AJCC) is based on an analysis of more than 94,000 cases of lung cancer internationally (Tables 8-1 and 8-5). Key changes include several modifications to T and M descriptors, including changes to tumor size cutoffs and additional designations for metastatic spread (M1a if contralateral lung and effusions, M1b if single extrathoracic metastases, M1c if multiple extrathoracic metastases in more than one organ). Certain stage groupings have also changed, reflecting the importance of size of the primary tumor to prognosis. It should be noted that a great majority of cases analyzed were surgical, regardless of stage, and that some stage changes reflect a selected database.[84]

Table 8-5 **Staging Groups by TNM Elements**			
	Descriptors		
Stage Groups	T	N	M
Occult Carcinoma	X	N0	M0
0	Tis	N0	M0
IA1	T1mi, T1a	N0	M0
IA2	T1b	N0	M0
IA3	T1c	N0	M0
IB	T2a	N0	M0
IIA	T2b	N0	M0
IIB	T1a, T1b, T1c, T2a, T2b, T3	N1	M0
IIIA	T1a, T1b, T1c, T2a, T2b	N2, N3	M0
IIIA	T4	N0, N1	M0
IIIB	T1a, T1b, T1c, T2a, T2b	N3	M0
IIIB	T3, T4	N2	M0
IIIC	T3, T4	N3	M0
IVA	Any T	Any N	Any M1a
IVA	Any T	Any N	Any M1b
IVB	Any	Any	M1c
Clinical Stage (5-year Survival)		Pathological Stage (5-year Survival)	
IA1	92%	IA1	90%
IA2	83%	IA2	85%
IA3	77%	IA3	80%
IIB	68%	IB	73%
IIA	60%	IIA	65%
IIB	53%	IIB	56%

OBTAINING A DIAGNOSIS

The diagnosis of lung cancer is most commonly made through cytologic or histologic evaluation of specimens obtained by transbronchial biopsy or percutaneous needle biopsy. Although the disease is usually discovered on chest x-ray, CT of the chest and upper abdomen is necessary to evaluate the extent of the primary disease, mediastinal extension, or lymphadenopathy, as well as the presence or absence of other parenchymal nodules in patients for whom surgical resection is a consideration. Positron-emission tomography (PET) scans are helpful primarily in detecting distant metastases, although they also assist in defining tumor size and in defining N2 stations appropriate for subsequent pathologic confirmation of cancer involvement. If a PET scan is done as part of the staging workup, a bone scan does not need to be performed. CT or magnetic resonance imaging (MRI) of the head is recommended for patients who are to be

treated with curative intent or for those with signs or symptoms suggestive of brain metastases.

Mediastinal nodal metastasis is a critical factor in determining tumor resectability (Table 8-1 and Fig. 8-4).[85,86] Mediastinoscopy has long been considered the gold standard for mediastinal staging and has been recommended for mediastinal lymph nodes larger than 1 cm on CT, even if they are not 18-fluorodeoxyglucose (FDG)–avid on PET. Patients with a normal mediastinum on CT whose lymph nodes also appear negative on a PET scan may not need to undergo preoperative mediastinoscopy, although the lymph nodes still must be sampled at the time of thoracotomy. The use of other techniques, including endobronchial ultrasound (EBUS) should be considered prior to definitive treatment (surgery or chemoradiation) for patients with a lower probability of mediastinal disease (CT and/or PET negative but with central mass or positive N1 nodes).

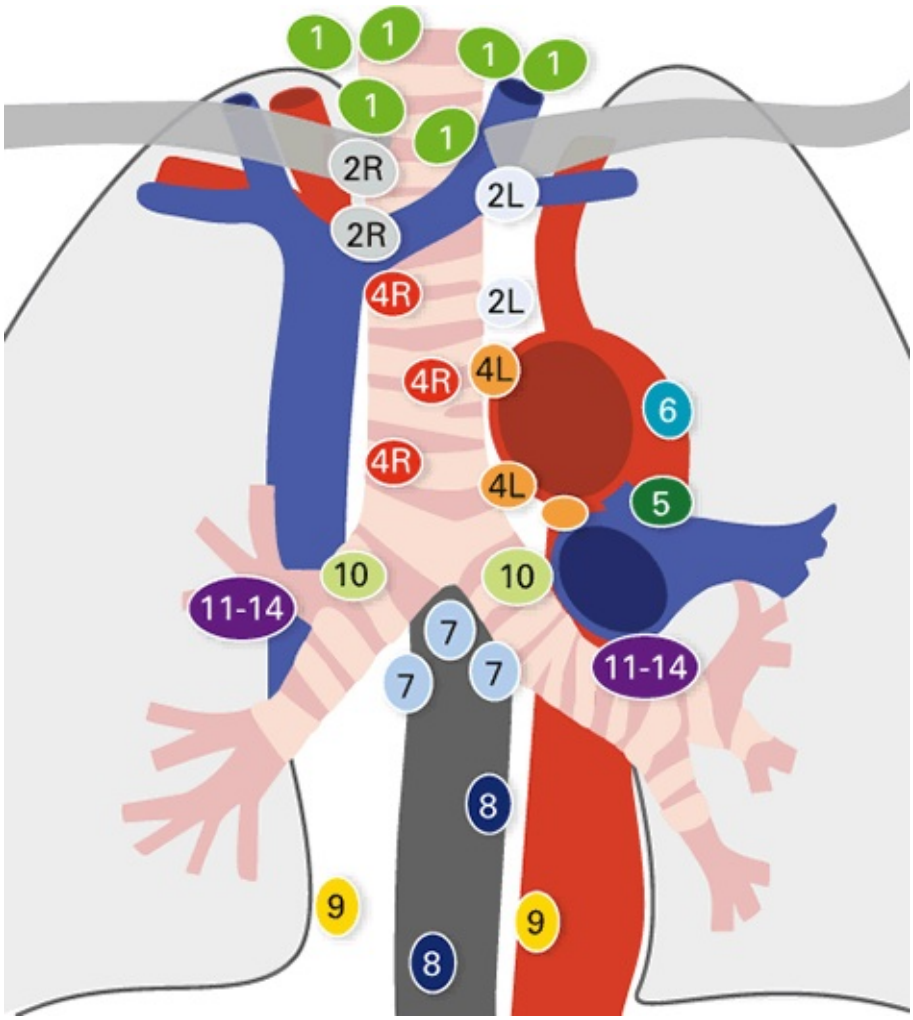

Fig. 8-4 Regional lymph node classification.

Supraclavicular nodes *1. Low cervical, supraclavicular and sternal notch nodes:* From the lower margin of the cricoid to the clavicles and the upper border of the manubrium. The midline of the trachea serves as border between 1R and 1L. **Superior mediastinal nodes 2 to 4** *2R. Upper paratracheal:* From the upper border of manubrium to the intersection of the caudal margin of innominate (left brachiocephalic) vein with the trachea. 2R nodes extend to the left lateral border of the trachea. *2L. Upper paratracheal:* From the upper border of manubrium to the superior border of aortic arch. 2L nodes are located to the left of the left lateral border of the trachea. *3A. Prevascular:* Nodes are not adjacent to the trachea, as are the nodes in Station 2, but they are anterior to the vessels. *3P. Prevertebral:* Nodes are not adjacent to the trachea, as are the nodes in Station 2, but behind the esophagus, which is prevertebral. *4R. Lower paratracheal:* From the intersection of the caudal margin of the innominate (left brachiocephalic) vein with the trachea to the lower border of the azygos vein. 4R nodes extend from the right to the left lateral border of the trachea. *4L. Lower paratracheal:* From the upper margin of the aortic arch to the upper rim of the left main pulmonary artery. **Aortic nodes 5 and 6** *5. Subaortic:* These nodes are located in the aortopulmonary window lateral to the ligamentum arteriosum. These nodes are not located between the aorta and the pulmonary trunk but lateral to these vessels. *6. Paraaortic:* These are ascending aorta or phrenic nodes lying anterior and lateral to the ascending aorta and the aortic arch.

Inferior mediastinal nodes 7 to 9 *7. Subcarinal. 8. Paraesophageal:* Nodes below carina. *9. Pulmonary ligament:* Nodes lying within the pulmonary ligaments. **Hilar, lobar, and (sub)segmental nodes 10 to 14**. These are all N1 nodes. *10. Hilar nodes:* These include nodes adjacent to the mainstem bronchus and hilar vessels. On the right, they extend from the lower rim of the azygos vein to the interlobar region; on the left, from the upper rim of the pulmonary artery to the interlobar region.

INVASIVE STAGING IN THE MEDIASTINUM

Accurate staging of the mediastinum is critical for patients with NSCLC to guide optimal therapy. Clinical staging has been shown to differ markedly from pathologic staging at the time of resection.[87] In a review of numerous clinical trials, the performance of transthoracic, transbronchial, and endoscopic ultrasound-guided needle aspirations or biopsies was compared with mediastinoscopy for staging disease in the mediastinum.[87] Transthoracic and endoscopic needle aspirations had similar sensitivities to mediastinoscopies, although the transthoracic and endoscopic ultrasound needle aspirations were generally performed only for patients with enlarged nodes detected by CT, resulting in fewer false-negative results. However, mediastinoscopy has a higher negative predictive value. Mediastinoscopy does not provide access to Stations 5 and 6 lymph nodes (aortopulmonary nodes), which provide lymphatic drainage for the left lung; assessment of these nodes generally requires a Chamberlain procedure (anterior mediastinotomy). EBUS has emerged as an alternative means to evaluate the mediastinum. Thus far, EBUS appears accurate and safe. Although unlikely to completely replace mediastinoscopy, it may reduce the number of these more invasive procedures.[88]

POSITRON-EMISSION TOMOGRAPHY

PET, a metabolic imaging scan using FDG, is more sensitive, specific, and accurate than CT and has been shown to prevent unnecessary invasive procedures and/or “futile thoracotomies” for patients whose disease has been subsequently proven to be at a more advanced stage.[89]

In a prospective study, a standard approach to staging of NSCLC (CT, ultrasound, and bone scan) was compared with PET to determine which approach could more accurately detect metastases in mediastinal lymph nodes and distant sites.[85] Mediastinal involvement was confirmed histopathologically, and distant metastases were confirmed by other imaging tests. The results of PET and CT followed by pathologic staging were compared in a study involving 168 mediastinal nodes in 54 patients.[86] PET had higher sensitivity and specificity than CT in both studies (Table 8-6). However, the limitations of PET include the cost, availability, inability to detect lesions smaller than 8 mm, and lack of specificity, particularly for patients with inflammatory or granulomatous disease. Thus, PET cannot replace pathologic confirmation of malignancy because the scan can yield false-positive results when an inflammatory process is present and false-negative results when low-metabolic lung tumors such as AIS or carcinoid tumors are present.

Table 8-6 **Comparison of Sensitivity and Specificity of PET and CT**

	Sensitivity (%)	Specificity (%)	Accuracy (%)
Detection of Mediastinal Metastases[85]			
PET*	91	86	–
CT	75	66	–
Staging of Mediastinal Disease[86]			
PET	96	93	94
CT	68	65	66

*The sensitivity and specificity of PET for detecting distant metastases were 82% and 93%, respectively.

Despite these problems, preoperative PET (in addition to a conventional workup) has been demonstrated to reduce the number of "futile" thoracotomies, as defined by benign disease, exploratory thoracotomy, pathologic stage IIIA (N2) or IIIB disease, postoperative relapse, or death within 12 months,[90] although it may not affect OS.[91] PET also has been used to detect distant metastases; indeed, it is in this area that some investigators believe PET may have its primary role in staging.[89] Negative results on PET for patients without symptomatic disease probably obviates the need for bone imaging.[89] PET may be useful for judging response to therapy, depending on the clinical context; PET scans done early after treatment have been demonstrated to be better predictors of survival than CT, although these data need to be confirmed in larger trials.[92]

KEY POINTS

- Preoperative evaluation should include determinations of forced vital capacity and a predicted postoperative value, a diffusing capacity, and the maximum oxygen consumption.
- Although PET is more sensitive and specific than CT for staging disease in the mediastinum, it does not replace mediastinoscopy, because of the incidence of false-positive and false-negative results (the one exception may be patients with a normal mediastinum on CT and a normal PET scan).
- PET is useful to guide lymph node biopsy and to evaluate for metastatic disease.
- Mediastinal lymph node sampling, with mediastinoscopy and/or EBUS, should be performed for all patients with enlarged or abnormal nodes detected on either CT or PET.

NON-SMALL CELL LUNG CANCER TREATMENT

Treatment of NSCLC is stage-specific. Within a given stage category, a number of additional relevant factors enter therapeutic decision-making, including histology and molecular profiling

for driver oncogenes. Of course, PS, comorbid conditions, and relevant social factors must also be taken into account.

STAGES I AND II DISEASE

Approximately one-third of all patients with lung cancer present with stage I or II disease. The treatment of choice for fit patients is surgical resection, which can result in cure for many patients. The preferred surgical procedure is lobectomy, although for patients in whom disease crosses a major fissure or involves the proximal mainstem bronchus, pneumonectomy may be required. Lobectomy has traditionally been the procedure of choice, even for patients with small, peripheral lesions, because wedge resections have been shown to be associated with increased local recurrence and decreased survival.[93] Lobectomy should include resection of bronchial, hilar, and selected mediastinal nodes based on published guidelines (at least 4R and 7 for right-sided tumors; at least 5/6 and 7 for left-sided tumors). Research is ongoing regarding the management of the small, ground-glass–appearing lesions discovered on low-dose, non–contrast-enhanced, thin-slice, helical CT. For example, because pure AIS does not feature lymphatic or hematogenous spread, it has been proposed that wedge resection without lymph node dissection may be adequate for localized tumors. For multifocal disease, some centers have performed lung transplantation, albeit with somewhat discouraging outcomes.[94]

For patients with medical contraindications to surgery but with adequate pulmonary function, conventional fractionated radiotherapy (e.g., 6000 cGy, or rads, in 30 fractions of 200 cGy each) results in cure for about 20% of patients. Advances in imaging and radiation delivery have resulted in the use of stereotactic radiation for lung tumors. With this technology, radiation delivery to surrounding normal lung parenchyma is substantially less than that seen with conventional radiotherapy. It is therefore possible to administer much higher, ablative, doses of radiation over a small number of fractions (e.g., up to 2000 cGy per fraction given every 2 to 3 days for three fractions). To date, outcomes with this technique appear promising. In a multicenter, phase II, U.S. trial of patients with medically inoperable stage I NSCLC, the 3-year rate of primary tumor control was 98%, 3-year distant failure rate 22%, 3-year disease-free survival 48%, and 3-year OS 56%.[95]

Stereotactic radiation, which entails radiation to the primary tumor but not to the draining lymph nodes, is considered only for patients with clinical stage I (T1N0M0 or T2N0M0) disease. Because of toxicities, stereotactic radiation is usually not performed when the tumor lies within 2 cm of the proximal bronchial tree. This technique is also usually restricted to tumors less than 5 cm.

In contrast to surgically resected early-stage tumors (see section on Adjuvant Chemotherapy), the role of chemotherapy following radiation therapy for medically inoperable early-stage NSCLC is unclear.

The risk of second lung cancers developing is high (approximately 2 to 3% annually) for patients with resected stage I NSCLC. Vitamin A and one of its derivatives (beta-carotene or *cis*-retinoic acid) have been found to be ineffective as chemopreventive therapy and actually deleterious in current smokers.[19-21] A study of secondary chemoprevention with selenium[96] also did not demonstrate a reduction in the incidence of second primary cancers.[97]

Patients with peripheral chest wall invasion (T3N0; stage IIB) should have an en bloc resection of the involved ribs and underlying lung. Five-year survival rates as high as 50% have been reported.[98]

PANCOAST TUMORS

Pancoast, or superior sulcus, tumors in the upper lobe adjoining the brachial plexus are frequently associated with Horner syndrome (ptosis, miosis, and anhidrosis) or shoulder and arm pain; the latter is caused by rib destruction, involvement of the seventh cervical vertebra or T1 nerve roots, or both. The Southwest Oncology Group (SWOG) intergroup phase II trial involving patients with T3/4N0/1M0 superior sulcus NSCLC established the current standard of care, which consists of cisplatin/etoposide and concomitant radiation therapy 45 Gy followed by attempted surgical resection and then two cycles of consolidation chemotherapy after surgery.[99] Among patients with available surgical specimens, 54 (65%) showed either a complete pathologic response or minimal microscopic disease on pathologic evaluation. The 2-year survival rate was 55% for all eligible patients and 70% for patients who had a complete resection.

Adjuvant Chemotherapy

The rationale for adjuvant chemotherapy for patients with early-stage lung cancer is based on the observation that distant metastases are the most common site of failure following potentially curative surgery. Interest in this treatment strategy grew after publication of a 1995 meta-analysis of more than 4300 patients in which those who received cisplatin-based regimens had an improved survival rate of approximately 5% at 5 years, with borderline statistical significance ($p = 0.08$).[100] Since that time, a number of randomized trials have evaluated the role of adjuvant chemotherapy following surgical resection of early-stage NSCLC (Table 8-7).[101-106] In a pooled analysis of five of these trials, there was a 5.4% absolute survival benefit at 5 years (hazard ratio [HR], 0.89; 95% CI; 0.82, 0.96; $p = 0.005$).[107] The Lung Adjuvant Cisplatin Evaluation study performed an individual patient meta-analysis of the five largest cisplatin-based adjuvant trials (ALPI, BLT, IALT, JBR.10, and ANITA). Importantly, the benefit of adjuvant chemotherapy varied considerably by disease stage. For stage IA NSCLC, adjuvant chemotherapy was associated with a trend toward worse survival (HR for death 1.40; 95% CI; 0.95, 2.06). For patients with stage IB disease, the HR was 0.93 (95% CI; 0.78, 1.10). In the Cancer and Leukemia Group B (CALGB) 9633 trial, patients with stage IB disease were randomly assigned to surgery alone or surgery followed by carboplatin/paclitaxel.[104] In long-term follow-up of this trial, only the subset of patients with tumors 4 cm or larger demonstrated a significant survival difference in favor of adjuvant chemotherapy (HR, 0.69; 95% CI; 0.48, 0.99; $p = 0.04$). The fact that this trial employed a carboplatin-based regimen further confounds interpretation, as cisplatin/paclitaxel was proved superior to carboplatin-paclitaxel in stage IV NSCLC, with a median survival of 9.8 months, versus 8.5 months ($p = 0.0019$).[108] Given these data, whether patients with stage IB disease and tumors 4 cm or larger should be offered adjuvant chemotherapy remains controversial. For patients with resected stage IA NSCLC, there are no supporting data in favor of adjuvant chemotherapy, and some trials and meta-analyses even suggest a detrimental effect. The reason for a potentially negative effect in stage IA disease is speculative.

Table 8-7 **Adjuvant Therapies Following Surgical Resection of Early-Stage Non-Small Cell Lung Cancer**

Study (Stage)*	Treatment	Patients	5-Year Survival (%)	Median Survival	Hazard Ratio	p Value
ECOG 3590 (II-IIIA)[101]	Surgery → radiation therapy vs. postoperative concurrent radiation therapy plus cisplatin and etoposide	242		39 months	0.92	0.56
		246		38 months		
ALPI (I-IIIA)[102]	Surgery vs. postoperative mitomycin, vindesine, and cisplatin	603	51		0.96	0.589
		606	43			
IALT (IB-IIIA)[103]	Surgery vs. postoperative cisplatin and etoposide, or vinca alkaloids	405	40		0.86	0.03
		361	44.5			
CALGB (IB)[104]	Surgery vs. postoperative carboplatin and paclitaxel	172	57		0.83	0.12
		172	59			
NCI-C (IB-II)[105]	Surgery vs. postoperative cisplatin and vinorelbine	241	54		0.80	0.03
		241	69			
ANITA (IB, II, IIIA)[106]	Surgery vs. postoperative cisplatin and vinorelbine	433	43	44 months	0.80	0.017
		407	51	66 months

*These studies used American Joint Commission on Cancer staging prior to 8th edition.

The role of adjuvant chemotherapy for resected stage II NSCLC is well established. In the Adjuvant Navelbine International Trialist Association (ANITA) trial, patients with stage IB to IIIA cancer were randomly assigned to surgery alone or surgery followed by four cycles of cisplatin/vinorelbine.[106] OS was significantly improved at 5 years (51% vs. 43%), although the survival benefit was limited to patients with stage II or IIIA disease. In a pooled analysis of cisplatin-based chemotherapy trials, there was a significant survival benefit (HR, 0.83; 95% CI; 0.73, 0.95) for stage II NSCLC. Accordingly, adjuvant chemotherapy is recommended following complete resection of stage II and stage III NSCLC.

The optimal regimen for adjuvant chemotherapy remains unclear. Almost all studies have employed cisplatin-containing doublets. The principal exception, CALGB 9633, which employed carboplatin/paclitaxel after resection of stage IB disease, did not meet statistical significance for OS (HR, 0.83; 95% CI; 0.6, 1.08; p = 0.12).[104] Whether this result is because of the stage IB population, the relatively small sample size (344 patients), or the chemotherapy regimen is not known. Nevertheless, cisplatin rather than carboplatin is recommended in the adjuvant, potentially curative, setting. Vinca alkaloids and etoposide have most commonly been combined with cisplatin in adjuvant trials. In the International Adjuvant Lung Trial (IALT), patients with resected stage I to IIIA disease were randomly assigned to either observation or chemotherapy (cisplatin plus either etoposide, vinorelbine, vinblastine, or vindesine).[103] Although the study was terminated early because of slow accrual, there was a significant improvement in median survival, disease-free survival, 5-year survival, and 5-year disease-free survival in favor of the chemotherapy arm (HR for survival, 0.86). A randomized trial by the National Cancer Institute of Canada (NCIC JBR.10) randomly assigned 482 patients with stage IB or II disease to postoperative observation or to treatment with vinorelbine and cisplatin. OS was significantly prolonged for the chemotherapy group compared with the observation group (94 months vs. 73 months; HR for death, 0.69; p = 0.04), as was relapse-free survival (not reached vs. 46.7

months; HR for recurrence, 0.60; p < 0.001). Five-year survival rates were 69% and 54% for the two groups, respectively (p = 0.03).[105] Of note, this 15% absolute benefit at 5 years is among the highest in all adjuvant chemotherapy trials across cancer types. In the ANITA trial, 840 patients with postoperative stage I (T2N0), II, or IIIA disease were assigned to surgery alone or surgery followed by cisplatin/vinorelbine. Median survival was 65.8 months in the treatment arm and 43.7 months in the observation arm (HR, 1.264; 95% CI; 1.05, 1.52; p = 0.013). Survival at 2, 5, and 7 years was 68%, 51%, and 45%, respectively, in the treatment arm and 63%, 43%, and 37% in the observation arm. Five-year survival by stages I, II, and IIIA were 62%, 52%, and 42%, respectively, in the treatment arm and 63%, 39%, and 26% in the observation arm.[105]

Efforts to improve on the efficacy of platinum doublet chemotherapy have focused on antiangiogenesis agents and targeted therapies. The ECOG 1505 clinical trial randomly assigned patients with resected early-stage NSCLC to adjuvant platinum-based chemotherapy with or without bevacizumab; bevacizumab added to platinum-based chemotherapy did not improve OS (HR, 0.99; 95% CI; 0.81, 1.21; p = 0.93) or disease-free survival (DFS) (HR, 0.98; 95% CI; 0.84, 1.14; p = 0.75). Median OS was more than 72 months in both cohorts, and no differences in OS or DFS were observed between four different adjuvant cisplatin-based chemotherapy regimens (docetaxel, vinorelbine, gemcitabine, and pemetrexed [pemetrexed in non-squamous cell only]). Though efficacy was comparable, patients with non-squamous cell carcinoma who received pemetrexed had significantly less total grade 3 to 5 toxicity (p < 0.001), vinorelbine was associated with more neutropenia, and gemcitabine was associated with more thrombocytopenia.

There is growing interest in the incorporation of molecularly targeted agents into the treatment of early-stage NSCLC. At this time, however, such an approach cannot be recommended outside a clinical trial. In the NCIC JBR.19 trial, which was terminated early, administration of the EGFR inhibitor gefitinib after resection of stages I to III NSCLC did not improve OS. Surprisingly, a subset analysis of a small number of patients with tumors harboring activating *EGFR* mutations—a population expected to derive particular benefit from such an approach—suggested the possibility of a detrimental effect from gefitinib.[109] In the RADIANT trial, 973 patients with stage IB to IIIA NSCLC were randomly selected to receive erlotinib or placebo for 2 years. In the 161 (16.5%) of patients in RADIANT whose tumors harbored an *EGFR* mutation, a trend toward increased DFS was observed with erlotinib but the change was not statistically significant. Similarly, the use of ALK inhibitors after surgery for advanced disease remains investigational. The ALCHEMIST trial is currently randomly assigning patients with stage IB to IIIA disease with *EGFR* mutations or *ALK* rearrangements to 2 years of adjuvant erlotinib or crizotinib or placebo.[110] The ALCHEMIST trial also has added an immunotherapy arm to see if the addition of a programmed cell death 1 (PD-1) antibody can improve on standard-of-care treatments in the adjuvant setting.

Neoadjuvant Chemotherapy

The potential advantages of neoadjuvant chemotherapy include:

- Improved tolerability when administered before surgery (90% of patients will receive the planned dose preoperatively and 60% postoperatively);
- Micrometastases treated earlier rather than later; and
- Downstaging with chemotherapy that may allow complete resection.

Two small randomized studies published in 1994 raised considerable interest in the role of neoadjuvant chemotherapy.[111,112] In these trials, each of which involved 60 patients, surgery alone was compared with surgery plus preoperative chemotherapy for stage IIIA disease. Both studies found improved survival for patients receiving neoadjuvant chemotherapy, although criticisms of these studies include their small size, imbalances between the two arms, and poor survival in the control arms.

In a larger randomized French trial, preoperative chemotherapy with mitomycin, ifosfamide, and cisplatin plus surgery was compared with surgery alone for 355 patients with resectable stages I (except T1N0), II, and IIIA (including N2) disease. No benefit with neoadjuvant chemotherapy was found.[113] A subset analysis suggested a survival advantage for neoadjuvant chemotherapy for N0 and N1 disease but not for N2 disease. A European intergroup study (Medical Research Council [MRC] LU22/Dutch Society of Physicians for Pulmonology and Tuberculosis [NVALT] 2/European Organisation for the Research and Treatment of Cancer [EORTC] 08012) randomly assigned 519 patients to receive surgery alone or to receive three cycles of platinum-based chemotherapy followed by surgery. There was no evidence of a benefit in survival (HR, 1.02; 95% CI; 0.80, 1.31; p = 0.86).[114]

Although level 1 evidence supports the role of adjuvant chemotherapy, the exact role of neoadjuvant chemotherapy is less clear. Randomized trials have shown that patients tolerate preoperative chemotherapy better, that dose delivery is better, and that a higher percentage of patients complete preoperative compared with postoperative therapy. Nevertheless, one study has demonstrated a survival advantage for preoperative therapy.[115] However, a meta-analysis of the hazard ratio for neoadjuvant chemotherapy in 15 randomized, controlled trials (2385 patients) showed a significant benefit of preoperative chemotherapy on survival (HR 0.87, 95% CI; 0.78, 0.96, p = 0.007) with an absolute survival improvement of 5 percentage points at 5 years (from 40% to 45%) that is comparable to the LACE meta-analysis of adjuvant chemotherapy clinical trials.[116]

KEY POINTS

- Treatment of stages I and II NSCLC involves surgical resection (if the patient is a candidate) or radiation therapy (if the patient is not a surgical candidate).
- Optimal management of Pancoast tumors consists of concurrent chemoradiation followed by surgical resection.
- Adjuvant chemotherapy consisting of a cisplatin-based combination is indicated for patients with stages II and IIIA disease after surgical resection; though controversial, it should be discussed with patients with larger tumors ≥ 4 cm with negative lymph nodes. Cisplatin is the preferred platinum compound in this curative setting because it has been shown to be more effective than a carboplatin-based regimen, even in stage IV disease. Level 1 evidence from randomized trials suggests that the second drug should be vinorelbine or etoposide, although many clinicians extrapolate from the advanced disease setting and use other cisplatin-based doublets as well, which is supported by current NCCN guidelines.

STAGE III DISEASE

Treatment of locally advanced NSCLC is one of the most controversial issues in the management of lung cancer. Treatment options include surgery or radiation therapy for local control plus chemotherapy to enhance local therapy and to control micrometastases. Interpretation of the results of clinical trials involving patients with locally advanced disease has been clouded by a number of issues, including changing diagnostic techniques, different staging systems, and heterogeneous patient populations with tumors that range from nonbulky stage IIIA (clinical N1 nodes with N2 nodes discovered only at the time of surgery or mediastinoscopy) to bulky N2 nodes (enlarged adenopathy clearly visible on chest x-rays or involvement of multiple node levels) to clearly inoperable stage IIIB disease.

For some subsets of stage IIB (T3N0), IIIA (T3N1), or IIIA (T4N0±1) tumors, the outcome may be less related to the potential of micrometastatic disease and more to the location of the tumor and its resectability (e.g., superior sulcus, chest wall, proximal airway). For each location, a determination must be made on the basis of the potential of surgical resectability and the likelihood of distant metastases, as evidenced by mediastinal metastases.

Nonbulky Stage IIIA Disease

The optimal treatment for nonbulky stage IIIA disease generally consists of a local approach (surgery and/or radiation therapy) plus a systemic treatment (chemotherapy). Possible combinations include surgery followed by adjuvant chemotherapy (with or without thoracic radiation), neoadjuvant chemotherapy (or chemoradiation) followed by surgery, or concurrent or sequential chemotherapy and radiation.

The potential benefit of adding surgery to combined chemoradiation for stage IIIA disease has been evaluated in a randomized, phase III intergroup trial (INT 0139).[117] This study randomly assigned 396 patients with stage T1-3N2M0 NSCLC to concurrent chemoradiation (45 Gy) plus two cycles of cisplatin/etoposide, followed by either surgical resection or continuation of radiation to 61 Gy total plus an additional two cycles of cisplatin/etoposide. Although PFS was significantly longer in the surgery arm (12.8 vs. 10.5 months; $p = 0.02$), there was no significant difference in OS (23.6 vs. 22.2 months; $p = 0.24$). There were more treatment-related deaths in the surgery arm (8% vs. 2%), with the majority of deaths among patients who required pneumonectomy. However, the survival curves subsequently separated so that by the third year, 5-year OS rates were 27.2% and 20.3% (OR for 5-year survival 0.63; 95% CI; 0.36, 1.10; $p = 0.10$). In the trimodality arm, more patients were alive without disease progression ($p = 0.008$), but more patients died without progression ($p = 0.021$). Consistent with other trials, achievement of pathologic N0 status at the time of surgery was associated with improved clinical outcomes (median OS, 34 months).

Occasionally, despite preoperative staging, patients thought to have stage I or II disease are found to have N2 nodal involvement at the time of surgery. For these patients with stage III disease, postoperative radiation therapy (PORT; 50 to 54 Gy) may be considered, usually after completion of adjuvant chemotherapy. In a PORT meta-analysis, this approach reduced locoregional recurrence but did not prolong survival.[118] However, in a more contemporary review of the National Cancer Data Base, patients who received PORT after complete surgical resection and adjuvant chemotherapy for N2 disease had prolonged OS compared with no PORT.[119]

Bulky Stage IIIA (N2) and Stage IIIB Disease

Bulky stage IIIA and stage IIIB tumors are generally considered unresectable, with the

preferred treatment consisting of combined chemoradiation. Chemotherapy plus radiation therapy is the treatment of choice for patients with bulky or inoperable stage IIIA or IIIB disease. Randomized studies have demonstrated an improvement in median and long-term survival with chemotherapy followed by radiation therapy compared with radiation therapy alone.[120,121]

The results from two randomized studies, one conducted in Japan and the other by the Radiation Therapy Oncology Group (RTOG), showed a survival advantage with concurrent chemoradiation compared with a sequential approach, albeit at the expense of increased toxicity. In the Japanese trial, two cycles of mitomycin C/vindesine/cisplatin (MVP) were given concurrently or sequentially with 56 Gy of radiation.[122] Patients in either arm who experienced a response received another two cycles of MVP after radiation therapy was completed. The RR and median survival were significantly improved with concurrent chemoradiotherapy (84% vs. 66%, p = 0.0002; 17 vs. 13 months, p = 0.04). The confirmatory randomized RTOG 9410 trial also showed improved survival with concurrent cisplatin, vinblastine, and radiation therapy compared with sequential chemoradiation (median survival, 17 vs. 13 months; p = 0.08).[123] Notably, the concurrent approach appeared to provide particular benefit to patients older than age 70.

Chemotherapy can be administered in either full systemic doses with radiation therapy, in weekly radiosensitizing doses, or in a combination of the two. Although single-agent weekly carboplatin has not resulted in a survival benefit when administered with radiation therapy, preliminary results from phase I and II studies (Locally Advanced Multimodality Protocol [LAMP]) of weekly doses of paclitaxel (50 mg/m^2) and carboplatin (AUC 2) with concurrent radiation therapy followed by consolidation paclitaxel and carboplatin proved promising.[124] A CALGB trial compared concomitant chemoradiotherapy, consisting of low-dose weekly carboplatin and paclitaxel, with induction therapy prior to the same concomitant chemoradiotherapy regimen. Median survival with chemoradiation was 11.4 months, compared with 14 months for induction chemotherapy followed by chemoradiation (p = 0.154). The median survival achieved in each of the treatment groups was low compared with other reports in the literature, possibly indicating that chemoradiation with induction chemotherapy followed by low-dose weekly carboplatin and paclitaxel is not optimal.

Thus, major questions remain unanswered regarding the best combination and scheduling of chemotherapy and radiation therapy. Although results from the Japanese trial demonstrated a slightly superior outcome with concurrent chemoradiotherapy, the mitomycin-based approach is not widely used in the United States. The RTOG trial involved an older chemotherapy regimen; none of the newer agents, such as carboplatin, paclitaxel, docetaxel, gemcitabine, and vinorelbine, have been tested in this context. SWOG 9504 demonstrated promising results with consolidation docetaxel following full-dose cisplatin/etoposide and concurrent radiation therapy, but these results were not confirmed in a randomized trial.[125-127] Indeed, consolidation docetaxel after concurrent chemoradiation led to more febrile neutropenia, pneumonitis, and hospitalizations and cannot be recommended. The efficacy of sensitizing doses of concurrent chemotherapy also has not been compared with full doses of chemotherapy in randomized trials. Thus, at this point, there is level 1 evidence for concurrent chemoradiation therapy with full-dose cisplatin and etoposide, and level 2 evidence (based on randomized phase II data) supporting weekly low doses of paclitaxel and carboplatin with concurrent radiation therapy followed by consolidation paclitaxel and carboplatin. One phase III trial[128] showed that standard 60-Gy thoracic radiotherapy is superior to a 74-Gy radiation dose with chemotherapy in terms of OS and locoregional control for treatment of stage III NSCLC.[129] These results are not

explained simply by an increase in toxicity. In the phase 3 PROCLAIM trial, 598 patients with stage IIIA/IIIB non-squamous NSCLC were randomly assigned to receive thoracic radiation (60-66 Gy) with either concurrent cisplatin/etoposide for two cycles followed by two cycles of consolidation platinum-based doublet chemotherapy or concurrent cisplatin/pemetrexed for three cycles followed by four cycles of pemetrexed consolidation. The cisplatin/pemetrexed arm was not superior to the cisplatin/etoposide arm in terms of OS (HR, 0.98; 95% CI, 0.79, 1.20; median, 26.8 vs. 25.0 months; p = .831), though the cisplatin/pemetrexed arm had a lower incidence of any drug-related grade 3 to 4 adverse events (64.0% vs. 76.8%; p = .001), including neutropenia (24.4% vs. 44.5%; p < .001).[130]

Currently, there is no established role for molecularly targeted agents in the treatment of locally advanced NSCLC. In SWOG 0023, patients with stage III NSCLC whose disease had not progressed after concurrent chemoradiation (with cisplatin/etoposide) and consolidation docetaxel were randomly assigned to the EGFR-TKI gefitinib or to placebo maintenance therapy.[131] Unexpectedly, though the sample size was small, OS was significantly worse in the gefitinib arm (median, 23 vs. 35 months; p = 0.01). This result remains largely unexplained, though the sample size was small. The antiangiogenic drug bevacizumab has been added to concurrent chemoradiotherapy for stage III NSCLC. In small series, this combination was associated with substantial toxicities, including an increased incidence of tracheoesophageal fistulae, and should not be used with concurrent thoracic radiotherapy.[132]

Stage III Recommendations

Treatment of patients with stage III, N2 NSCLC is not standardized, as indicated in the previous discussion. Although results from ongoing or recently completed randomized studies are maturing, some general guidelines for treating a patient can be identified:

- Clinical N0 disease by CT and PET—A resection should be performed, with mediastinal sampling or complete dissection at the time of surgery. If microscopic N2 (or N1) disease is detected at surgery, postoperative chemotherapy should be administered. For N2 disease detected at surgery, PORT can be considered.
- Nonbulky N2 by CT (e.g., one node measuring 1 to 2 cm) and/or by PET—The patient's age, PS, and comorbid conditions should be considered. Level 1 evidence exists for a combined modality approach with chemotherapy and radiation therapy. If the patient is a surgical candidate, it is not unreasonable to have a discussion regarding the use of surgery plus preoperative chemotherapy and/or radiation therapy, stressing that the optimal treatment sequence has not been clearly identified. Some surgeons recommend resampling the mediastinal nodes after two cycles of the induction chemotherapy, rationalizing that if the N2 nodes remain positive following chemotherapy, a definitive resection should not be attempted and the patient should proceed with definitive radiation therapy or with combined chemotherapy and radiation. Combined preoperative chemoradiation should be administered cautiously and only to a fit patient who will be undergoing resection by an experienced thoracic surgeon (given the high incidence of postoperative deaths). Particular caution should be exercised for patients undergoing a right-sided pneumonectomy. Overall, chemotherapy plus concurrent thoracic radiation therapy remains the standard of care in this setting.
- Bulky N2 nodes—Chemotherapy plus concurrent radiation therapy is indicated. The presence of pathologically involved N2 nodes should be confirmed when possible,

because enlarged nodes detected on CT will be pathologically negative for approximately 30% of patients. The patient's age, PS, and comorbid conditions must be considered. Concurrent chemoradiotherapy provides a small survival benefit, albeit at the expense of an increase in toxicity, and thus should be reserved for patients with good PS. Weekly, low-dose, concurrent chemotherapy has not been compared with full-dose chemotherapy in randomized trials, although it is often administered concurrently with radiation therapy if followed by two to three cycles of standard-dose chemotherapy.

KEY POINTS

- Optimal treatment of "nonbulky" stage IIIA disease (e.g., small, single-station node) continues to evolve but optimally involves both systemic chemotherapy and local therapy (surgery and/or radiation). For patients with multistation N2 disease or bulky N2 nodes (3 cm or larger), concurrent chemotherapy plus radiation therapy is considered standard of care.
- For nonbulky N2 disease, a trimodality approach with chemoradiotherapy followed by surgery can be considered, though patients requiring pneumonectomy (particularly right-sided pneumonectomy) had poor survival. Management decisions regarding stage IIIA NSCLC should be made by a multidisciplinary thoracic tumor board.
- Curative intent treatment of stage IIIB NSCLC similarly involves combined-modality treatment with chemotherapy and radiation therapy. Evidence from randomized trials suggests that concurrent chemotherapy and radiation therapy will result in the best survival, albeit with an increase in toxicity.
- The optimal chemoradiation schedule remains debatable; there is level 1 evidence for concurrent chemoradiation therapy with full-dose cisplatin and etoposide, and level 2 evidence (based on randomized, phase II data) supporting weekly low doses of paclitaxel and carboplatin with concurrent radiation therapy, followed by consolidation paclitaxel and carboplatin.

STAGE IV DISEASE

Chemotherapy improves survival for patients with metastatic NSCLC (a 1-year survival rate of approximately 10% for untreated patients compared with 35 to 40% for treated patients). In addition, chemotherapy may reduce symptoms and improve quality of life; therefore, it is usually recommended for patients with good PS. Because chemotherapy is not curative, goals for treatment should be discussed with the patient, including palliation of symptoms and a modest improvement in survival.

The principal factors predictive of response to chemotherapy and survival are PS and bulk of disease. Favorable prognostic factors include no weight loss, female sex, normal level of serum lactate dehydrogenase, and no bone or liver metastases.

First-Line Treatment

Chemotherapy. Chemotherapy for metastatic NSCLC has traditionally consisted of a platinum-based doublet regimen. Results from randomized studies have shown an improvement in

survival, symptoms, and quality of life for patients treated with cisplatin-based therapy compared with patients receiving best supportive care. Median survival and 1-year survival rates have increasingly improved with use of second- and third-generation chemotherapy regimens (Table 8-8).

Table 8-8 Survival Rates for Chemotherapy for Non-Small Cell Lung Cancer

	Chemotherapy Agents	Median Survival (months)	1-Year Survival (%)	2-Year Survival (%)
Best supportive care only		4–5	5–10	< 5
First-generation chemotherapy regimens	Cisplatin, vinblastine, mitomycin, vindesine	5–6	10–15	< 5
Second-generation chemotherapy regimens	Carboplatin, etoposide	6	20–25	< 10
Third-generation chemotherapy regimens	Paclitaxel and docetaxel, gemcitabine, vinorelbine, pemetrexed, nab-paclitaxel	8–9	35–40	10
Nonsquamous histology (no hemoptysis)	Carboplatin and paclitaxel plus bevacizumab	12	50	20
Nonsquamous histology	Cisplatin plus pemetrexed	12	50	20
EGFR mutations	EGFR-TKI before or after doublet chemotherapy	18–27		

Abbreviations: EGFR, epidermal growth factor receptor; TKI, tyrosine kinase inhibitor.

Until recently, findings from numerous randomized studies have not shown a clinically significant advantage of any platinum-based doublet regimen, although there are differences in toxicity, cost, schedule, and convenience. However, there are now data supporting different treatment approaches depending on the histologic subtype of NSCLC, based on efficacy (pemetrexed) and safety (bevacizumab). Pemetrexed is an inhibitor of thymidylate synthase and other folate-dependent enzymes, including dihydrofolate reductase and glycinamide ribonucleotide formyltransferase. A phase III trial of more than 1700 patients with chemotherapy-naive disease has been reported, comparing pemetrexed/cisplatin with gemcitabine/cisplatin.[133] OS was the same in the two arms, with an improved toxicity profile in the pemetrexed arm. However, in a prespecified subset analysis, OS was statistically superior for cisplatin/pemetrexed compared with cisplatin/gemcitabine for patients with adenocarcinoma (12.6 vs. 10.9 months) and large cell carcinoma histology (10.4 vs. 6.7 months). Conversely, patients with squamous cell histology experienced a significant improvement in survival with cisplatin/gemcitabine compared with cisplatin/pemetrexed (10.8 vs. 9.4 months). This and other studies have led to approval of pemetrexed for the first-line, maintenance, and second-line treatment of nonsquamous cell NSCLC. One proposed explanation for the differential pemetrexed sensitivity of squamous and nonsquamous NSCLC is higher expression and activity of thymidylate synthase in squamous tumors.[134]

Bevacizumab. Bevacizumab has been approved for the management of non–squamous cell carcinoma based on results from the Eastern Cooperative Oncology Group (ECOG) 4599 phase III trial of 878 patients randomly assigned to chemotherapy (paclitaxel and carboplatin) or to chemotherapy plus 15 mg/kg of bevacizumab every 3 weeks.[57] Median survival for patients who received chemotherapy plus bevacizumab was 12.3 months, compared with 10.3 months for patients who received chemotherapy alone (HR. 0.79; p = 0.003). Median duration

of PFS for patients who received chemotherapy plus bevacizumab was 6.2 months, compared with 4.5 months for those who received chemotherapy alone (HR, 0.66; $p < 0.001$), with corresponding RRs of 35% and 15%, respectively ($p < 0.001$). However, because of the grade 3 to 4 bleeding episodes observed in the phase II study that preceded this one, it should be noted that eligibility for this study was restricted to patients with non–squamous cell carcinoma (because of higher levels of severe hemoptysis observed in squamous tumors) and no brain metastases, as well as no hemoptysis, bleeding disorders, or anticoagulation requirement. Despite these restrictions, significant bleeding was more frequent for patients who received chemotherapy plus bevacizumab (4.4% vs. 0.9%; $p = 0.001$). There were 15 treatment-related deaths in the group of patients who received chemotherapy plus bevacizumab, including 5 resulting from pulmonary hemorrhage. Thus, the risks and benefits of bevacizumab should be clearly delineated to patients with advanced NSCLC.

A second randomized study of bevacizumab involving more than 1000 patients has been conducted (the Avastin in Lung [AVAiL] trial).[135] Unlike the ECOG study, this study involved gemcitabine and cisplatin and randomly assigned patients to chemotherapy plus placebo, chemotherapy with 7.5 mg/kg of bevacizumab every 3 weeks, or chemotherapy with 15 mg/kg of bevacizumab every 3 weeks. The study met its primary endpoint of PFS, with HRs of 0.75 and 0.82 for the low- and high-dose bevacizumab arms, respectively. However, the absolute benefit was modest (median PFS, 6.7 and 6.5 months vs. 6.1 months), with no improvement in survival. It is unclear whether the lack of survival benefit is a result of the differences in chemotherapy doublets between the ECOG study and the AVAiL trial, differences in bevacizumab dose, or differences in study design, of which there were many.

Subsequent experience with bevacizumab and other antiangiogenic agents in lung cancer and other malignancies has provided further insight into the nature of their vascular complications, in some instances suggesting that it may be feasible to expand patient eligibility for these agents. Squamous cell tumors remain an absolute contraindication to bevacizumab therapy. Although it has been proposed that squamous cell histology may be a surrogate marker of central tumor location and proximity to vascular structures, neither of these anatomic characteristics has emerged as an independent risk factor for severe pulmonary hemorrhage. In the AVAiL trial, central lesions (defined as tumors in which the center of the mass was within the hilar structure) were present in 38% of patients and were not associated with increased rates of grade 3 to 4 pulmonary hemorrhage. The only potential radiographic risk factor identified to date is baseline tumor cavitation (OR, 4.5; 95% CI; 0.73, 28.33; $p = 0.06$).[136]

The FDA approval of bevacizumab for the treatment of glioblastoma multiforme has supported the concept of using bevacizumab for patients with intracranial malignancy. The phase II PASSPORT trial administered bevacizumab plus chemotherapy to 115 patients with brain metastases previously treated with radiation or surgery. No cases of CNS hemorrhage occurred.[137] The use of bevacizumab for patients receiving antiplatelet agents was evaluated in a pooled analysis of five randomized trials in NSCLC, colorectal cancer, and breast cancer, in which the concurrent administration of bevacizumab, chemotherapy, and low-dose prophylactic aspirin did not increase the risk of bleeding compared with chemotherapy and aspirin alone.[138] The use of bevacizumab for patients receiving therapeutic anticoagulation has not been described extensively. In the AVAiL trial, 86 patients in whom venous thromboembolism developed during the study were treated with full-dose anticoagulation. Once on a stable anticoagulation regimen, patients who had been randomly assigned to receive bevacizumab were permitted to resume it. Patients who were taking anticoagulants experienced higher bleeding rates than patients not taking them, regardless of whether they received

bevacizumab.[139] As a result of these and other reports, bevacizumab is now being used for patients with previously treated brain metastases. Although not an absolute contraindication, given the limited data available, caution should be exercised before initiating bevacizumab for patients receiving anticoagulants.

Immunotherapy—First Line. Because of the success and approval of PD-1 and PD-1 ligand (PD-L1) antibodies as second-line treatment for metastatic NSCLC, these drugs are increasingly being studied as first-line NSCLC treatment (Table 8-9). In the KEYNOTE-024 trial, 305 patients with PD-L1 expression on at least 50% of tumor cells and no *EGFR* mutation or *ALK* translocation were randomly assigned to receive either pembrolizumab or the investigator's choice of platinum-based chemotherapy. Crossover from the chemotherapy group to the pembrolizumab group was allowed at disease progression. The primary endpoint of PFS was superior in the pembrolizumab arm compared to chemotherapy arm (median PFS, 10.3 months; 95% CI; 6.7, not reached, vs. median PFS, 6.0 months; 95% CI; 4.2, 6.2) (HR, 0.50; 95% CI; 0.37, 0.68; $p < 0.001$). OS was also significantly and substantially improved in the pembrolizumab arm (HR, 0.60; 95% CI; 0.41, 0.89; $p = 0.005$). The response rate (RR) was higher with pembrolizumab (44.8% vs. 27.8%), and treatment-related adverse events of any grade were less frequent (occurring in 73.4% vs. 90.0% of patients), as were serious treatment-related adverse events (26.6% vs. 53.3%).[140] Based on these data, pembrolizumab is now FDA-approved as first-line treatment for stage IV NSCLC with PD-L1 expression on at least 50% of tumor cells using the companion diagnostic DAKO 22C3 antibody.

Table 8-9 **Selected Trials of Immunotherapy Agents in Non-Small Cell Lung Cancer**

Checkpoint Inhibitor	Target	Biomarker Antibody	Randomized First-Line Trials (vs. Platinum-Based Chemotherapy)	Randomized Second-Line Trials (vs. Single-Agent Docetaxel)
Pembrolizumab[140,217]	PD-1	DAKO 22C3 (PD-L1)	KEYNOTE-024; 305 patients; eligibility, ≥ 50% PD-L1 expression; PFS HR, 0.50; 95% CI; 0.37, 0.68; $p < 0.001$; OS HR 0.60; 95% CI; 0.41, 0.89; $p = 0.005$; ORR, 44.8% vs. 27.8%	KEYNOTE-010; 1034 patients; eligibility ≥ 1% PD-L1 expression; for 2 mg/kg: HR, 0.71; 95% CI; 0.58, 0.88; $p = 0.0008$; for 10 mg/kg HR, 0.61; 95% CI; 0.49, 0.75; $p < 0.0001$
Nivolumab[214]	PD-1	DAKO 28-8 (PD-L1)	CHECKMATE 026; 541 patients; ≥ 5% PD-L1 expression; PFS HR, 1.15; 95% CI; 0.91, 1.45; OS HR 1.02; 95% CI; 0.8, 1.3	CHECKMATE 017; 272 patients; squamous NSCLC; median OS, 9.2 months vs. 6.0 months, $p < 0.001$; HR, 0.59; 1-year OS, 42% vs. 24%; CHECKMATE 057; 582 patients; non-squamous; median OS, 12.2 months (95% CI; 9.7, 15.0) vs. 9.4 months (95% CI; 8.1, 10.7) HR, 0.73; $p = 0.002$). 1 year OS 51% vs. 39%
Atezolizumab[218]	PD-L1	Ventana SP142 (TC/IC)	Final results pending	OAK; 850 patients; median OS, 13.8 months vs. 9.6 months; HR 0.73, 95% CI 0.62, 0.87, $p = 0.0003$

More recently, the FDA approved pembrolizumab in combination with carboplatin and pemetrexed agnostic of PD-L1 expression in non–squamous NSCLC. This approval was based on data from the KEYNOTE-021 trial. In one cohort of this phase II trial, 123 untreated patients were randomly assigned to either the triplet carboplatin/pemetrexed/pembrolizumab or the

doublet carboplatin/pemetrexed. The primary endpoint of ORR was superior with the triplet (55% vs. 26%; p = 0.0016) as was PFS (HR, 0.53; p = 0.01).[141] Thus, for NSCLC for non–squamous NSCLC, the combination of carboplatin/pemetrexed and pembrolizumab is a potential treatment option. OS data for the combination is immature and it is unclear at this point whether the triplet enhances OS compared to sequencing platinum-based chemotherapy and pembrolizumab separately. Results from the confirmatory randomized phase 3 trial of this triplet (KEYNOTE-189) are eagerly anticipated.

The CHECKMATE 026 trial randomly assigned 541 patients whose tumors were PD-L1–positive. The primary endpoint was PFS in patients with 5% or greater PD-L1 expression. Among these patients, nivolumab did not improve median PFS compared to investigators' choice of chemotherapy (4.2 months vs. 5.9 months; HR, 1.15; 95% CI; 0.91, 1.45). Overall survival was also not improved (median OS, 14.4 months for nivolumab vs. 13.2 months for chemotherapy; HR, 1.02; 95% CI; 0.8, 1.3). The discrepancy between the survival outcomes for pembrolizumab and nivolumab in the first-line setting is unclear and cannot be explained just by selection of the 50% versus 5% PD-L1 expression cutpoint, since in the CHECKMATE 026 subset analysis, survival endpoints were not improved with nivolumab even when PD-L1 expression was 50% or greater.

EGFR Inhibitors. There are two main approaches to targeting EGFR: TKIs and monoclonal antibodies. TKIs (e.g., erlotinib, gefitinib) cross the cell membrane, binding to and inhibiting the function of the intracellular tyrosine kinase domain. Monoclonal antibodies bind to the extracellular domain of EGFR, interfering with ligand binding and receptor activation.

It is clear that EGFR-TKIs provide superior radiographic RR and PFS compared with conventional chemotherapy for patients with tumors harboring activating *EGFR* mutations (Table 8-10).[142-161] Although no survival benefit has been observed in randomized studies, this has been postulated to be a result of patients whose disease has progressed crossing over from the chemotherapy arm to the EGFR-TKI arm. Importantly, clinicopathologic features appear insufficient to predict the presence of *EGFR* mutations. In the Iressa Pan-Asian Survival Study (IPASS) trial, only 60% of East Asians with adenocarcinoma who were never- or former light smokers had *EGFR* mutations.[148] It should be noted that despite the emphasis on the use of EGFR-TKIs in *EGFR*-mutated cancers, randomized studies such as BR.21 have demonstrated a benefit in PFS and OS in an unselected patient population in the second- and third-line settings.[83]

Table 8-10 **Selected Phase III Trials of Epidermal Growth Factor Receptor (EGFR) Inhibitors for Non-Small Cell Lung Cancer (NSCLC)**

Trial*	Population	Line of Therapy	Treatment	Number of Patients	Primary Outcome(s)
RADIANT	*EGFR* FISH-positive stage IB-IIIA	Adjuvant	Adjuvant erlotinib × 2 yr vs. placebo	973	DFS, 50.5 mo (EGFR FISH + erlotinib) vs. 48.2 mo (placebo) (p = 0.32); 46.4 mo (*EGFR* mutation + subset erlotinib) vs. 28.5 mo (placebo) (p = 0.039; not significant because of hierarchical testing)
NCIC JBR.10[142]	Unselected stage IB-IIIA	Adjuvant	Adjuvant gefitinib vs. placebo	Closed after 500 (of 1200 planned)	OS median survival: 5.1 yr (gefitinib) vs. not reached (placebo) (p = 0.130)
Rigas et al.[143]	Unselected, unresectable stage III	Stage III maintenance	Chemoradiation (cisplatin/docetaxel) ± maintenance erlotinib	253	PFS, 13.5 mo (erlotinib) vs. 10.4 mo (placebo) (p = 0.12)
SWOG 0023[131]	Unselected, unresectable stage III	Stage III maintenance	Chemoradiation (cisplatin/etoposide) then consolidation docetaxel ± maintenance gefitinib	Closed after 243 (of 672 planned)	OS, 23 mo (gefitinib) vs. 35 mo (placebo) (p = 0.01)
RTOG 0617[126]	Unselected, unresectable stage III	Stage III	Chemoradiation (carboplatin/paclitaxel) ± cetuximab	465	OS, 23.1 mo (cetuximab) vs. 23.5 mo (placebo) (p = 0.484)
TALENT[144]	Unselected stage IIIB-IV	First-line metastatic	Cisplatin/gemcitabine ± erlotinib	1172	OS, 10.8 mo (chemo plus erlotinib) vs. 11.0 mo (chemo alone) (p = 0.49)
TRIBUTE[145]	Unselected stage IIIB-IV	First-line metastatic	Carboplatin/paclitaxel ± erlotinib	1059	OS, 10.6 mo (erlotinib) vs. 10.5 mo (placebo) (p = 0.95)
INTACT-1[146]	Unselected stage IIIB-IV	First-line metastatic	Cisplatin/gemcitabine ± gefitinib	1093	OS, 9.9 mo (gefitinib 500 mg/day) vs. 9.9 mo (gefitinib 250 mg/day) vs. 10.9 mo (placebo) (p = 0.46)
INTACT 2[147]	Unselected stage IIIB-IV	First-line metastatic	Carboplatin/paclitaxel ± gefitinib	1037	OS, 8.7 mo (gefitinib 500 mg/day) vs. 9.8 mo (gefitinib 250 mg/day) vs. 9.9 mo (placebo) (p = 0.64)
IPASS[148]	East Asian nonsmokers or former light smokers with stage IIIB-IV adenocarcinoma	First-line metastatic	Gefitinib vs. carboplatin/paclitaxel	1217	12-mo PFS, 24.9% (gefitinib) vs. 6.7% (carboplatin/paclitaxel) (p < 0.001)
WJTOG3405[149]	Stage IIIB-IV with *EGFR* mutations in Japan	First-line metastatic	Gefitinib vs. cisplatin/docetaxel	172	PFS, 9.2 mo (gefitinib) vs. 6.3 mo (cisplatin/docetaxel) (p < 0.001)
First-SIGNAL[150]	Korean never-smokers with IIIB-IV	First-line metastatic	Gefitinib vs. cisplatin/gemcitabine	313	OS, 20.3 mo (gefitinib) vs. 23.1 mo (cisplatin/gemcitabine) (p = 0.43)
NEJ002[151]	Stage IIIB-IV with *EGFR* mutations in Japan	First-line metastatic	Gefitinib vs. carboplatin/paclitaxel	200	PFS, 10.4 mo (gefitinib) vs. 5.5 mo (carboplatin/paclitaxel) (p < 0.001)
OPTIMAL[152]	Stage IIIB-IV with *EGFR* mutations in China	First-line metastatic	Erlotinib vs. gemcitabine/carboplatin	165	PFS, 13.1 mo (erlotinib) vs. 4.6 mo (gemcitabine/carboplatin) (p < 0.0001)
FLEX[153]	EGFR-positive stage IIIB-IV	First-line metastatic	Cisplatin/vinorelbine ± cetuximab	1125	OS, 11.3 mo (chemo plus cetuximab) vs. 10.1 mo (chemo alone) (p = 0.04)
BMS099[154]	Unselected stage IIIB-IV	First-line metastatic	Carboplatin/taxane ± cetuximab	676	PFS, 4.4 mo (chemo plus cetuximab) vs. 4.2 mo (chemo alone) (p = 0.24) [secondary endpoint, OS, 9.7 mo (chemo plus cetuximab) vs. 8.4 mo (chemo alone) (p = 0.17)]
SATURN[155]	Unselected stage IIIB-IV	First-line maintenance	4 cycles platinum doublet chemotherapy followed by maintenance erlotinib vs. placebo	889	6-mo PFS, 31% vs. 17% (p < 0.0001) [secondary endpoint, OS, 12 mo (erlotinib) vs. 11 mo (placebo); p < 0.05)]
ATLAS[156]	Non-squamous stage IIIB-IV	First-line maintenance	4 cycles platinum doublet chemotherapy followed by maintenance bevacizumab ± erlotinib	768	PFS, 4.8 mo (bevacizumab + erlotinib) vs. 3.7 mo (bevacizumab alone) (p = 0.001)
BR21[83]	Unselected stage IIIB-IV	Second- and third-line	Erlotinib vs. placebo	731	OS, 6.7 mo (erlotinib) vs. 4.7 mo (placebo) (p < 0.001)
ISEL[157]	Unselected stage IIIB-IV	Second-line	Gefitinib vs. placebo	1692	OS, 5.6 mo (gefitinib) vs. 5.1 mo (placebo) (p = 0.09)
INTEREST[158]	Unselected stage IIIB-IV	Second-line	Gefitinib vs. docetaxel	1466	OS, 7.6 mo (gefitinib) vs. 8.0 mo (docetaxel) (p > 0.05)
EURTAC[159]	Stage IV *EGFR*-mutation-positive in Europe	First-line metastatic	Erlotinib vs. carboplatin/docetaxel or carboplatin/gemcitabine	174	PFS, 9.7 mo vs. 5.2 mo (p < 0.0001)
LUX-Lung 3[160]	Stage IV, *EGFR*-mutation-positive	First-line, metastatic	Afatinib vs. cisplatin/pemetrexed	345	PFS, 13.6 mo vs. 6.9 months (p = 0.001)
LUX-Lung 6[161]	Stage IV, *EGFR*-mutation-positive	First-line, metastatic	Afatinib vs. cisplatin/gemcitabine	364	PFS, 11.0 mo vs. 5.6 mo (p < 0.0001)
LUX-Lung 7[163]	Stage IV, *EGFR*-mutation-positive	First-line, metastatic	Afatinib vs. gefitinib	319	PFS, 11.0 months vs. 10.9 months; HR, 0.73; 95% CI; 0.57, 0.95; p = 0.017
LUX-Lung 8[211]	Stage IV squamous NSCLC	Second-line, metastatic	Afatinib vs. erlotinib	795	OS, 7.9 mo vs. 6.8 mo, p = 0.0077). PFS, 2.6 mo [95% CI vs. 1.9 mo; HR, 0.81; p = 0.0103)
ILND[196]	Stage IV EGFR wt NSCLC	Maintenance therapy vs. second-line, metastatic	Erlotinib maintenance vs. second-line erlotinib	643	OS, 9.7 mo vs. 9.5 mo; HR, 1.02; 95% CI; 0.85, 1.22; log-rank p = 0.82.

Abbreviations: chemo, chemotherapy; DFS, disease-free survival; OS, overall survival; PFS, progression-free survival; wt, wild-type.
*These studies used American Joint Commission on Cancer staging prior to 8th edition.

Afatinib is an irreversible EGFR inhibitor and a HER2 inhibitor approved by the FDA for first-line treatment of patients with metastatic NSCLC with tumors harboring *EGFR*-activating mutations.[160,161] Approval was based on afatinib's improving median PFS compared with cisplatin/pemetrexed for patients with NSCLC with *EGFR*-mutated tumors (median PFS, 11.1 vs. 6.9 months; HR, 0.58; p < 0.001). Despite an initial dramatic response to EGFR inhibitors among patients with *EGFR*-mutated NSCLC, resistance generally develops within 2 years. Approximately half of these cases are associated with a secondary *T790M* mutation, which results in steric hindrance to EGFR-TKI binding (analogous to the *T315I* mutation in chronic myeloid leukemia) and altered ATP handling.[162,163] Additional cases with secondary resistance develop because of overexpression of c-Met, a receptor tyrosine kinase that activates downstream components of the EGFR signal transduction cascade ("molecular cross talk").[164]

A subset of *EGFR*-mutated tumors can become resistant to EGFR-TKI therapy by transforming their histology into small cell lung cancer histology and may respond to regimens such as those used for small cell lung cancer.[165] Mutations in PI3CA and HER2 amplification, among other bypass tracts, have also been implicated as resistance mechanisms. Therapeutic strategies to overcome these processes, including EGFR inhibitors with potent activity against EGFR-T790M (the most common resistant mechanism to currently approved EGFR TKIs and with novel combination regimens such as afatinib and the EGFR-monoclonal antibody cetuximab[166]), remain under investigation.

Indeed, the third-generation EGFR TKI osimertinib that binds potently to mutant EGFR harboring the *T790M* gatekeeper resistance mutation has been approved for use in advanced *EGFR*-mutant NSCLC with the *T790M* mutation after progression on prior EGFR-TKI. For these patients, the median PFS was 9.6 months and the objective RR was 61%. PFS and objective RR was substantially lower in treated patients with EGFR-T790M–negative tumors (PFS, 2.8 months; ORR, 21%).[167] Based on these data demonstrating high ORR and prolonged PFS, osimertinib was approved by the FDA for *EGFR*-mutant NSCLC harboring EGFR-T790M.

Although EGFR inhibitors improve PFS as first-line therapy for patients with tumors harboring activating *EGFR* mutations, it has not been shown that the order in which these EGFR inhibitors are received affects OS. In the IPASS trial, the gefitinib arm had clinically and significantly longer PFS as compared with the carboplatin/paclitaxel arm in *EGFR*-mutated tumors. There was no significant difference in OS, presumably because of the high proportion of crossover to gefitinib in the carboplatin/paclitaxel arm. Similarly, a registry study of *EGFR*-mutated NSCLC from Spain has demonstrated no difference between first- or second-line administration of EGFR inhibitors in OS.[168] In the Northeast Japan Study Group (NEJ) 002 trial, 200 patients with EGFR-mutated tumors were randomly assigned to carboplatin/paclitaxel or gefitinib. Gefitinib yielded superior PFS (10.8 vs. 5.4 months; HR, 0.3; 95% CI; 0.22, 0.41; $p < 0.001$) and radiographic RR (74% vs. 31%; $p < 0.001$). Although there was a numerical improvement in median OS (30.5 vs. 23.6 months), it was not statistically significant ($p = 0.31$).[151] A key observation from the IPASS trial is that, for patients with *EGFR* wild-type tumors, PFS with gefitinib in the first-line setting is substantially inferior to PFS with chemotherapy (HR, 2.85; 95% CI; 2.05, 3.98; $p < 0.001$), which is not the case in the second-line setting. A clinical trial in a predominantly European population that compared erlotinib to cisplatin-based doublet chemotherapy also showed much higher RRs and median PFS for patients with metastatic lung cancers harboring *EGFR* mutations (RR, 58 vs. 15%; median PFS, 9.7 vs. 5.2 months; $p < 0.0001$).[159]

Results combining EGFR inhibitors with cytotoxic chemotherapy are mixed. Four randomized trials (INTACT [Iressa NSCLC Trial Assessing Combination Treatment]-1, INTACT-2, TALENT [Tarceva Lung Cancer Investigation], and TRIBUTE [Tarceva Responses in Conjunction with Paclitaxel and Carboplatin]) failed to demonstrate a survival benefit, an outcome that has been attributed to enrollment of an unselected population and to potential pharmacodynamic interference between cytostatic EGFR-TKIs and cell-cycle–dependent chemotherapeutic agents.[169] Achieving pharmacodynamic separation by sequencing treatment to prevent G1-cell-cycle arrest from EGFR inhibitors from interfering with optimal chemotherapeutic effect was tested in the FASTACT-2 trial. In a predominantly Asian population enriched for *EGFR*-activating mutations, combination platinum and gemcitabine was intercalated with erlotinib. Compared with platinum/gemcitabine alone, this combination yielded improved PFS and OS (7.6 months vs. 6 months, $p < 0.0001$; 18.3 months vs. 15.2 months, $p = 0.042$). Patient benefit was restricted primarily to patients with tumors harboring *EGFR*-activating mutations (PFS,

16.8 vs. 6.9 months, p < 0.0001; OS, 31.4 vs. 20.6 months, p = 0.009).[170] Despite the FASTACT-2 results, single-agent EGFR-TKI still remains the first-line standard of care for patients with advanced NSCLC harboring *EGFR*-activating mutations.

In contrast to EGFR-TKIs, the effect of anti-EGFR monoclonal antibodies in NSCLC does not appear to be associated with the presence of activating *EGFR* mutations, nor is the effect associated with the presence of *KRAS* mutations, as has been shown in colorectal cancer.[171,172] Two phase III clinical trials incorporating anti-EGFR monoclonal antibodies have been performed. The BMS099 trial randomly assigned patients to platinum/taxane chemotherapy with or without cetuximab.[154] No difference in OS was noted. The First-line in Lung cancer with ErbituX (FLEX) trial randomly assigned patients to cisplatin/vinorelbine with or without cetuximab.[153] The cetuximab-containing arm demonstrated a statistically significant improvement in OS (HR, 0.87; 95% CI; 0.76, 0.99; p = 0.04), with an increase in median OS from 10.1 to 11.3 months. Whether differences in the chemotherapy regimen, geographic setting, or inclusion criteria (FLEX mandated EGFR-positive tumors, defined as at least one cell staining positive on IHC) underlie the different results of the BMS099 and FLEX trials is not known. As for first-line treatment in stage IV squamous cell NSCLC, another EGFR monoclonal antibody, necitumumab, modestly improved OS when added to cisplatin and gemcitabine. In the SQUIRE trial, 1093 patients were randomly assigned to receive either cisplatin/gemcitabine or cisplatin/gemcitabine plus necitumumab. The addition of necitumumab modestly improved OS (median OS, 11.5 vs. 9.9 months; HR, 0.84; p = 0.012) and PFS (HR, 0.85; p = 0.020). No difference in ORR was noted (31% vs. 29%; p = 0.400).[173]

Treatment of ALK and ROS1 Rearranged NSCLC

Crizotinib. In 2011, the FDA approved the ALK inhibitor crizotinib for the treatment of NSCLC harboring *EML4-ALK* fusions. The efficacy of crizotinib in ALK-positive NSCLC was initially seen in an expanded cohort of a multicenter phase I study.[174] Tumor specimens from approximately 1500 patients with advanced NSCLC were screened for *ALK* translocations. A total of 82 patients, most of whom were treated previously, were enrolled. The radiographic RR was 57% and stable disease was 33%, yielding a clinical benefit rate of 90%. The estimated 6-month PFS rate was 72%. A retrospective analysis looked at outcomes of 82 patients with *ALK*-positive disease who were given crizotinib and compared them with 23 control patients with *ALK*-positive disease who did not receive crizotinib. Survival of 30 patients with *ALK*-positive disease who were given crizotinib in the second- or third-line setting was significantly longer than in the 23 control patients with *ALK*-positive disease given any second-line therapy other than crizotinib (median OS, not reached vs. 6 months; 1-year OS, 70% vs. 44%; and 2-year OS, 55% vs. 12%; p = 0.004).[175] A phase III clinical trial (PROFILE 1007) confirmed that crizotinib had a higher RR and PFS compared with investigators' choice of docetaxel or pemetrexed for patients with *ALK*-positive tumors whose disease progressed after first-line chemotherapy (ORR, 65% vs. 20%; median PFS, 7.7 vs. 3 months; p < 0.0001).[176] As for first-line treatment, in a phase III trial (PROFILE 1014), crizotinib improved median PFS compared with standard platinum and pemetrexed chemotherapy (10.9 months vs. 7 months; HR, 0.45; p < 0.001) in *ALK*-rearranged metastatic NSCLC.[177] Thus, crizotinib should be employed as first-line treatment in *ALK*-rearranged NSCLC.

A high RR (72%) and exceptional median PFS (19.2 months) for patients with NSCLC harboring a *ROS1* gene rearrangement treated with crizotinib has also been observed in clinical trials; and crizotinib is now FDA approved for advanced ROS1 rearranged NSCLC.[47]

Ceritinib. Ceritinib is an oral TKI of ALK that is 20 times more potent than crizotinib. The FDA approved ceritinib in 2014 for the treatment of *ALK*-rearranged NSCLC after progression of the disease on crizotinib. This approval was based on a clinical trial in metastatic *ALK*-rearranged NSCLC showing an RR of 58% for patients who received at least 400 mg of ceritinib daily. For patients who had progressive disease on crizotinib, the RR was 56% and PFS 7.0 months.[178]

Alectinib. Alectinib is another oral TKI of ALK that is more potent than crizotinib. The FDA approved alectinib in 2015 for the treatment of *ALK*-rearranged NSCLC after progression of the disease on crizotinib. This approval was based on clinical trials in metastatic *ALK*-rearranged NSCLC showing an RR of 50% in patients with progressive disease on crizotinib with a median duration of response of 11.2 months.[179] It is also highly active in the CNS, with a CNS response rate of 64.0% (95% CI; 49.2, 77.1), a CNS disease control rate of 90.0% (95% CI; 78.2, 96.7), and a median CNS duration of response of 10.8 months in a pooled analysis.[180] Alectinib is currently being studied in the first-line setting and has superior PFS compared to crizotinib in two phase III, randomized clinical trials in the first-line setting (the ALEX study and the J-ALEX study). Impressively, in the ALEX study, investigator-assessed median PFS was not reached for alectinib (95% CI; 17.7 months to not estimable) and was 11.1 months for crizotinib (HR, 0.47; 95% CI; 0.34, 0.65; $p < 0.001$).[181] In the Japanese J-ALEX study results were comparable with median PFS not reached (95% CI: 20.3-Not Estimated) with alectinib while it was 10.2 months (95% CI: 8.2-12.0) with crizotinib.[182] Overall survival data are not yet mature, but based on these strongly positive studies in terms of PFS, alectinib will likely become the standard first-line treatment for *ALK*-rearranged NSCLC.

Additional ALK Inhibitors in Development. Brigatinib is another next-generation ALK inhibitor that was granted accelerated approval by the FDA for crizotinib-refractory *ALK*-rearranged NSCLC. This approval was based on the ALTA study, in which 222 patients were randomly assigned to brigatinib at doses of either 90 mg once daily (112 patients) or 180 mg once daily following a 7-day lead-in at 90 mg once daily (110 patients).

On independent review, the ORR was 48% (95% CI; 39, 58) in the 90-mg arm and 53% (95% CI, 43, 62) in the 180-mg arm. Median progression-free survival was 9.2 months (95% CI, 7.4 to 15.6) and 12.9 months (95% CI, 11.1 to not reached) in the 90-mg arm and 180-mg arm, respectively.[183] A small subset of patients (6%) experienced early pulmonary toxicity, which is why the 90-mg daily lead-in dose escalating to 180 mg daily is the FDA-approved dose.

Lorlatinib has in vitro activity against a broad spectrum of *ALK-TKI* resistance mutations and has received breakthrough designation for the treatment of *ALK*-rearranged NSCLC in patients who have previously received an ALK inhibitor. In a phase I–II trial, lorlatinib demonstrated activity in *ALK*-rearranged NSCLC, including *ALK* tumor harboring the *ALK G1202R* mutation that is refractory to other ALK-TKIs, such as alectinib.[184]

Oligoprogressive Disease in Metastatic *EGFR*-Mutant and *ALK*-Rearranged NSCLC. Among patients with tumors harboring *ALK* translocations or *EGFR* mutations treated with TKIs, occasionally progression occurs in limited sites, such as the CNS, while the remainder of the cancer remains controlled (oligoprogressive disease). In these situations, irradiating the site of progression or resecting isolated brain metastasis, for example, and then continuing the TKI may result in a lengthening of clinical benefit.[185]

Older Patients. Treatment of patients age 65 or older tends to be complicated by comorbid conditions and by patients taking multiple medications. However, studies show that fit older patients are likely to benefit as much from chemotherapy as their younger counterparts. Evidence from a phase III study in which patients older than age 70 with advanced disease were randomly assigned to best supportive care or to weekly vinorelbine indicated that patients who received vinorelbine had better scores on quality-of-life scales than the control group, as well as fewer lung cancer–related symptoms. However, patients in the chemotherapy group experienced more severe toxicity-related symptoms.[186] There was a significant survival advantage for patients who received vinorelbine (median survival, 28 weeks vs. 21 weeks). More recently, it has been shown that, despite an increase in toxic effects, platinum-based doublet chemotherapy yields superior outcomes to single-agent chemotherapy in fit elderly individuals. In a phase III trial conducted by the Intergroupe Francophone de Cancerologie Thoracique, 451 previously untreated patients ages 70 to 89 (median, 77) with ECOG PS of 0 to 2 were randomly assigned to carboplatin/paclitaxel or monotherapy with vinorelbine or gemcitabine. A total of 27% of patients in each arm had an ECOG PS of 2. Median OS was 10.3 months in the carboplatin/paclitaxel arm, compared with 6.2 months in the monotherapy arm (HR, 0.64; 95% CI; 0.62, 0.78; $p < 0.0001$).[187] Subset analyses of other randomized trials show that the RR, toxicity, and survival for fit older patients receiving a platinum-based treatment for NSCLC appears to be similar to the same variables for younger patients; however, for patients age 70 or older, comorbidity is greater and the frequency of leukopenia and neuropsychiatric toxicity are higher. Hence, advanced age alone should not preclude appropriate treatment.

Patients with Poor PS. The survival rates for patients with a poor PS (ECOG PS of 2, 3, or 4) are significantly shorter than the rates for patients with a good PS. Patients with a poor PS also are less likely to be able to tolerate treatment. Retrospective subset analyses suggest that patients with a PS of 2 may derive a modest benefit from chemotherapy. However, given the overall short survival—particularly for patients with a PS of 3 or 4—and the minimal benefit derived from chemotherapy, these patients probably should not be treated outside of a clinical study. A possible exception is patients with tumors harboring activating *EGFR* mutations or ALK or ROS1 fusions, especially if poor PS is a result of the lung cancer. In general, EGFR and ALK inhibitors may be better tolerated than conventional chemotherapy and, for these patients, may result in rapid clinical and radiographic responses.

One clinical trial compared carboplatin (AUC 5) and pemetrexed to pemetrexed alone for patients with stage IV NSCLC with a Zubrod PS of 2. A substantial improvement was observed in median OS with the combination compared with pemetrexed alone (9.3 vs. 5.3 months; $p = 0.001$).[188]

Duration of Therapy and Maintenance Therapy. The role of maintenance treatment for patients with metastatic NSCLC remains under active investigation. Although results from earlier randomized studies did not show a survival difference with prolonged (more than six) cycles of chemotherapy compared with fewer (four to six) cycles (Table 8-11),[189-194] several additional clinical trials have challenged that paradigm. Two maintenance strategies have been investigated: so-called switch maintenance and continuation maintenance. The goal of continuation maintenance is to delay progressive disease by continuing an effective agent. Switch maintenance seeks to initiate a new second-line agent early to delay onset of progressive disease.

Table 8-11 **Selected Randomized Trials of Maintenance Therapy for Advanced Non-Small Cell Lung Cancer**

Reference	Treatment Comparison	Type of Trial	Median Survival (months)	1-Year Survival (%)	p Value
Westeel et al.[189]	6 months of vinorelbine	Switch maintenance	13	53	Not significant
	Best supportive care		10	40	
Socinski et al.[190]	Four cycles of carboplatin plus paclitaxel	Continuation maintenance	7	28	Not significant
	Carboplatin plus paclitaxel until disease progression		9	35	
Smith et al.[191]	Three cycles of mitomycin C, vindesine, and cisplatin	Three cycles vs. six cycles	6	22	Not significant
	Six cycles of same regimen		7	25	
Fidias et al.[192]	Four cycles of gemcitabine plus carboplatin, with docetaxel on disease progression	Switch maintenance	9.1	38	Not significant
	Four cycles of gemcitabine plus carboplatin, followed immediately by docetaxel for six cycles		11.9	48.5	
Ciuleanu et al.[193]	Four cycles of platinum-based therapy, followed by placebo	Switch maintenance	10.6		0.012
	Four cycles of platinum-based therapy, followed by pemetrexed		13		
Cappuzzo et al.[155]	Four cycles of platinum-based therapy, followed by placebo	Switch maintenance	11		0.0088
	Four cycles of platinum-based therapy, followed by erlotinib		12		
Paz-Ares et al.[194]	Four cycles of cisplatin and pemetrexed, followed by placebo	Continuation maintenance	11		0.0195
	Four cycles of cisplatin and pemetrexed, followed by pemetrexed		13.9		

Three trials have been reported that suggest a benefit with prolonged-duration therapy.[195-197] In one study, patients who had stable or responsive disease following their initial four cycles of gemcitabine/carboplatin were randomly assigned to receive maintenance docetaxel immediately following induction chemotherapy or at progression.[192] Median PFS for immediate docetaxel was significantly greater than for delayed docetaxel (5.7 vs. 2.7 months; p = 0.0001). Median OS for immediate docetaxel also was greater than for delayed docetaxel, although the difference was not significant (12.3 months vs. 9.7 months; p = 0.0853). Interestingly, the median OS for patients assigned to immediate docetaxel and those assigned to delayed docetaxel who received the specified therapy at the time of progression was identical. These findings raise the question of whether switch maintenance therapy may actually be similar to early use of second-line therapy at the first sign of progressive disease. A second study investigating maintenance pemetrexed employed a slightly different trial design.[193] A total of 633 patients with stable or responsive disease were randomly assigned in a 2:1 fashion to observation or pemetrexed following induction chemotherapy with platinum-based chemotherapy. Pemetrexed resulted in significantly better survival (13.4 months vs. 10.6 months; HR, 0.79; 95% CI; 0.65, 0.95; p = 0.012) and PFS. The improvement in survival was

observed primarily among patients with nonsquamous histology (15.5 months vs. 10.3 months, OS HR, 0.70; it was not the primary endpoint, but it was a preplanned secondary analysis). A third phase III study has examined the role of erlotinib maintenance therapy.[155] In the Sequential Tarceva in Unresectable NSCLC (SATURN) trial, 889 patients whose disease did not progress during first-line platinum-based chemotherapy were randomly assigned to receive erlotinib or placebo. There was a statistically significant improvement in PFS (HR, 0.71; 95% CI; 0.62, 0.82; $p < 0.001$) and OS (HR, 0.81; 95% CI; 0.70, 0.95; $p = 0.009$), with a median OS of 12 months (erlotinib) compared with 11 months (placebo). However, in one phase III clinical trial (IUNO), OS and PFS with maintenance erlotinib were not superior to those for second-line erlotinib treatment (OS, 9.7 vs. 9.5 months; HR, 1.02; 95% CI; 0.85, 1.22; log-rank $p = 0.82$) in patients whose tumor did not harbor an *EGFR*-activating mutation.[198] Based on the failure of erlotinib maintenance to improve any clinical outcomes, the FDA modified the approved indication of erlotinib to NSCLC harboring *EGFR*-activating mutations.

A phase III clinical trial (PARAMOUNT) randomly assigned patients with advanced nonsquamous NSCLC to four cycles of cisplatin and pemetrexed followed by observation compared with continuation maintenance pemetrexed every 3 weeks until progression or intolerable toxic effects occurred. Continuation pemetrexed improved PFS, with a median PFS of 4.4 months compared with 2.8 months (HR, 0.62; 95% CI; 0.49, 0.79; $p < 0.0001$), and OS, with a median OS of 16.9 months compared with 14.0 months after induction (HR, 0.78; 95% CI; 0.64 to 0.96; $p = 0.0195$).[194]

Currently, switch-maintenance therapy with pemetrexed is FDA-approved, as is continuation maintenance with pemetrexed. This new treatment paradigm has raised many questions, including whether the apparent benefit is a result of the timing of therapy or the higher rates of administering effective second-line agents and how maintenance strategies should be implemented for patients receiving pemetrexed- or bevacizumab-containing first-line regimens.

Number of Drugs. Although findings from numerous phase I and II studies have demonstrated the feasibility of triplet chemotherapy combinations, the results of most randomized trials have not demonstrated a survival advantage and have been at the expense of enhanced toxicity and cost. Thus, regimens that employ three cytotoxic drugs cannot be routinely recommended for patients with advanced NSCLC.

In randomized studies, single-agent paclitaxel, gemcitabine, or docetaxel was compared with double-agent cisplatin plus paclitaxel, gemcitabine, or docetaxel.[195-199,199-203] Findings from all of these trials showed a survival advantage for the two-drug regimens. These results can be interpreted either as demonstrating the advantages of cisplatin for the treatment of advanced NSCLC or as evidence of the superiority of doublet compared with single-agent therapy.

Cisplatin Compared with Carboplatin. Meta-analyses have suggested that cisplatin may have a modest benefit in terms of survival as compared with carboplatin for patients with advanced disease, albeit with a different toxicity profile.[204,205] In one direct comparison, a phase III trial of the Spanish Lung Cancer Group randomly assigned patients to paclitaxel with either cisplatin or carboplatin. Efficacy endpoints showed superiority of the cisplatin-based regimen with about a 1-month improvement in OS.[205] Although this difference may be of limited clinical consequence for patients with metastatic disease, it may be more important in the adjuvant or locally advanced setting, where cure is the goal. In metastatic, incurable disease, where the goal is palliation, carboplatin is acceptable, since administration of cisplatin with higher rates of renal insufficiency, neuropathy, and hearing loss may impact quality of life.

Nonplatinum-Based Regimens. Given the toxicities associated with cisplatin, there has been considerable interest in utilizing nonplatinum agents. In general, randomized studies have failed to show superiority of any nonplatinum regimen compared with platinum-based, third-generation regimens, although toxicities vary.[206] Consequently, nonplatinum regimens are not commonly used in current practice.

KEY POINTS

- Cytotoxic chemotherapy improves survival and symptoms for patients with metastatic NSCLC.
- Platinum-based doublet chemotherapy is considered standard of care and typically administered for four to six cycles for patients with good PS.
- Bevacizumab (15 mg/kg every 3 weeks) prolongs survival when administered with carboplatin/paclitaxel to eligible patients with advanced non–squamous cell carcinoma as demonstrated in a large randomized trial.
- Fit elderly patients tolerate chemotherapy and derive the same survival benefit as their younger counterparts.
- EGFR-TKIs should be considered standard of care in the first-line setting for patients with tumors harboring *EGFR*-activating mutations.
- Crizotinib should be considered standard of care in the first-line setting for patients with tumors harboring ALK and ROS1 fusions. For ALK fusions recent clinical trials indicate that next-generation ALK inhibitors such as alectinib may supplant crizotinib for first-line therapy of ALK rearranged NSCLC.
- Pembrolizumab is standard first-line therapy for metastatic NSCLC with high PD-L1 expression (≥ 50%).

Second- and Third-Line Therapy and Beyond

Currently, four agents (docetaxel, pemetrexed, and ramucirumab in combination with docetaxel and nivolumab) are approved for second-line therapy for advanced NSCLC regardless of the tumor's molecular characteristics. In two randomized trials, second-line docetaxel was evaluated for patients who did not respond to first-line therapy. In one trial, docetaxel at a dose of 75 mg/m^2 significantly prolonged survival compared with best supportive care.[207] Although this dose of docetaxel resulted in an RR of only 7%, improved time to disease progression and survival was seen for patients treated with docetaxel. Moreover, docetaxel also improved quality of life and reduced weight loss and the need for pain medications. Previous exposure to paclitaxel did not affect response to docetaxel, suggesting non–cross-resistance between the two agents. In the second study, docetaxel was compared with either vinorelbine or ifosfamide.[208] Although OS was not significantly different among the three groups, the 1-year survival associated with docetaxel was notably better than that associated with the control treatment (32% vs. 19%; p = 0.025).

For a number of years, single-agent chemotherapy was considered the standard treatment for metastatic NSCLC after progression on platinum-based chemotherapy. Until recently, a

large number of clinical trials pairing a second drug with single-agent chemotherapy failed to show an OS benefit. Ramucirumab (a monoclonal antibody that targets VEGFR2) was the first drug to show an OS benefit when paired with chemotherapy in this setting. This antiangiogenesis agent, in combination with docetaxel has been approved for the treatment of metastatic NSCLC with progression of disease on or after platinum-based treatment. Unlike bevacizumab, which is contraindicated in squamous histology NSCLC, ramucirumab is approved and has benefit in this disease. Approval was based on the randomized, phase III REVEL trial, which randomly assigned 1253 patients with stage IV NSCLC after progression on platinum-based chemotherapy to docetaxel with or without ramucirumab. OS (median 10.5 vs. 9.5 months; $p = 0.023$), PFS (median, 4.5 vs. 3.0 months; $p < 0.0001$), and RR (23% vs. 14%; $p < 0.001$) were all improved with the addition of ramucirumab.[60]

A phase III study compared pemetrexed with docetaxel.[209] Although no difference in survival was observed (1-year survival of 29.7% in both arms), patients randomly assigned to receive docetaxel were more likely to have febrile neutropenia (12.7% vs. 1.9%; $p = 0.001$), infections (3.3% vs. 0%; $p = 0.004$), and hospitalizations for neutropenic fevers (13.4% vs. 1.5%; $p = 0.001$) than patients who received pemetrexed, resulting in the FDA's approval of pemetrexed as second-line therapy for NSCLC.

In a randomized, placebo-controlled, double-blind clinical trial conducted by the National Cancer Institute of Canada (BR.21), patients with stage IIIB or IV NSCLC and a PS of 0 to 3 who had received one or two prior chemotherapy regimens were randomly assigned in a 2:1 ratio to receive either oral erlotinib at a dose of 150 mg daily or placebo.[83] Median survival rates were 6.7 months and 4.7 months for erlotinib and placebo, respectively (HR, 0.70; $p < 0.001$). The only predictive factor for survival benefit was smoking status, for which current or former smokers had an HR of 0.9, and never-smokers had an HR of 0.4. The VeriStrat serum proteomic test can predict lack of benefit to second-line erlotinib for patients with NSCLC unselected for an EGFR-activating mutation. In the prospective randomized PROSE trial, patients with a poor VeriStrat proteomic classification had worse OS when treated with erlotinib compared with standard chemotherapy (HR, 1.72; $p = 0.022$).[210] No differences in survival were noted with a VeriStrat good classification.

As discussed earlier, approval of erlotinib has been narrowed by the FDA to canonical *EGFR*-activating mutations. However, the irreversible EGFR-TKI afatinib has been granted FDA approval for the treatment of advanced squamous NSCLC as second-line treatment. Approval was based on a large randomized, phase III study (LUX-LUNG 8).[211] This trial randomly assigned 795 patients with advanced squamous cell lung cancer to afatinib or erlotinib. PFS was the primary endpoint and was significantly longer with afatinib than with erlotinib (median, 2.4 months vs. 1.9 months; HR 0.82; $p = 0.0427$). OS was also modestly greater in the afatinib group than in the erlotinib group (median, 7.9 months vs. 6.8 months; $p = 0.0077$).

The following points may be taken into consideration: even in highly clinically enriched populations, *EGFR* mutations occur in only about 60% of patients, and *EGFR* mutations occur in up to 10% of patients who lack typical clinical predictors[28,212]; for patients with tumors harboring *EGFR* mutations, PFS is similar if an EGFR-TKI is administered as first-, second-, or third-line therapy[168]; in the first-line setting, patients with *EGFR* wild-type tumors have superior PFS with conventional chemotherapy compared with EGFR-TKI therapy.[83] Afatinib is approved for squamous histology advanced NSCLC, but erlotinib did not show a benefit in the IUNO[198] trial in *EGFR* wild-type advanced NSCLC. EGFR-TKIs are generally well tolerated, with rash and diarrhea the principal toxic effects. Interstitial pneumonitis occurs rarely in North American and western European populations.

Immunotherapy: Second Line and Beyond

Immunotherapy has assumed a prominent role in the treatment of lung cancer. Immune checkpoint inhibitors such as PD-1 and PD-L1 antibodies were the first immunotherapies approved for the treatment of advanced NSCLC. The PD-1 checkpoint acts to regulate T-cell antigen recognition in the tumor microenvironment. Tumors can express the ligand to PD-1 (PD-L1) that binds to PD-1 to downregulate the immune response within the tumor microenvironment. Three PD-1/PD-L1 antibodies are currently approved for second-line treatment of advanced NSCLC: atezolizumab (PD-L1), nivolumab (PD-1), and pembrolizumab (PD-1). As discussed previously, pembrolizumab is the only PD-1 antibody approved for first-line treatment.

Nivolumab is a monoclonal antibody to PD-1 and was the first immunotherapy approved for the treatment of lung cancer. It is currently approved for advanced NSCLC with progression during or after platinum-based chemotherapy. The approval in squamous NSCLC was based on the phase III CHECKMATE 017 trial, which randomly assigned 272 patients with stage IV squamous cell lung cancer with progression during or after platinum-based chemotherapy to nivolumab or docetaxel. OS was substantially improved (median, 9.2 vs. 6.0 months, $p < 0.001$; HR, 0.59; 1-year OS, 42% vs. 24%).[213] RRs are not high (approximately 17%), but some patients can achieve long-term clinical benefit. A similar phase III clinical trial randomly assigned 588 patients with advanced nonsquamous NSCLC (CHECKMATE 057) and demonstrated an impressive OS benefit with nivolumab as compared with docetaxel. Median OS was 12.2 months (95% CI; 9.7, 15.0) in the nivolumab group and 9.4 months (95% CI; 8.1, 10.7) in the docetaxel group (HR, 0.73; 95% CI; 0.59, 0.89; $p = 0.002$).[214] At 1 year, the OS was 51% (95% CI; 45, 56) with nivolumab compared to 39% (95% CI; 33, 45) with docetaxel. The RR was 19% with nivolumab compared to 12% with docetaxel ($p = 0.02$). Interestingly, median PFS did not favor nivolumab over docetaxel (median, 2.3 and 4.2 months, respectively), but the rate of PFS at 1 year was higher with nivolumab (19% and 8%, respectively). The clear separation of the Kaplan–Meier curve at later points past the median for OS and PFS highlights that a subset of patients with advanced NSCLC can derive long-term benefit from PD-1 blockade. In advanced squamous NSCLC, tumor PD-L1 expression was not predictive of benefit. However, in advanced nonsquamous NSCLC, tumor-membrane expression of the PD-1 ligand was associated with greater efficacy. Treatment-related adverse events of grade 3 or 4 were reported in 10% of patients in the nivolumab group compared to 54% of patients in the docetaxel group. Immune-mediated adverse events, including pneumonitis, endocrine dysfunction, hepatitis, and colitis, are potential side effects; immune-mediated pneumonitis is the most frequent cause of treatment-related death (approximately 2%).[215]

Pembrolizumab is another PD-1 inhibitor approved for the treatment of advanced NSCLC. Among 495 patients who received pembrolizumab in the KEYNOTE-001 trial, ORR was 19.4%, with median duration of response of 12.5 months, median PFS of 3.7 months, and median OS of 12 months. With pembrolizumab, tumor expression of PD-L1 correlated with efficacy; for patients whose proportion of tumor PD-L1 expression was at least 50%, ORR was over 45%.[216] In the larger KEYNOTE-010 trial, patients with advanced NSCLC postprogression during or after platinum-based chemotherapy and tumors expressing at least 1% PD-L1 were enrolled. Of the 1034 patients, 345 were allocated to pembrolizumab 2 mg/kg, 346 were allocated to pembrolizumab 10 mg/kg, and 343 were allocated to docetaxel. Median OS was 10.4 months with pembrolizumab 2 mg/kg, 12.7 months with pembrolizumab 10 mg/kg, and 8.5 months with docetaxel. OS was longer for pembrolizumab 2 mg/kg and for pembrolizumab 10 mg/kg as compared with docetaxel (HR, 0.71, 95% CI; 0.58, 0.88; $p = 0.0008$; and HR, 0.61,

95% CI; 0.49, 0.75; p<0.0001, respectively).[217]

Among patients with at least 50% of tumor cells expressing PD-L1, OS was significantly longer with pembrolizumab than with docetaxel (2 mg/kg: median, 14.9 months vs. 8.2 months; HR, 0.54; 95% CI; 0.38, 0.77; p = 0.0002; 10 mg/kg: 17.3 months vs. 8.2 months; HR, 0.50; 95% CI; 0.36, 0.70; p < 0.0001). Likewise, for this patient population, PFS was significantly longer with pembrolizumab than with docetaxel (2 mg/kg: median, 5.0 months vs. 4.1 months; HR, 0.59; 95% CI; 0.44, 0.78; p = 0.0001; 10 mg/kg: 5.2 months vs. 4.1 months; HR, 0.59, 95% CI; 0.45, 0.78; p < 0.0001). Approval for second-line pembrolizumab for patients with NSCLC harboring 1% or more PD-L1 expression by the companion diagnostic DAKO22C3 antibody is based on this KEYNOTE-010 trial.

In comparison with nivolumab, which was approved without a companion diagnostic for advanced NSCLC, pembrolizumab was granted accelerated approval for patients with advanced NSCLC whose tumors express PD-L1 on IHC. Several other PD-1 and g63 PD-L1 antibodies are in advanced stages of clinical development, with different IHC companion diagnostic assays. Efforts to harmonize differing companion assays for detection of PD-L1 and tumor-infiltrating lymphocytes to associate with clinical benefit for these immunotherapies are underway. PD-L1 IHC assays for lung cancer were compared in the Blueprint Project, which was undertaken by the International Association for the Study of Lung Cancer. It found agreement in patient tumor comparison for nivolumab and pembrolizumab companion PD-L1 immunohistochemistry (For ≥ 1% PD-L1 expression 94.7% agreement between DAKO 28-8 and DAKO 22C3 antibodies by IHC).[218,219]

Approval of the PD-L1 antibody atezolizumab in advanced NSCLC is based on the phase III OAK trial, which randomly assigned 850 patients to receive either atezolizumab or docetaxel. OS was significantly longer with atezolizumab compared with docetaxel (median OS, 13.8 months; 95% CI; 11.8, 15.7; vs. median OS, 9.6 months; 95% CI; 8.6, 11.2; HR, 0.73; 95% CI; 0.62, 0.87; p = 0.0003). OS in the TC1/2/3 or IC1/2/3 population was also improved with atezolizumab compared with docetaxel (median OS, 15.7 months; 95% CI; 12.6, 18.0 with atezolizumab; vs. median OS, 10.3 months; 95% CI; 8.8, 12.0] with docetaxel; HR, 0.74; 95% CI; 0.58, 0.93]; p = 0.0102). Patients in the PD-L1 low or undetectable subgroup (TC0 and IC0) also had improved survival with atezolizumab (median OS, 12.6 months vs. 8.9 months; HR, 0.75; 95% CI; 0.59, 0.96). Improvement in OS was similar in patients with squamous histology (HR, 0.73; 95% CI; 0.54, 0.98]; 112 patients in the atezolizumab group and 110 in the docetaxel group) or non–squamous histology (HR, 0.73; 95% CI; 0.60, 0.89]; 313 and 315 patients, respectively). Fewer patients had treatment-related grade 3 or 4 adverse events with atezolizumab (90 [15%] of 609 patients) versus docetaxel (247 [43%] of 578 patients).[220] Additional PD-L1 antibodies, such as avelumab and durvalumab are in development and are being studied in later-stage clinical trials.

ISOLATED BRAIN METASTASES

For patients with controlled disease outside the brain who have an isolated cerebral metastasis in a resectable area, resection followed by whole-brain radiation therapy is superior to whole-brain radiation therapy alone and may improve survival. Another therapeutic option for tumors smaller than 3 cm in diameter is stereotactic radiosurgery (SRS), which uses a stereotactic fixation system and non-coplanar convergent beams that create a sharp peripheral dose fall-off along the edge of the target. SRS spares the surrounding normal tissue, enabling the use of a single, large fraction of radiation. Previous trials suggested that survival is improved when SRS

is administered with whole-brain radiation therapy. However, in a meta-analysis from the three largest randomized clinical trials of SRS and whole-brain radiation therapy that included patients with solid tumors and one to four brain metastases, SRS alone was superior to SRS plus whole-brain radiation therapy for OS in patients age 50 or younger (HR, 0.64; 95% CI; 0.42, 0.99).[221]

PARANEOPLASTIC SYNDROMES

Humoral-associated hypercalcemia is most commonly related to squamous cell cancers and least commonly to small cell lung cancer. Manifestations of hypercalcemia depend more on the rate of onset than on the degree of elevation and include mental status changes, polydipsia, gastrointestinal symptoms, and nephrolithiasis. In addition to treatment of the malignancy, therapy includes intravenous hydration and administration of bisphosphonates and calcitonin. Use of diuretics, which may exacerbate volume depletion, is discouraged. Hypertrophic pulmonary osteoarthropathy is characterized by clubbing of the digits and, when severe, painful periostitis of the long bones. Hypertrophic pulmonary osteoarthropathy is most common with adenocarcinoma, although it is not pathognomonic for cancer; it may also occur with other pulmonary diseases.

KEY POINTS

- PD-1 or PD-L1 blockade with nivolumab, atezolizumab, or pembrolizumab improves OS compared with docetaxel as second-line treatment of advanced NSCLC and is approved for treatment in this setting. Pembrolizumab is currently the only PD-1/PD-L1 antibody approved for first-line treatment of patients with advanced NSCLC whose tumors harbor PD-L1 expression of ≥ 50%.
- The addition of the VEGFR2 antibody ramucirumab to docetaxel modestly improves OS.

SMALL CELL LUNG CANCER

STAGING

Small cell lung cancer is usually classified as either limited or extensive because of its propensity to metastasize quickly and the fact that micrometastatic disease is presumed to be present in all patients at diagnosis. Limited-stage disease is typically defined as being encompassed within one radiation port and is usually limited to the hemithorax and to regional nodes, including mediastinal and ipsilateral supraclavicular nodes. Extensive-stage disease is usually defined as disease that has spread outside those areas. Though small cell lung cancer is typically graded using the Veterans Administration staging system of limited-stage disease compared to extensive-stage disease, current guidelines also recommend staging by the AJCC TNM staging system.

PROGNOSTIC FACTORS

As with NSCLC, the major pretreatment prognostic factors for small cell lung cancer are stage of disease, PS, serum lactate dehydrogenase, and sex. If the patient's initial poor PS is the result of the underlying malignant disease, symptoms often disappear quickly with treatment,

resulting in a net improvement in quality of life. However, major organ dysfunction from nonmalignant causes often results in a patient's inability to tolerate chemotherapy.

PRETREATMENT EVALUATION

Common sites of metastases include the brain, liver, bone marrow, and bone. For this reason, a full staging workup consists of a complete blood-cell count, liver-function tests, CT scan with contrast of chest and upper abdomen, CT or MRI of the brain, and consideration of PET or bone scan. Bone marrow aspiration is not recommended unless an otherwise unexplained hematologic abnormality is present (e.g., nucleated red blood cells are seen on peripheral-blood smear, neutropenia, or thrombocytopenia).

This complete workup should probably not be undertaken unless the patient is a candidate for combined-modality treatment with chest radiation and chemotherapy, the patient is being evaluated for a clinical study, or the information is helpful for prognostic reasons. If the patient is not a candidate for combined-modality treatment or a clinical study, it is usually appropriate to stop the staging at the first evidence of extensive-stage disease. In addition, because the chance of metastasis to the bone marrow only is less than 10%, biopsy of bone marrow is usually unnecessary except in certain cases of limited-stage disease in which demonstration of localized disease may be important for prognostic or psychosocial reasons or for clinical trial eligibility. PET scanning can provide useful information and can replace bone scanning.

TREATMENT

The cornerstone of treatment for patients with small cell lung cancer is combination platinum-based chemotherapy. Until recently, no clear survival advantage was demonstrated for any regimen. With standard chemotherapy—etoposide with either cisplatin or carboplatin—an ORR of 75 to 90% and a complete RR of 50% for localized disease can be anticipated. For extensive-stage disease, an ORR of approximately 50% and a complete or near-complete RR of approximately 25% are common. Tumor regressions usually occur quickly, often within the first two cycles of treatment, and provide rapid palliation of tumor-related symptoms. Despite these high RRs, median survival time remains approximately 14 months for limited-stage disease and 9 months for extensive-stage disease. Less than 5% of patients with extensive-stage disease survive more than 2 years. Although initial results of treatment with irinotecan plus cisplatin showed improved survival (compared with etoposide plus cisplatin) in a Japanese population, these results were not confirmed in U.S. studies.[222,223]

Dose Intensity

Dose intensity has been evaluated in a number of randomized studies. Most—although not all—failed to show a benefit in survival, regardless of whether the chemotherapy was delivered in higher doses or more frequently (dose density). In addition, a meta-analysis of chemotherapy dose intensity for small cell lung cancer in which doses not requiring bone marrow transplantation support were evaluated showed no consistent correlation between dose intensity and outcome.[224] The role of marrow-ablative doses of chemotherapy with subsequent progenitor cell replacement (e.g., autologous bone marrow transplantation) was evaluated in several phase I and II clinical trials, and results for survival were not promising. In a randomized, phase III study comparing high-dose chemotherapy with conventional-dose chemotherapy, the high-dose regimen with stem cell support prolonged relapse-free survival but

not OS.[225]

Duration and Maintenance of Therapy

The findings from most randomized studies do not show a survival benefit for prolonged administration of chemotherapy or for consolidation chemotherapy. The results of several randomized studies have demonstrated no survival benefit for prolonged first-line treatment when compared with treatment initiated on relapse. The optimal duration of treatment for patients with small cell lung cancer is four to six cycles.

Second-Line Therapy

The chance of response to second-line agents correlates with the relapse occurred following induction chemotherapy; patients who experience relapse more than 3 months after completing first-line chemotherapy are considered to have sensitive disease and are more likely to have a response than patients who experience disease progression during or within 2 to 3 months after receiving a first-line regimen (resistant disease). The only drug approved for second-line therapy for small cell lung cancer in the United States is topotecan, which is associated with a 20 to 40% RR for patients with sensitive disease and with a median survival of 22 to 27 weeks.[226] A phase III trial comparing the novel anthracycline amrubicin to topotecan as second-line treatment of small cell lung cancer showed no difference in OS, although PFS was modestly superior.[227] Temozolomide also has modest activity in second- or third-line treatment for extensive-stage small cell lung cancer, including among patients with platinum-refractory disease and brain metastases. As in glioma, tumor methylguanine methyltransferase (MGMT) methylation status may predict benefit.[228] For patients with refractory disease, the RR in phase II studies has ranged from 3 to 13%. Median survival is approximately 20 weeks. Patients with sensitive disease also may have a response to repeat treatment with the first-line regimen. Other drugs that have modest activity in phase II studies in the second-line setting include combination cyclophosphamide/doxorubicin/vincristine and single-agent paclitaxel.

Immune checkpoint inhibitors (both PD-1/PD-L1 and cytotoxic T-lymphocyte antigen 4 [CTLA-4] antibodies) have been studied alone and in combination in extensive-stage small cell lung cancer. Nivolumab in combination with the CTLA-4 antibody ipilimumab appears to increase the response rate (26% ORR) and duration of response, but with an increase in immune-related adverse events.[229] Given the propensity for paraneoplastic syndromes in small cell lung cancer and the potentially fatal immune-related adverse events, caution must be used when treating patients who have small cell lung cancer with immune checkpoint inhibitors.

Older Patients

As is the case with NSCLC, treatment of older patients is often complicated by poor PS and comorbid conditions. However, unlike older patients with NSCLC, older patients with small cell lung cancer may not benefit from single-agent therapy. Two randomized studies in which single-agent etoposide was compared with standard combination chemotherapy were stopped early because the single-agent arm was associated with a shorter median and long-term survival and a decreased quality of life.[230,231] Therefore, the standard treatment of fit older patients remains combination chemotherapy administered on a 3-week schedule.

Chemotherapy plus Radiation to the Thorax

Radiation therapy to the thorax in addition to chemotherapy is associated with a small but significant improvement in long-term survival for patients with limited-stage disease, providing an additional 5% improvement in 3-year survival compared with chemotherapy alone.[232] Chemotherapy given concurrently with thoracic radiation is superior to sequential chemoradiation in terms of survival; however, it is associated with substantially more esophagitis and hematologic toxicity. To decrease the morbidity associated with such treatment, as well as to improve overall outcome, investigative efforts have focused on optimizing the radiation fields, fractionation, and schedule. In one randomized study, twice-daily hyperfractionated radiation was compared with a once-daily schedule; both were administered concurrently with four cycles of cisplatin and etoposide. Survival was significantly higher with the twice-daily regimen (median survival, 23 months vs. 19 months; 5-year survival, 26% vs. 16%), albeit at the expense of more grade 3 esophagitis.[233] In another randomized trial, early administration of thoracic radiation as part of the combined-modality therapy for limited-stage disease was superior to late or consolidative thoracic radiation.[234] These data suggest that patients with good PS who have limited disease should receive concurrent chemoradiation, preferably administered twice daily in an accelerated, hyperfractionated approach. However, because of logistical considerations, once-daily radiation is the most commonly used treatment schedule in clinical practice.

A randomized clinical trial of 498 patients with extensive-stage small cell lung cancer with a response to platinum-based induction chemotherapy showed that thoracic radiotherapy, when added to prophylactic cranial radiation, significantly increased PFS. Though median OS, regardless of whether patients received thoracic radiotherapy, was 8 months, and OS at 1 year was not significantly prolonged (33% vs. 28%; $p = 0.066$), an improvement in 2-year OS was statistically significant (13% vs. 3%; $p = 0.04$).[235] Some of the features of the overall patient population were atypical for extensive-stage small cell lung cancer, such as 46% isolated intrathoracic progression in the control group. Thus, thoracic radiotherapy can be considered for patients with extensive-stage small cell lung cancer that responds to platinum-based chemotherapy; though, in view of the atypical features of the trial population, more studies are required before this approach can be considered the standard of care.

Prophylactic Cranial Irradiation

Brain metastases are the first site of relapse for approximately one-third of patients who have relapsing small cell lung cancers. Another third of such patients will have both brain and systemic metastases as the first sites of relapse and the remaining one-third will have systemic-only disease. Because of the morbidity associated with brain metastases, the role of prophylactic cranial irradiation has been studied in numerous randomized trials. These findings have generally demonstrated that prophylactic cranial irradiation decreases the risk of brain metastases by approximately half without enhanced neurotoxicities, including cognitive dysfunction, ataxia, and seizures. A meta-analysis of seven randomized trials concluded that prophylactic cranial irradiation increased 3-year survival, with a net gain of 5%.[236] In the United States, patients are typically administered 24 Gy in 12 fractions. The optimal dose and schedule are not clear; however, the meta-analysis demonstrated a trend toward improved control with higher doses.

Although prophylactic cranial irradiation had generally been reserved for patients with limited-stage disease in whom a complete response is achieved with induction chemotherapy, a study from the EORTC showed a survival benefit for patients with extensive-stage disease who had a

response to induction chemotherapy.[237] Patients with extensive-stage small cell lung cancer who had a response to chemotherapy were randomly assigned to undergo prophylactic cranial irradiation or no further therapy. Irradiation was associated with an increase in median OS from 5.4 to 6.7 months and an improvement in the 1-year survival rate (27.1% vs. 13.3%) in the radiation group and control group, respectively, in addition to a lower risk of brain metastases (risk of metastases at 1 year, 14.6% vs. 40.4%). Thus, prophylactic cranial irradiation should be considered for all patients who have a complete or very good partial response after induction therapy.

Treatment of Paraneoplastic Syndromes

In small cell lung cancer, the most common paraneoplastic syndrome is syndrome of inappropriate secretion of antidiuretic hormone (SIADH), which occurs in up to 5% of patients. The hallmark of SIADH is euvolemic, hypotonic hyponatremia (in the absence of thyroid or adrenal dysfunction). Clinical features include confusion, seizures, and altered sensorium. In addition to treatment of the underlying malignancy, treatment includes fluid restriction, demeclocycline, and hypertonic saline in severe cases. Care must be taken to avoid overly rapid correction of hyponatremia, which could result in central pontine myelinolysis. Treatment of Lambert–Eaton syndrome and other neurologic paraneoplastic syndromes with corticosteroids, other immunosuppressive agents, intravenous gamma globulin, and plasmapheresis have been used with varying success.[80] Response to edrophonium is poor.[238]

KEY POINTS

- Small cell lung cancer often demonstrates features of neuroendocrine differentiation, which may be identified histopathologically, and it may be associated with paraneoplastic syndromes.
- Small cell lung cancer is exquisitely sensitive to both chemotherapy and radiation therapy, although resistant disease often develops.
- Etoposide with either cisplatin or carboplatin remains the standard of care for the treatment of patients with small cell lung cancer, with an optimal duration of four to six cycles.
- Concurrent chemotherapy and thoracic radiation confers a survival benefit and potential cure for patients with limited-stage small cell lung cancer.
- Prophylactic cranial irradiation reduces the incidence of symptomatic brain metastases and prolongs disease-free survival and OS for patients with limited-stage disease and in those with extensive-stage disease that has a major response to therapy.
- The addition of thoracic radiotherapy to prophylactic cranial irradiation can be considered for patients with extensive-stage small cell lung cancer and response to chemotherapy based on a clinical trial showing improved PFS and 2-year OS.
- Results with second-line chemotherapy for small cell lung cancer are poor for patients with “refractory” disease, in whom first-line treatment failed within 2 to 3 months.

PALLIATION FOR PATIENTS WITH LUNG CANCER

BISPHOSPHONATES

Bisphosphonates (zoledronate) have resulted in the reduction of skeletal-related complications such as pain, hypercalcemia, pathologic fractures, and spinal cord and nerve compression, as well as improvements in the quality of life for patients with metastatic bone disease who are likely to have a prolonged clinical course (Table 8-12).[238]

Table 8-12 Palliative Approaches for Complications of Lung Cancer

Superior Vena Cava Syndrome	▪ Chemotherapy alone (mild symptoms)
	▪ Concurrent chemoradiation therapy (severe symptoms)
	▪ Radiation therapy to the thorax (patients with non-small cell lung cancer)
	▪ Placement of stent
Pleural Effusion	▪ Intermittent thoracentesis
	▪ Pleurodesis
	▪ Long-term catheter drainage
	▪ Systemic chemotherapy
Bronchial Obstruction	▪ High-dose endobronchial radiation therapy
	▪ Placement of stent
	▪ Neodymium–yttrium–aluminum-garnet (Nd-YAG) endobronchial laser therapy
	▪ Electrocautery
	▪ Photodynamic therapy
Cachexia	▪ Megestrol acetate (160 to 800 mg daily)
Bone Metastases	▪ Bisphosphonates (zoledronate)
	▪ RANK-ligand inhibitor (denosumab)
Brain Metastases	▪ Corticosteroids
	▪ Resection or stereotactic radiation and whole-brain radiation (for isolated brain metastases for patients with non-small cell lung cancer)
	▪ Whole-brain radiation therapy (for multiple metastases)

RANK-LIGAND INHIBITOR

The monoclonal antibody to the receptor activator of nuclear kappa B (RANK) ligand denosumab was noninferior to zoledronate in delaying or preventing skeletal-related complications for patients with advanced cancer, including patients with lung cancer, in a

randomized, double-blind study of denosumab compared with zoledronic acid in the treatment of bone metastases for patients with advanced cancer (excluding breast and prostate cancer) or multiple myeloma.[240] The incidence of osteonecrosis is similar to that with bisphosphonates.

RADIATION THERAPY

Palliative radiation therapy often is helpful for controlling pain related to bone metastases or for improving neurologic function for patients with brain metastases. Radiation therapy to the thorax may help control hemoptysis, superior vena cava syndrome, airway obstruction, laryngeal-nerve compression, and other local complications.

CHEMOTHERAPY

Randomized trials involving patients with NSCLC and patients with small cell lung cancer have shown that chemotherapy reduces the incidence of cancer-related symptoms such as pain, cough, hemoptysis, and shortness of breath.

COLONY-STIMULATING FACTORS

Filgrastim, a granulocyte colony-stimulating factor, decreases the incidence of neutropenic fevers, the median duration of neutropenia, days of hospitalization, and days of antibiotic treatment for patients with extensive-stage small cell lung cancer. However, as discussed previously, the clinical benefit of maintaining a dose-intense approach for patients with this disease has not been established. In addition, caution must be exercised when using myeloid growth factors for patients receiving combined-modality treatment that consists of both chemotherapy and radiation therapy to the thorax, as this combination has been associated with an increase in thrombocytopenia.[241]

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome occurs when the superior vena cava becomes obstructed either directly by a tumor or by metastases to regional lymph nodes. Common symptoms include distention of the collateral veins over the anterior chest wall and neck; swelling and puffiness of the neck, face, throat, eyes, and arms; headache; and cyanosis. Although once thought to represent a medical emergency, in almost all cases, the symptoms are mild enough that treatment can be delayed until a histologic diagnosis has been determined. Radiation therapy is used to treat patients with NSCLC or other less chemosensitive tumors, whereas patients with extensive-stage small cell lung cancer and mild symptoms often may be treated with chemotherapy alone. Concurrent chemoradiation therapy usually is necessary for patients with both small cell lung cancer and NSCLC who present with severe symptoms. Other options include the placement of vascular stents, although the literature regarding their role is relatively sparse.

PLEURAL EFFUSION

Palliative thoracentesis should be performed for patients who are symptomatic from pleural effusions, and management with intermittent thoracentesis can frequently be effective if the effusion does not reaccumulate quickly. When reaccumulation is rapid, pleurodesis may be considered. The two most common methods of a pleurodesis are through a chest tube or via

thoracoscopy. Common sclerosing agents include doxycycline, talc, and bleomycin; talc is the most effective. Unfortunately, the procedure is effective in only about 50% of cases and is associated with discomfort and a prolonged hospital stay. For these reasons, long-term drainage through a semipermanent catheter is being used more frequently. Systemic therapy often reduces the effusion for patients with small cell lung cancer.

KEY POINT

- Every attempt should be made to palliate the symptoms of patients with lung cancer. In addition to systemic anticancer therapies, these include multidisciplinary management of painful bone metastases, dyspnea caused by pleural effusions, and maintenance of adequate analgesia.

THYMIC MALIGNANCIES

The thymus contains two major cell populations: epithelial cells and lymphocytes. A number of different tumors can arise in the anterior mediastinum, including thymomas, Hodgkin and non-Hodgkin lymphomas, carcinoid tumors, and germ cell neoplasms. Thymomas are malignant neoplasms originating within the epithelial cells of the thymus, which often contain admixtures of lymphocytes.[242] Thymic carcinomas also are tumors of the thymic epithelium, but they are associated with a paucity of lymphocytes and are more aggressive and have a worse prognosis. Most thymomas are well encapsulated, but they are considered malignant because of their invasive potential. Cytokeratin is a useful diagnostic marker to distinguish thymomas from non–epithelial cell malignancies.

Thymomas are the most common (~20 to 30%) of all anterior mediastinal tumors in adults. Although they usually present in the fourth and fifth decades of life, cases have been reported from infancy into the ninth decade. At presentation, one-third of patients have an asymptomatic anterior mediastinal mass on chest x-ray; one-third have local symptoms such as cough, superior vena cava syndrome, and dysphagia; and one-third have myasthenia gravis. Distant metastases are uncommon, with the most common metastatic site being the pleura.

A number of paraneoplastic syndromes have been associated with thymomas. Myasthenia gravis—an autoimmune disorder caused by circulating acetylcholine-receptor antibodies resulting in acetylcholine-receptor deficiency at the motor end plate—occurs in approximately one-third of patients with thymoma, although it is rarely seen with thymic cancers. Surgical removal of all thymic tissue, not just tumor tissue, usually results in an attenuation of the severity of myasthenia gravis, although complete disappearance of all symptoms of the disorder is uncommon. Patients should have their serum antiacetylcholine receptor antibody levels measured prior to surgery to determine whether they have myasthenia gravis (to avoid respiratory failure during surgery).

Approximately two-thirds of patients with myasthenia gravis will have thymic lymphoid hyperplasia, and 10 to 15% will have thymoma. Myasthenia gravis is characterized by diplopia, dysphagia, weakness of the ocular muscles, and easy limb fatigability (proximal > distal). Interestingly, thymomas associated with myasthenia gravis tend to be less aggressive, and histologically, they tend to have a larger lymphocyte-to-epithelial-cell ratio. Other paraneoplastic syndromes include pure red cell aplasia, vasculitides, hypogammaglobulinemia, and other

autoimmune disorders. Thymectomy may result in normalization of the bone marrow for up to 40% of patients with pure red cell aplasia, although the procedure rarely results in a return to normal immunoglobulin levels for patients with immunodeficiency.

The Masaoka staging for thymoma is based on encapsulation of the tumor and invasion into surrounding organs and distant sites outside the chest (Table 8-13).[243] Important prognostic factors include WHO histologic grade, complete resection status, and size.[242,243] Negative prognostic factors include:

- Tumor size > 10 cm;
- Tracheal or vascular compromise;
- Age < 30;
- Presence of hematologic paraneoplastic syndromes;
- Incomplete surgical resection;
- Thymic carcinoma histology.

Table 8-13 **Modified Masaoka Clinical Staging of Thymoma**[242]

Masaoka Stage	Diagnostic Criteria
Stage I	Macroscopically and microscopically completely encapsulated
Stage II	(A) Microscopic transcapsular invasion
	(B) Macroscopic invasion into surrounding fatty tissue or grossly adherent to but not through mediastinal pleura or pericardium
Stage III	Macroscopic invasion into neighboring organs (i.e., pericardium, great vessels, lung)
	(A) Without invasion of great vessels
	(B) With invasion of great vessels
Stage IV	(A) Pleural or pericardial dissemination
	(B) Lymphatic or hematogenous metastasis

The treatment of choice for thymoma is resection. Long-term survival for patients with encapsulated, noninvasive (stage I) tumors is excellent, approaching 90 to 95% at 10 years. The role played by postoperative radiation after an R0 resection is controversial but sometimes the procedure is used for completely resected stage II–IV thymomas. Adjuvant PORT is often recommended for patients with invasive disease.[243] For patients in whom complete resection is not possible because of extensive invasion, debulking with a subtotal resection followed by radiation therapy may result in improved survival. One small study suggested that chemotherapy plus radiation therapy may be more beneficial than either treatment alone.[244]

The optimal management of incompletely resected or unresectable thymomas is

controversial. Achieving a complete (R0) resection is an important prognostic indicator. Thymomas are generally chemosensitive tumors; thus, debulking with chemotherapy for locally advanced thymomas to attempt to increase the potential for an R0 (complete) resection is sometimes performed. Given the small number of patients, no randomized trials have been performed to identify the best chemotherapy regimen for inoperable or recurrent thymomas. Comparing response across trials, anthracycline-containing regimens increase the RR.[245] Commonly used regimens include cisplatin/doxorubicin/cyclophosphamide,[246] etoposide/ifosfamide/cisplatin,[247] and cisplatin/etoposide.[248]

Thymic carcinomas are aggressive and characterized by a high degree of histologic anaplasia and architectural atypia. A number of different subtypes have been described, although more than half are undifferentiated. These tumors often metastasize to regional lymph nodes and distant sites; thus, they have a worse prognosis than thymomas, with 5-year survival rates of 20 to 30%. Responses to carboplatin and paclitaxel have been described.[249]

KEY POINTS

- Thymomas are often encapsulated, well differentiated, and associated with paraneoplastic syndromes such as myasthenia gravis.
- The optimal treatment of thymoma is thymectomy and complete surgical resection, in which case the survival is excellent.
- The most important prognostic factors after resection are Masaoka stage, histology, complete resection status, and size.
- Thymic carcinomas are more aggressive than thymomas.
- Regimens incorporating anthracyclines increase RRs in thymoma.

MESOTHELIOMA

Mesothelioma arises from mesothelial cells—the cells that form the serosal lining of the pleura, pericardium, and peritoneal cavities. Although benign mesotheliomas have been described, most are malignant and have an aggressive clinical course.[250]

Malignant mesotheliomas are rare, with approximately 2500 new cases diagnosed annually in the United States. Although approximately 80% are associated with exposure to asbestos, only approximately 5% of asbestos workers are diagnosed with mesothelioma. In contrast to lung cancer and asbestosis, smoking does not increase the risk of mesothelioma. Unlike asbestosis, in which there is a dose–response relationship, this association does not exist for mesothelioma, with the exception of chrysotile asbestos, which may be oncogenic only at high doses.

The various types of asbestos are divided into two major groups: serpentine, represented by chrysotile, the most common form of asbestos in the Western world; and rodlike amphiboles, which include crocidolite, the most oncogenic type of asbestos.

Carcinogenic effects of asbestos appear to result from its physical properties rather than from its chemical structure, with long, rodlike fibers of narrow diameter being more likely to induce tumors in laboratory animals. It has been postulated that chrysotile asbestos fibers are less carcinogenic because the fibers can be partially digested and removed from the lungs,

whereas amphibole asbestos is more resistant to solubilization by cellular enzymes and therefore accumulates in the lungs. The fibers cause mutagenic changes by several different mechanisms, including direct physical effects on chromosomes; the production of hydroxyl radicals and superoxide anions leading to DNA strand breaks and deletions; stimulation of EGFR autophosphorylation, activation, and signal transduction; and increased production of inflammatory cytokines. The expression of the simian virus 40 large-tumor antigen in mesothelioma cells and not in nearby normal cells, as well as the capacity of antisense T-antigen treatment to arrest mesothelioma cell growth in vitro, suggest that simian virus 40 may also contribute to the development of mesothelioma, particularly for patients exposed to asbestos. Mesothelioma also has been associated with exposure to Thorotrast and its radiation effects.

Three histologic variants of mesothelioma have been described: epithelial, which is the most common form and is associated with the best prognosis; sarcomatoid; and mixed. To distinguish mesotheliomas from metastatic adenocarcinomas, the periodic acid–Schiff stain is frequently used before and after diastase digestion. Neutral mucopolysaccharides that are strongly positive on periodic acid–Schiff staining are found in intracellular secretory vacuoles and in intra-acinar vacuoles in most adenocarcinomas but are rarely found in most mesotheliomas. In addition, immunohistochemical staining for CD15, Ber-EP-4, TTF1, and carcinoembryonic antigen are usually absent in mesotheliomas but are positive in most adenocarcinomas, whereas mesothelioma is characterized by staining for calretinin, Wilms tumor antigen (WT1), vimentin, CK5/6, mesothelin, or HBME-1 (an antimesothelial cell antibody).[251]

Mesothelioma most commonly develops in the fifth to seventh decade, and it affects men and women in a 5:1 ratio. The onset of disease occurs 20 to 50 years after exposure. Family members also are at higher risk of mesothelioma, presumably because of exposure to asbestos fibers brought home on the clothing and bodies of individuals who work with asbestos.

The typical presentation consists of dyspnea or chest-wall pain secondary to a pleural effusion. Most mesotheliomas (60%) occur on the right side, and bilateral involvement of the chest wall is present at the time of diagnosis in less than 5% of cases. Repeated cytologic examination of pleural fluid may be negative, necessitating either a thoracoscopy or thoracotomy, despite the risk of seeding the biopsy site or surgical scar with tumor. Mesothelin-related peptide is a serum marker that may be predictive of disease recurrence after surgical resection.[252] Osteopontin is a glycoprotein that binds integrin and CD44 receptors, and it may distinguish patients with malignant mesothelioma from those with benign disease.[225] Fibulin-3 levels in pleural fluid and plasma has also emerged as a diagnostic and prognostic marker with potentially better sensitivity, specificity, and reproducibility than osteopontin levels.[253]

Mesotheliomas tend to be locally invasive. For approximately 20% of patients, a chest-wall mass develops over tracts resulting from thoracentesis, chest tubes, or thoracotomy. Direct involvement of the ribs, diaphragm, pericardium, and vertebrae is common. Although various staging classifications have been described, the staging system proposed by the International Mesothelioma Interest Group emphasizes the importance of the local extent of the tumor and node involvement.[254]

Evaluation of surgical resectability often includes echocardiography to delineate cardiac involvement and MRI to delineate diaphragmatic involvement, in addition to chest CT and PET scans. The choice of surgical resection for mesothelioma is controversial. Extrapleural pneumonectomy results in a lower local recurrence rate and has traditionally been considered the procedure of choice, though no conclusive OS benefit has been demonstrated. Extrapleural

pneumonectomy includes en bloc resection of the parietal pleura, lung pericardium, and diaphragm. Given the extent of the resection and long duration of anesthesia needed, this procedure should be reserved for patients younger than age 65 who are in good health.

Treatment of resectable mesothelioma traditionally consists of a trimodality approach. The best results have been described in a retrospective series reported by Sugarbaker et al. in which median survival was 19 months for 176 patients treated with extrapleural pneumonectomy (EPP), four to six cycles of adjuvant chemotherapy, and adjuvant radiation therapy to the ipsilateral hemithorax and mediastinum.[254] Patients with pure epithelial type and no node involvement had a significantly better outcome than patients with sarcomatoid/mixed histology or node involvement. Survival at 2 and 5 years for the 103 patients with epithelial cell–type tumors were 38% and 15%, respectively, compared with 16% at 2 years, with no 5-year survival for the 74 patients with sarcomatous or mixed cell types. Indeed, given the poor outcomes noted with sarcomatoid tumors, in some centers the presence of this histology guides treatment away from aggressive surgical intervention.

A large retrospective review suggested that pleurectomy with decortication may also provide long-term benefit.[255] Surgical management of mesothelioma and whether to perform pleurectomy with decortication compared with EPP for patients with resectable disease is controversial. The small randomized Mesothelioma and Radical Surgery (MARS) feasibility study showed a survival benefit for 26 patients who did not undergo EPP compared with the 24 patients who did (14.4 months for the EPP group vs. 19.5 months for the no-EPP group; HR, 1.90; 95% CI; 0.92, 3.93; exact p = 0.082).[256]

The role of preoperative (neoadjuvant) chemotherapy is also being explored. A multicenter phase II trial of neoadjuvant pemetrexed and cisplatin followed by EPP and hemithoracic radiation showed a median survival in the overall population of 16.8 months (77 patients) and of 29 months for patients completing all therapy (40 patients; 2-year survival, 61%).[257]

For patients with unresectable disease, effusions may be controlled by thoracoscopy with talc pleurodesis. Pleurectomy with decortication, although rarely curative, also can be used to control effusions. Smaller doses of radiation (21 Gy in three fractions) may prevent seeding of the surgical wound by mesothelioma cells.

The prognosis is poor for patients who have unresectable disease at presentation, with a median survival of approximately 12 months. Single-agent chemotherapy yields RRs of 5 to 20%, with the active agents including doxorubicin, cisplatin, pemetrexed, and gemcitabine.[258,259] Combination chemotherapy, which is usually cisplatin-based, has increased response rates as initial systemic treatment. Single-agent gemcitabine is associated with an RR of 12% or less, findings from a phase II study of gemcitabine plus cisplatin showed a 48% RR.[260] The best results have been reported with pemetrexed and cisplatin. A phase III study in which cisplatin was compared with cisplatin plus pemetrexed demonstrated a 9-month median survival for patients treated with cisplatin alone and a 12-month survival for patients treated with the combination (p = 0.02), making this regimen until recently the standard of care for patients with advanced mesothelioma. RRs were 41.3% and 16.7% in the pemetrexed/cisplatin arm and control arm, respectively.[261] In a randomized, phase 3 trial, bevacizumab added to cisplatin and pemetrexed improved OS (median, 18.8 months; 95% CI; 15.9, 22.6, vs. 16.1 months, 95% CI; 14.0, 17.9; HR, 0.77; 95% CI; 0.62, 0.95; p = 0.0167). More grade 3 or higher hypertension (23 vs. 0%) and thrombotic events (6 vs. 1%) were noted with bevacizumab. Thus, cisplatin and pemetrexed with bevacizumab should be considered the new standard of care in unresectable malignant pleural mesothelioma patients who are bevacizumab eligible.[262]

KEY POINTS

- Approximately 80% of pleural mesotheliomas are associated with exposure to asbestos, including indirect exposure.
- The epithelial histologic form of mesothelioma is associated with a better prognosis than the sarcomatoid or mixed histology forms.
- A trimodality approach consisting of surgery, chemotherapy, and radiation therapy should be considered for younger patients with good PS, particularly patients with negative mediastinal nodes and the epithelial variant.
- First-line chemotherapy for patients with mesothelioma consists of cisplatin and pemetrexed with the addition of bevacizumab for unresectable mesothelioma in bevacizumab-eligible patients.

Recent Updates

- Cisplatin/gemcitabine improved survival compared to cisplatin/5-fluorouracil as first line treatment for recurrent or metastatic nasopharyngeal cancer. (Zhang L, *Lancet* 2016)
- PET/CT can effectively be used to determine need for neck dissection following completion of chemoradiation. (Mehanna H, *N Engl J Med* 2016)
- Nivolumab and pembrolizumab have been approved by the FDA for treatment of platinum refractory recurrent or metastatic head and neck squamous cell carcinoma. (Ferris R, *N Engl J Med* 2016; Seiwert TY, *Lancet Oncol* 2016; Baum J, *J Clin Oncol* 2017)
- In the American Joint Committee on Cancer (AJCC) 8th edition, p16-positive oropharyngeal tumors will be staged using a unique staging system to reflect the better prognosis associated with HPV-related oropharyngeal tumors. (Lydiatt WM, *Cancer J Clin* 2017)

OVERVIEW

The term “head and neck cancer” refers to a heterogeneous group of malignant tumors arising from the epithelial lining of the upper aerodigestive tract. The specific primary sites are subdivided by anatomic boundaries: lip and oral cavity, pharynx (nasopharynx, oropharynx, and hypopharynx), larynx, and nasal cavity and paranasal sinuses (Table 9-1, Fig. 9-1). Squamous cell cancer or a variant is the most common histologic type, accounting for 85 to 95% of head and neck cancers. Etiologic factors include tobacco and alcohol use and viruses, such as the human papillomavirus (HPV) and the Epstein–Barr virus (EBV) (Table 9-2). Head and neck cancers are generally categorized as early-stage disease (stage I or II), locally advanced disease (stage III, IVa, or IVb), or metastatic disease (IVc). Early-stage disease is usually treated with single modality therapy with either surgery or radiation, whereas locally advanced disease is generally treated with multimodality therapy, which commonly includes chemotherapy. Systemic therapy by itself is palliative and is the mainstay for metastatic disease. The other two anatomic sites included in the head and neck region are the thyroid and salivary glands. Surgical resection remains the standard of care for localized and resectable thyroid and salivary gland tumors. Depending on the pathologic findings, there is a role for radioactive iodine for the former and external-beam radiation for the latter. For patients with differentiated thyroid cancer, radioactive iodine is the first treatment of choice for metastatic disease. Two tyrosine kinase inhibitors are approved for treatment of radioactive iodine–refractory disease. Two tyrosine kinase inhibitors are approved for the management of medullary thyroid cancer. There is no standard systemic therapy licensed for patients with

unresectable salivary gland cancers.

Table 9-1 **Head and Neck Cancer: Primary Sites**	
Oral Cavity and Lip	▪ Floor of mouth
	▪ Oral tongue
	▪ Buccal mucosa
	▪ Alveolar ridges
	▪ Hard palate
	▪ Retromolar trigone
Pharynx	▪ Nasopharynx (includes superior surface of soft palate)
	▪ Oropharynx (includes inferior surface of soft palate, uvula, base of tongue, tonsil, posterior pharyngeal wall)
	▪ Hypopharynx (pyriform sinus, postcricoid, posterior wall)
Larynx	▪ Supraglottic larynx (false cords, arytenoids, epiglottis)
	▪ Glottic larynx (includes commissures)
	▪ Subglottic larynx
Nasal Cavity and Paranasal Sinuses	▪ Nasal cavity
	▪ Maxillary sinuses
	▪ Ethmoid sinuses
	▪ Frontal sinuses
	▪ Sphenoid sinuses

Table 9-2 Characteristics of Virus-Associated Head and Neck Cancers		
	Human Papillomavirus	**Epstein–Barr Virus**
Anatomic site	Oropharynx	Nasopharynx
Anatomic subsite	Lingual and palatine tonsils, base of tongue	Pharyngeal walls, fossa of Rosenmüller
Percent virus associated		WHO I: 70–80%
	60–70%	WHO II and III: 100%
Associated histopathology	Basaloid	Lymphoepithelioma
Viral transmission	Sexual	Oral
Viral genome	Episomal/integrated	Episomal/ integrated
Viral oncogenes	*E6* and *E7*	*LMP-1* and *EBNA1*
Cofactors	Tobacco and alcohol	Diet and genetics
Clinical presentation	Unknown primary neck mass	Distant metastases, neck mass
Prognosis controlled for stage	Improved	Improved

EPIDEMIOLOGY

In 2016, it was estimated that head and neck cancers would account for approximately 3% (61,760) of all estimated new cancers and about 2% (13,190) of all estimated cancer deaths in the United States.[1] Worldwide, head and neck cancer accounts for more than 550,000 cancer cases and 380,000 deaths from cancer annually.[2] Head and neck cancer affects men and women in a ratio of 2.5:1, although the ratio varies according to the primary site (e.g., 4:1 for cancer of the oropharynx, 7:1 for cancer of the larynx). The median age at diagnosis is approximately 60. Oropharyngeal cancer incidence has increased significantly since the 1980s, predominantly in developed countries and among younger individuals, likely because of the role of HPV infection, particularly among men, and is associated with a better prognosis.[3] The age-adjusted incidence and mortality for head and neck cancer overall are highest among black men, and the stage-specific survival rates are lower for this group.

RISK FACTORS

TOBACCO AND ALCOHOL

Epidemiologic data document a multiplicative risk relationship between tobacco and alcohol. For example, the relative risk of oral and pharyngeal cancer is increased nearly 40-fold for patients with a 40 pack-year smoking history who consume 30 or more alcoholic drinks per week.[4] Age

younger than 18 years at onset and a duration of smoking of more than 35 years are significant risk factors. Overall, an estimated 75% of head and neck cancers can be attributed to tobacco and alcohol use, highlighting the importance of tobacco and alcohol counseling in medical practice and as part of prevention strategies. The carcinogens found in significant levels in tobacco that are considered directly mutagenic are benzopyrene and nicotine-derived nitrosamine ketone (NNK), or 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone. The type of tobacco product used affects the distribution of observed primary sites. Smokeless tobacco and other orally chewed carcinogens—such as betel quid, a combination of betel leaf, lime, and areca nut, commonly used in India and parts of Asia—are associated with the development of cancers of the oral cavity. Black, air-cured tobacco (commonly found in cigars and pipe tobacco) is more irritating to the respiratory mucosa than blonde or flue-cured tobacco (more commonly found in cigarettes) and is associated with a higher risk for head and neck cancer.

DIET

Because many patients with head and neck cancer are malnourished at the time of diagnosis, dietary deficiencies have been postulated as risk factors, and both laboratory and epidemiologic data suggest that vitamin A and its analogues may be protective. Plummer–Vinson syndrome, which is most commonly seen in women younger than age 50, is associated with iron deficiency anemia, hypopharyngeal webs, dysphagia, and a higher risk for cancers of the postcricoid region and hypopharynx.

OCCUPATIONAL EXPOSURE

Most tumors of the sinonasal tract originate in the maxillary sinus, and the proportion that have squamous cell histology is lower than other more common head and neck cancers (approximately 50%). Of note, these cancers are associated with certain occupational exposures (e.g., nickel, radium, mustard gas, chromium, and byproducts of leather tanning and woodworking).

VIRUSES

Human Papillomavirus (HPV)

HPV has emerged as an important cause of oropharyngeal cancer.[5] In the United States between 1984 and 1989, only 16% of oropharyngeal cancers were related to HPV, as compared with 73% of oropharyngeal cancers between 2000 and 2004, revealing a 4-fold increase during the past two decades.[6] This trend has been striking, given the decrease in tobacco use in the United States.[7] The rapid increase in the incidence of oropharyngeal cancers among men younger than age 60, with no or minimal use or history of alcohol or tobacco abuse, has become particularly apparent during the past decade.[8,9]

Genetic material from high-risk oncogenic strains (most commonly HPV types 16 and 18) is found in approximately 60% of oropharyngeal cancers arising from the palatine and lingual tonsils.[6,10] The transforming potential results from viral proteins E6 and E7, which inactivate the tumor suppressor proteins p53 and retinoblastoma protein (pRb) and result in loss of cell-cycle regulation, cellular proliferation, and chromosome instability.[11] More recently, HPV 16 E6 seropositivity has been reported to be present more than 10 years before the diagnosis of oropharyngeal cancer.[12] These tumors are clinically and molecularly distinct from HPV-negative tumors. The histology of HPV-associated tumors is frequently described as basaloid or poorly

differentiated squamous cell cancer, and the initial presentation often is as an unknown primary or small primary tumor with large cystic neck node(s). The verrucous cancer subtype of squamous cell cancer is strongly associated with HPV. Patients with HPV-associated tumors tend to be younger, have a history of minimal tobacco and alcohol exposure, and often have a history of high-risk sexual behavior.

Patients with oropharynx carcinoma who are HPV-positive have a strikingly improved survival compared with patients who are HPV-negative. A retrospective multivariate analysis of patients treated in the RTOG 0129 trial revealed significantly improved 3-year survival among patients who were HPV-positive compared with patients who were HPV-negative (84% vs. 57%).[10] Patients with HPV-positive tumors had a 58% reduction in risk for death compared with patients with HPV-negative tumors (hazard ratio [HR], 0.42; 95% CI; 0.27, 0.66). Patients with HPV-associated tumors also appear to have a lower risk for the development of a second primary malignancy (SPM).[13]

In a multicenter Eastern Cooperative Oncology Group study, patients with newly diagnosed stage III or IV head and neck squamous cell carcinoma (HNSCC) were treated with induction chemotherapy followed by concomitant chemotherapy and radiation; 60% of oropharynx primary tumors were found to be HPV-positive.[14] Two-year progression-free (86% vs. 53%; $p = 0.02$) and overall survival rates (95% vs. 62%; $p = 0.005$) were significantly better for patients with HPV-associated cancer than for those with HPV-negative cancers. In a retrospective analysis of Surveillance, Epidemiology, and End Results Program data, patients with HPV-positive oropharyngeal cancer had a 4-fold higher survival than patients who were HPV-negative (131 months vs. 20 months).[6]

More recently, retrospective data have confirmed that patients with HPV-positive oropharyngeal tumors have better survival in the setting of recurrent or metastatic disease compared with patients with HPV-negative disease.[15] The same survival benefit does not extend to HPV-positive or p16-positive tumors from non-oropharyngeal head and neck sites.[16] In the phase III EXTREME study, which evaluated the addition of cetuximab to a platinum and 5-fluorouracil doublet in patients with recurrent or metastatic HNSCC, HPV- or p16-positive disease had improved overall survival compared with patients with HPV- or p16-negative patients, regardless of treatment arm.[17] In a retrospective analysis of locally advanced oropharyngeal cancers treated in the RTOG 0129 or 0522 trial, patients with p16-positive tumors had an improved survival after disease progression compared with patients with p16-negative tumors, with a median overall survival of 2.6 years compared with 0.8 years, respectively ($p < 0.001$).[15] In a review of patients for whom archival tissue was available and treated in Eastern Cooperative Oncology Group trials for recurrent or metastatic head and neck cancer, the observed response rates to treatment and overall survival were improved in HPV- or p16-positive patients compared with patients with tumors negative for both HPV and p16.[18]

Although in situ hybridization, which is available at a limited number of referral centers, is considered an important test to confirm the presence of HPV, tumoral expression of p16 protein reflects biologically relevant HPV infection, is not genotype-specific, and is an excellent surrogate for HPV status.[19] Expression of p16 is upregulated when HPV E7 oncoprotein degrades pRb, whereas p16 expression in HPV-negative tumors is silenced by epigenetic promoter methylation or genetic mutation.[8] In RTOG 0129, immunohistochemical analysis of tumoral p16 protein expression performed numerically better than detection of HPV DNA in identifying the good prognostic group (HR, 0.33; 95% CI; 0.21, 0.53). With this in mind, the 8th edition of AJCC will use p16 overexpression by immunohistochemistry, defined as ≥ 75% tumor

expression with at least a moderate staining intensity marker, as a surrogate for HPV-positivity in oropharyngeal cancers and will stage this tumor independently from non-HPV-positive oropharyngeal cancers.[20]

There is also a new oral rinse that can detect DNA from HPV subtype 16. Rettig et al. demonstrated that patients with oropharyngeal cancer with detectable HPV-16 DNA have a poorer prognosis than those whose rinse is negative.[21]

Epstein–Barr Virus

Nasopharyngeal cancer is strongly associated with EBV. Cancer of the nasopharynx is especially common among individuals from endemic areas in southern China and northern Africa, where World Health Organization (WHO) type II (nonkeratinizing) and III (undifferentiated cancer) are more common. WHO type I (keratinizing) is more common in Western countries and appears to more likely be related to tobacco exposure or possibly HPV.[22,23] The EBV genome can be found in nasopharyngeal cancer tissues and dysplastic lesions that progress to invasive disease. However, the exact role of this virus in etiology is still being defined, and evidence of EBV can be found in nonmalignant nasopharyngeal tissue as well.

KEY POINTS

- Tobacco and alcohol use are the major risk factors for squamous cell cancer of the head and neck, and the use of both results in a multiplicative increase in risk.
- There is evidence for a causal association between high-risk oncogenic HPV and cancers of the oropharynx (e.g., tonsil, base of tongue); these cancers are increasing in incidence in the United States.
- The survival prognosis is substantially better for HPV-positive cancers than for HPV-negative cancers.
- The incidence of second primary cancers for patients with a history of squamous cell cancer of the head and neck is 3 to 7% annually; common sites include the head and neck, lung, and esophagus.

HEAD AND NECK CARCINOGENESIS

MOLECULAR PROGRESSION MODEL

A molecular progression model of multistep carcinogenesis has been elucidated for the transformation of normal mucosa to invasive squamous cell cancer.[24] The earliest genetic alteration noted during transition from normal mucosa to hyperplastic mucosa is the loss of genetic material from chromosome region 9p21 and inactivation of the *p16* tumor suppressor gene. The next step during the transition from hyperplastic mucosa to dysplasia is the loss of 3p and 17p with inactivation of the *p53* gene. Transition from dysplasia to carcinoma in situ is associated with loss of chromosome regions 11q, 13q, and 14q; during transition to invasive squamous cell carcinoma, there is loss of chromosome regions 6p, 8p, and 4q.[24] More than half of patients with tobacco- and alcohol-associated HNSCC have disease with the *TP53* gene

mutation and downregulation of p16 protein. In contrast, HPV-associated HNSCC characteristically demonstrates wild-type *TP53* and *RB1* genes and upregulation of p16 protein levels.

ORAL PREMALIGNANCY

Patients with head and neck cancer, specifically oral cancers, often have diffuse mucosal abnormalities related to tobacco use, alcohol use, and betel quid chewing. Oral premalignancy, or intraepithelial neoplasia, is the precursor to invasive oral cancer. Understanding the stepwise molecular events that define the risk for progression to invasive disease and identifying potential targets for intervention are areas of intense research interest. The loss of genomic material containing tumor suppressor genes (loss of heterozygosity or allelic imbalance) of regions on chromosomes 3p, 9p, 11q, and 17p, as well as p16 promoter hypermethylation and *p53* mutation, are steps in the progression of intraepithelial neoplasia to invasive cancer.

Leukoplakia

Histologically, leukoplakia is the most common precancerous lesion in the oral mucosa. Clinically, it appears as white plaques distributed on the lip, buccal mucosa, floor of the mouth, hard palate, tongue, and soft palate. The majority (approximately 80%) are benign lesions that can be kept under observation without treatment. The sites of leukoplakia at highest risk for severe (high-grade) dysplastic change or transformation to cancer are lesions on the tongue, lip vermilion, and floor of the mouth. Understanding molecular events such as loss of 3p and/or 9p in the transformation of leukoplakia to invasive cancer may allow for stratification of patients by risk; this also may enable novel therapies to be tested in this population.

Erythroplakia

In contrast with leukoplakia, erythroplakia presents as a red, velvety patch that is separated from the surrounding normal tissue by a distinct interface, and it occasionally has a pebbled or granular appearance. Erythroplakia is associated with a 90% incidence of severe dysplasia, carcinoma in situ, or invasive disease on microscopic examination. Erythroplakia may occur on the tongue, lower lip, floor of the mouth, buccal mucosa, and oral commissure. Dysplasia is a common finding in most erythroplakic lesions, and the degree of dysplasia is increased compared with dysplasia associated with leukoplakia. The molecular changes noted with leukoplakia are also noted in the erythroplakic lesions.

FIELD CARCINOGENESIS AND SECOND PRIMARY TUMORS OF THE AERODIGESTIVE TRACT

Field carcinogenesis is a concept proposed in the 1950s that has been supported by many epidemiologic and molecular studies. Exposure to risk factors such as alcohol and tobacco results in carcinogen distribution over large areas in the upper aerodigestive tract, and the exposed mucosa (the field) is a potential site for development of premalignant and invasive cancer. Given the central role of tobacco in the genesis of many head and neck cancers, medical comorbidity and synchronous or metachronous SPMs are common among these patients (3 to 7% per year, depending on whether tobacco use continues).[25] A tumor is considered synchronous if it occurs within 6 months after detection of the first primary tumor; a metachronous tumor is one that occurs more than 6 months after detection of the first primary

tumor. Geographically, these tumors should be separate and distinct with at least 1 cm of normal mucosa intervening. Synchronous lesions tend to present as premalignant mucosal lesions located in the head and neck, whereas metachronous lesions present as distinct tumors in the head and neck, lung, or esophagus.[26] Within the aerodigestive tract, the most frequent site of an SPM is the lung, followed by the esophagus.

The risk and distribution of SPMs vary significantly according to the subsite of the index cancer. In a population-based cohort study of 75,087 patients with HNSCC in the Surveillance, Epidemiology, and End Results program, the risk of SPM was highest for hypopharyngeal cancer. Since the 1990s, during the HPV era, the risk for an SPM associated with oropharyngeal cancer has declined to the lowest risk level of any subsite. The most common SPM site for patients with oral cavity and oropharyngeal cancer was the head and neck; for patients with laryngeal and hypopharyngeal cancer, the most frequent site was the lung.[13] A solitary pulmonary nodule is not rare in the workup of a new pharyngeal or laryngeal cancer and should not be assumed to be a metastasis, particularly for a patient with early-stage head and neck cancer. For example, a patient with early glottic cancer, no involved neck nodes, and a lung nodule is much more likely to have an SPM than metastatic disease, mandating a curative treatment approach for both primary tumors.

PREVENTION AND CHEMOPREVENTION

Stopping the use of tobacco and alcohol (the two primary risk factors for HNSCC) is central to any prevention program. Counseling combined with the use of a pharmacologic intervention, such as a tapering nicotine patch, doubles success rates; however, very few smokers succeed in quitting on their first attempt. Important reasons for smoking cessation that clinicians can discuss with their patients include the fact that the rate of SPM is higher among patients who continue to smoke and that continuing to smoke may adversely influence the effectiveness and tolerance of cancer treatment.

PREVENTION TRIALS USING RETINOIDS

Testing of retinoids to halt or reverse the processes that ultimately lead to epithelial carcinogenesis began in the mid-1980s. Trials investigating 13-cis-retinoic acid in high and low doses for primary prevention showed that high-dose 13-cis-retinoic acid was able to reverse oral intraepithelial neoplasia for approximately two-thirds of premalignant lesions and was able to maintain the effect for the duration of treatment. However, intolerable side effects precluded chronic, long-term dosing.[27] As secondary prevention after curative treatment of early-stage head and neck cancer, placebo-controlled, randomized trials of isotretinoin have failed to demonstrate benefit for prevention of a second primary tumor,[28,29] overall survival,[29] and disease-free survival,[28] although a favorable effect of tobacco cessation has been reported.[29] No systemic therapy to prevent head and neck cancer can be recommended at present. Enrollment of patients with oral premalignant mucosal changes in suitable clinical trials is encouraged.

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING

In general, cancers of the oral cavity, pharynx, and larynx are characterized by disease confined to the primary site with or without spread to regional nodes at the time of diagnosis and late metastatic spread. Less than 10% of patients have distant disease at presentation. Thus, initial disease staging and management focus on the extent of local–regional involvement

and the effect of the choice of treatment on speech and swallowing function, as well as on the risk for recurrence.

KEY POINTS

- Stopping the use of tobacco and alcohol, the two primary risk factors for squamous cell cancer of the head and neck, is central to any prevention program.
- Chemopreventive agents currently are not part of standard clinical practice but remain under active investigation.

PRESENTING SIGNS AND SYMPTOMS

Clinical signs and symptoms vary with the anatomic site affected. For example, patients with oral cavity cancer may present with mouth sores, a nonhealing ulcer, or pain. Symptoms of oropharyngeal cancer can range from sore throat to chronic dysphagia, persistent odynophagia, and otalgia. Patients with hypopharyngeal or supraglottic laryngeal cancer often seek medical attention at a later stage with sore throat, hoarseness, difficulty swallowing, or neck mass as the initial presenting sign. Tumors of the glottic larynx tend to be diagnosed at an earlier stage than those of the supraglottic larynx or hypopharynx because hoarseness is an early symptom at the glottic subsite. The Eustachian tubes are frequently invaded by nasopharyngeal disease, leading to ear fullness, otalgia, or otitis media—a diagnosis in an adult patient that mandates careful assessment of the nasopharynx. With more advanced nasopharyngeal tumors, double vision may be the presenting symptom because of invasion of the cavernous sinuses and the branches of the third, fourth, and particularly sixth cranial nerves, which track with these vascular structures. Spread to distant metastatic sites is more common at presentation in patients with advanced neck disease and in patients who have nasopharyngeal or hypopharyngeal primary sites.

Cervical Lymphadenopathy

The discovery of a painless lump in the neck is a common presenting symptom for a patient with head and neck cancer. The location of cervical adenopathy, denoted by dividing the neck into levels, may direct the physician to the primary site (Fig. 9-2). For example, cancers of the oral cavity typically spread to lymph nodes in the submental and submandibular areas (level I); oropharyngeal and laryngeal cancer spread to the upper and midneck (levels II and III); nasopharyngeal cancer spreads to the upper neck and posterior triangle (levels II and V); and disease confined to the lower part of the neck or supraclavicular area should raise suspicion about a primary lesion below the clavicle or in the thyroid (levels IV and V). Spread to the neck is uncommon for patients with primary cancers of the glottic larynx or paranasal sinuses. Involvement of the neck nodes is prognostically significant, reducing the cure proportion for a given tumor stage by approximately 50%.

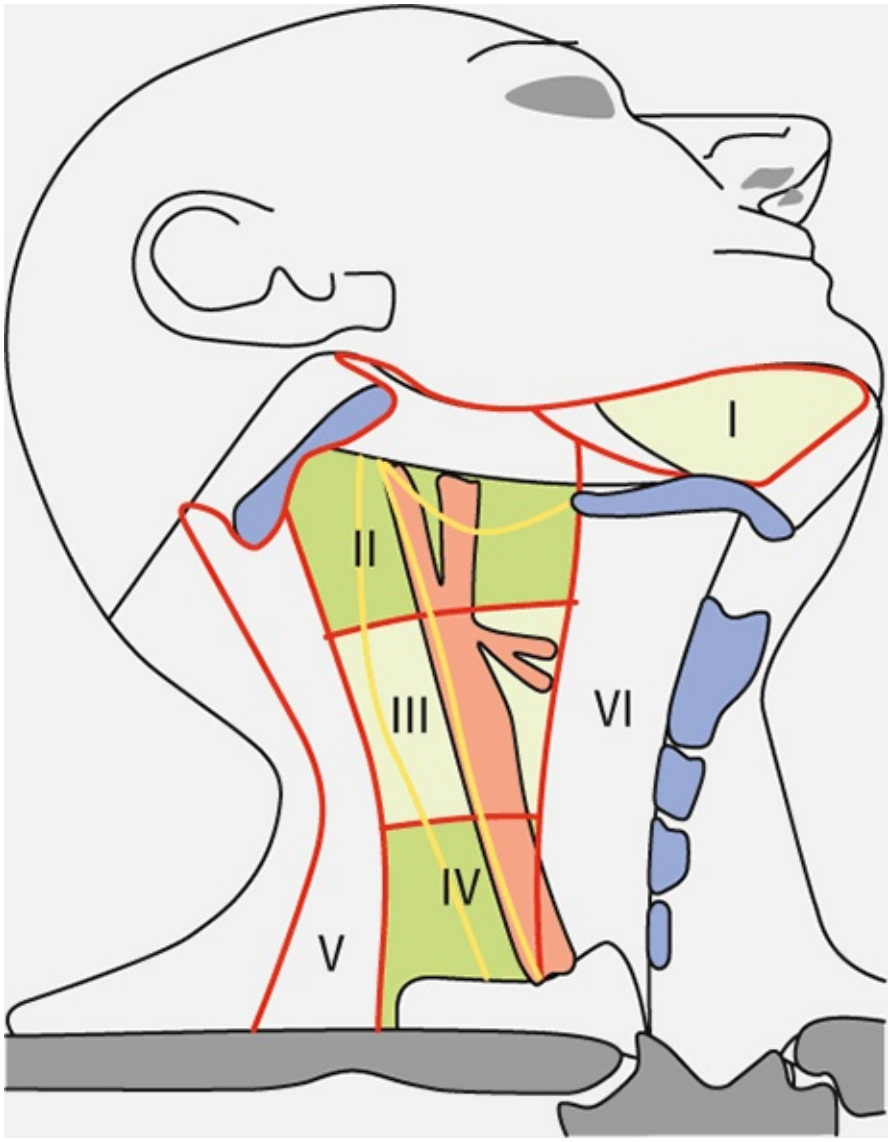

Fig. 9-2 Cervical lymph node levels.

Effectiveness of adjuvant radiotherapy in patients with oropharyngeal and floor of mouth squamous cell carcinoma and concomitant histological verification of singular ipsilateral cervical lymph node metastasis (pN1-state)—a prospective multicenter randomized controlled clinical trial using a comprehensive cohort design. *Trials*. 2009;10:118. PMID 20028566. © *Moergel et al; licensee BioMed Central Ltd. 2009*

DIAGNOSTIC EVALUATION

A comprehensive examination of the head and neck with the assistance of mirrors or fiber-optic scopes is central to the evaluation. Because lymph nodes track along the internal jugular vein, examination of the neck for enlarged lymph nodes is facilitated by rotating the head toward the side being examined to promote relaxation of the sternocleidomastoid muscle on that side.

Endoscopy

Examination under anesthesia often is necessary and important, especially for patients with tumors of the larynx or pharynx. The routine application of so-called “triple endoscopy” (laryngoscopy or pharyngoscopy plus bronchoscopy and esophagoscopy) to rule out synchronous tumors is controversial. If the primary site is known, the diagnostic yield of bronchoscopy or esophagoscopy is generally low. However, most clinicians agree that these procedures are indicated for patients with evidence of diffuse mucosal abnormalities in the setting of a malignant neck node without a clear primary site, particularly when the lymph node

is located in the lower part of the neck, which increases the likelihood of a lung or esophageal primary tumor. In addition, endoscopy has a low yield in nonsmokers, as a synchronous second primary cancer is less likely in these patients.

Imaging

Recommendations for imaging the primary site and the neck include computed tomography (CT) or magnetic resonance imaging for demarcating the extent of disease. A high-quality CT scan performed with contrast medium is less expensive than magnetic resonance imaging (MRI) and is sufficient in most cases. An extensive search for distant metastases for patients with head and neck cancer who do not have suspicious symptoms is not routinely done because the overall incidence of spread below the clavicle at the time of presentation is low (10% or less), particularly in the absence of lymph node involvement. Hence, routinely performing positron-emission tomography (PET)/CT or other body imaging in all patients is neither clinically indicated nor cost-effective. A chest x-ray is performed as much to rule out a second primary lung cancer or to document chronic obstructive pulmonary disease as to identify lung metastases.

A high-resolution CT scan is more sensitive than a chest x-ray for identifying a new primary site or metastases, and it could have a specific indication for patients presenting with bulky N2 or N3 neck disease or a primary site of the hypopharynx, both of which are risk factors for distant metastatic spread. Formal imaging of the liver and bones should be carried out only if clinically indicated based on symptoms or a biochemical abnormality, such as hypercalcemia or an elevation in serum alkaline phosphatase. By contrast, evaluation for metastatic disease with a body CT scan and bone scan, or by using 18-fluorodeoxyglucose (FDG)-PET/CT, is an appropriate part of the workup for patients with nasopharyngeal cancer with lymph node involvement. In this setting, the incidence of distant metastases approaches 60%, and bone is the most common site of metastasis.

FDG-PET is appropriate when the primary site is unknown or to evaluate an equivocal finding on cross-sectional imaging; however, routine application of this test is expensive, and if disease management will not be affected, it is not indicated. FDG-PET does not replace cross-sectional imaging of the primary site and neck, and is best interpreted in the context of a separate or fused cross-sectional study performed with contrast. As with any diagnostic test, FDG-PET is not without fault. False-positive results can be related to dental disease or to an inflammatory process in the neck or elsewhere, and uptake by lesions smaller than 1 cm is inconsistent. FDG-PET with a fused, contrast-enhanced CT scan may be useful for identifying spread to regional nodes in the N0 neck, the identification of which would alter radiation portals or the choice of neck dissection to be performed.[30-32] The sensitivity and specificity to detect nodal metastases is 90% and 94%, respectively.

Tissue Diagnosis

Histologic proof of cancer typically is obtained by performing a biopsy of the primary site, a neck node, or both. At least initially, needle aspiration of a lymph node is preferred to excisional biopsy, especially for an apparently malignant node with an occult primary lesion. This approach is both safe and feasible, and the theoretical risk of seeding malignant cells along the needle track has not been a problem in the clinic. Straightforward squamous cell cancers should pose few challenges to the cytopathologist; poorly differentiated tumors or lymphomas are more problematic. If an excisional biopsy is necessary, its results may be incorporated into the

definitive treatment of the patient. A surgeon capable of performing a neck dissection should be involved if squamous cell cancer is suspected.

STAGE CLASSIFICATION

The stage groupings for all primary sites are based on the tumor, node, and metastasis (TNM) classification of the AJCC 8th edition and the Union for International Union Against Cancer (UICC). The TNM system is based on both clinical examination and radiographic information. A few general rules for clinical staging can be identified:

- Primary tumors of the oral cavity and oropharynx that are 4 cm or larger are classified as T3; those with massive local invasion of adjacent structures are classified as T4.
- Vocal cord paralysis in the setting of a primary tumor of the larynx or hypopharynx indicates a stage of no less than T3.
- The nasopharynx is the one primary site for which an alternative staging system—the Ho staging system—is commonly used, particularly in Asia. Because definitions for component stages vary between the AJCC/UICC and Ho systems, these differences must be considered when reviewing the published results of therapy.
- For all primary sites (Table 9-3) except the nasopharynx and p16-positive oropharyngeal cancers (Table 9-4), the TNM stage grouping is the same; clinical lymph node involvement indicates an overall stage of at least stage III; the presence of distant metastases indicates stage IVC disease, and locally advanced resectable and unresectable stage IV disease (without distant metastases) are designated as IVA and IVB, respectively.
- Oral cavity T stage has been updated to incorporate depth of invasion into staging in addition to previously included size and sites of local invasion.
- The general nodal staging system now incorporates extranodal extension into the N staging to reflect the poorer prognosis associated in tumors with positive extranodal extension.
- The term “early-stage disease” refers to stages I and II disease and to low-volume stage III disease (e.g., T1 or T2 and N0 or N1); the term “locally” or “locally regionally advanced disease” refers to stages III and IV disease, specifically a large primary tumor (T3 or T4) or the presence of multiple or bulky neck nodes (N2 or N3).

Table 9-3 **American Joint Committee on Cancer Staging: Lip and Oral Cavity, Oropharynx, Hypopharynx, and Larynx**

Primary Tumor (T)	**Tx**	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
Lip and Oral Cavity	**T1**	Tumor 2 cm or less in greatest dimension
	T2	Tumor greater than 2 cm but no more than 4 cm in greatest dimension
	T3	Tumor greater than 4 cm in greatest dimension
	T4	(lip) Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (i.e., chin or nose)
	T4a	(oral cavity) Tumor invades adjacent structures (e.g., through cortical bone, into deep [extrinsic] muscle of tongue [genioglossus, hyoglossus, palatoglossus, and styloglossus], maxillary sinus, skin of face)
	T4b	Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery
Oropharynx	**T1**	Tumor 2 cm or less in greatest dimension
	T2	Tumor greater than 2 cm but no more than 4 cm in greatest dimension
	T3	Tumor greater than 4 cm in greatest dimension
	T4a	Tumor invades the larynx, deep/extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible
	T4b	Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery
Hypopharynx	**T1**	Tumor limited to one subsite of hypopharynx and 2 cm or less in greatest dimension
	T2	Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures greater than 2 cm but no more than 4 cm in greatest diameter without fixation of hemilarynx
	T3	Tumor greater than 4 cm in greatest dimension or fixation of hemilarynx
	T4a	Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, esophagus, or central compartment soft tissue
	T4b	Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
Larynx-Supraglottis	**T1**	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
	T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
	T3	Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic tissues, paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
	T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
	T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis	**T1**	Tumor limited to the vocal cord(s) with normal mobility
	T2	Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility
	T3	Tumor limited to the larynx with vocal cord fixation and/or invades paraglottic space, and or minor thyroid cartilage erosion
	T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
	T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Regional Lymph Nodes (N)	NX	Regional lymph nodes cannot be assessed		
	N0	No regional lymph node metastasis		
	N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension		
	N2	Metastasis in a single ipsilateral lymph node, greater than 3 cm but no more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none greater than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none greater than 6 cm in greatest dimension		
	N2a	Metastasis in a single ipsilateral lymph node, greater than 3 cm but no more than 6 cm in greatest dimension		
	N2b	Metastasis in multiple ipsilateral lymph nodes, none greater than 6 cm in greatest dimension		
	N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension		
	N3	Metastasis in a lymph node, greater than 6 cm in greatest dimension		
Distant Metastasis (M)	MX	Distant metastasis cannot be assessed		
	M0	No distant metastasis		
	M1	Distant metastasis

Unresectable T4 Lesion

There is general agreement among surgeons regarding the following criteria for unresectability: base of skull involvement, fixation to the prevertebral fascia, carotid encasement, and involvement of the pterygoid musculature. Additional criteria that many would consider appropriate are the inability to perform an adequate reconstruction for a functional result, a low likelihood of achieving negative margins, and a requirement for total glossectomy. Assignment to the stage IVB category has implications for prognosis (i.e., less favorable) and treatment (i.e., primary surgical management not planned). For these primary sites, stage IVB disease now includes patients with T4b, any N category, and no metastasis (M0), or any T category and N3 (any neck node larger than 6 cm in greatest diameter). Stage IVC includes any T and N category as well as M1 disease.

HPV-Related Oropharyngeal Cancer

The AJCC staging system was updated to account for p16 status in staging of oropharyngeal tumors given the marked difference in prognosis between patients with p16-positive and p16-negative tumors. Based on the work of groups such as the International Collaboration on Oropharyngeal Cancer Network for Staging and others, the new staging system for p16-positive oropharyngeal tumors uses the nasopharyngeal classification for nodal disease without the lower neck lymph node variable and combining of T4a and T4b into a single T4 category. The new system has three stages for nonmetastatic disease: stage I (T0-T2N0-N1), stage II (T0-T2N2 or T3N0-N2), and stage III (T4 or N3) and stage IV (M1) for metastatic disease.[33] Additionally, cancers of unknown primary origin in patients who are HPV- or EBV-positive may now be regarded as oropharyngeal cancers or nasopharyngeal cancers, respectively.[20]

KEY POINTS

- Many presenting signs and symptoms are associated with a particular primary site (e.g., hoarseness may refer to the larynx or hypopharynx, and a unilateral otitis media may refer to the nasopharynx).
- The location of pathologic lymph nodes in the neck may suggest the primary site.
- The initial staging evaluation for head and neck cancer includes comprehensive examination of the head and neck, imaging of the primary site and neck, chest imaging, and routine lab screenings.
- Early-stage disease is defined as disease limited to a small primary tumor (T1 or T2) with low risk nodal involvement. Locally or locally regionally advanced disease is defined as the presence of a large primary tumor (T3 or T4) or the presence of large, multiple, or contralateral regional node involvement (N2 or N3).
- Criteria for unresectable disease include base of skull involvement, fixation to the prevertebral fascia, carotid encasement, and involvement of the pterygoid musculature.

Table 9-4 American Joint Committee on Cancer Staging: Nasopharyngeal Carcinoma

Classification of Nasopharyngeal Carcinoma	WHO Classification	Former Terminology		
	Type I: Squamous cell carcinoma	Squamous cell carcinoma		
	Type II: Nonkeratinizing carcinoma	Transitional cell carcinoma		
	Without lymphoid stroma	Intermediate cell carcinoma		
	With lymphoid stroma	Lymphoepithelial carcinoma (Regaud)		
	Type III: Undifferentiated carcinoma	Anaplastic carcinoma		
	Without lymphoid stroma	Clear cell carcinoma		
	With lymphoid stroma	Lymphoepithelial carcinoma (Schminke)		
Primary Tumor (T)	TX	Primary tumor cannot be assessed		
	T0	No evidence of primary tumor		
	Tis	Carcinoma in situ		
	T1	Tumor confined to the nasopharynx, extends to oropharynx and/or nasal cavity without parapharyngeal extension		
	T2	Tumor with parapharyngeal extension		
	T3	Tumor involves bony structures and/or paranasal sinuses		
	T4	Tumor with intracranial extension and/or involvement of cranial nerves, infratemporal fossa, hypopharynx, orbit, or masticator space		
Regional Lymph Nodes (N)	NX	Regional lymph nodes cannot be assessed		
	N0	No regional lymph node metastasis		
	N1	Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa		
	N2	Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa		
	N3	Metastasis in a lymph node(s) greater than 6 cm and/or to supraclavicular fossa		
	N3a	Greater than 6 cm in dimension		
	N3b	Extension to the supraclavicular fossa		
Distant Metastasis (M)	MX	Distant metastasis cannot be assessed		
	M0	No distant metastasis		
	M1	Distant metastasis

PRINCIPLES OF DISEASE MANAGEMENT

Historically, surgery and radiation therapy have been the central treatment modalities for head and neck cancers because they have curative potential. Management of the primary site and management of the neck are separate but related concerns that influence decisions about which modality is used or the integration of combined-modality therapy. Although chemotherapy may enhance the effects of radiation therapy, chemotherapy by itself is not curative. TNM stage groupings are helpful for defining prognosis and treatment options. Management of head and neck cancer is best served by multidisciplinary treatment planning that involves not only a surgeon, medical oncologist, and radiation oncologist but also dentists, prosthodontists, nutritionists, audiologists, speech and swallowing therapists, physical and occupational therapists, social workers, and psychiatrists, as necessary. Plans for rehabilitation are an

integral part of this process.

NEWLY DIAGNOSED T1 OR T2, N0 OR N1, AND M0 (STAGES I, II, AND LOW-BULK III) DISEASE

Single-modality treatment with surgery or radiation is typically used for previously untreated stage I, stage II, or low-bulk stage III disease—essentially, a small primary tumor with or without a single ipsilateral node measuring 3 cm or less in diameter. Cure rates for this group are quite favorable, ranging from 52 to 100%, depending on the primary site. Strategies to decrease the morbidity associated with treatment and to prevent SPMs have been research priorities. The chosen modality depends on local expertise, anticipated functional outcome, and patient preference. For example, a T1N0M0 tumor of the glottic larynx can be managed with surgery or radiation. The 5-year overall survival rates associated with primary surgery (e.g., cordectomy and hemilaryngectomy) and primary radiation therapy (with salvage surgery as necessary) have been comparable (approximately 90%).[34] A cordectomy requires less time than radiation therapy and initially is cheaper, but repeat procedures may be necessary and could lead to a related decrease in function. Radiation therapy is associated with excellent control rates and voice function outcome, but it requires a 6-week course and initially may be more expensive.

NEWLY DIAGNOSED, HIGHER-VOLUME STAGE III AND STAGES IVA AND IVB DISEASE

If a higher-volume stage III or a stage IV tumor is resectable, the standard approach is surgery followed by adjuvant radiation therapy with or without concomitant chemotherapy based on pathologic risk features (see section on Principles of Surgery), or combined chemotherapy and radiotherapy if organ preservation is desired. If the tumor is unresectable, the approach is radiation and concomitant chemotherapy. Cure rates are less favorable for this group, ranging from 10 to 65%, depending on the primary site and disease extent. Data from randomized trials support integrated chemotherapy and radiation as standard treatment options for patients with advanced, resectable cancers of the larynx and hypopharynx (with the intent of avoiding total laryngectomy) and for patients with cancers of the oropharynx when a nonsurgical approach is chosen. For patients with advanced tumors of the oropharynx, nasopharynx, or unresectable squamous cell cancers of the upper aerodigestive tract, combined-modality therapy with chemoradiation improves survival compared with radiation alone[35-41] (Table 9-5). When primary chemoradiation therapy is used, surgery is reserved for persistent disease or for recurrence of resectable disease.

Table 9-5 Concurrent Chemoradiotherapy Standard of Care	
Organ Preservation	**Regimen**
Larynx	RT/cisplatin[38]
Oropharynx	RT/cisplatin or RT/carboplatin/5-FU[39,40] Consider RT/cetuximab if not candidates for platinum therapy[43,44]
Nasopharynx	RT/cisplatin followed by cisplatin/5-FU[42]
Unresectable disease	RT/cisplatin[41]
Postoperative adjuvant	RT/cisplatin[45,46]

Abbreviations: 5-FU, 5-fluorouracil; RT, radiotherapy.

For locally advanced, resectable cancers of the oral cavity, primary surgical management with appropriate reconstruction and/or postoperative radiation therapy is the mainstay of treatment because anticipated functional outcomes are favorable even for more advanced tumors.

RECURRENT DISEASE WITHOUT A SURGICAL OR RADIATION OPTION, OR M1 DISEASE

For patients who receive chemotherapy but for whom surgery or radiation therapy is not an option (including patients with distant metastases), disease is generally not curable, and the median survival ranges from 5 to 10 months with various available standard drugs based on prior clinical trials. Data now indicate that survival for patients with HPV-positive disease is longer than for patients with HPV-negative tumors even in the metastatic setting.[18] The identification of more effective chemotherapy and integration of targeted agents have been a priority for this patient group. Immunotherapy, using programmed death 1 antibodies, has now been approved for patients in whom platinum-based therapies have failed.

KEY POINTS

- Single-modality treatment with surgery or radiation therapy is typically used with curative intent for previously untreated stage I, stage II, or low-bulk stage III (T1-2N1) disease.
- Combined-modality treatment with surgery and radiation or chemoradiation therapy is typically used with curative intent for previously untreated, higher-volume stage III (T3N0-1) and stage IV disease without distant metastases.
- Metastatic disease below the clavicle and local–regional recurrent disease without a surgical or radiation option are generally incurable and treated with palliative intent.

PRINCIPLES OF SURGERY

SURGERY OF THE PRIMARY TUMOR

Complete removal of a tumor with negative margins defines an adequate surgical resection. Transoral robotic and endoscopic technology is now available and facilitates the accomplishment of such resections in a less invasive manner, but these techniques require special expertise and experience to apply well. Depending on the primary site and the size of the tumor, complete surgical extirpation may necessitate removal of key structures, such as the larynx, eye, or mandible. The potential adverse effect on cosmesis and function underscores the importance of rehabilitation as part of the treatment strategy. A variety of skin and bone flaps, as well as customized obturators and prosthetics, successfully address many defects that arise from surgery. Function-preserving procedures are applicable for selected patients in whom negative margins are achieved, while uninvolved structures necessary for function are preserved. Examples include various subtotal laryngectomy procedures, for which adding a postoperative course of radiation therapy often compromises the functional outcome. Thus, all of these factors must be considered when deciding the best therapeutic option for each patient.

As the spectrum of reconstructive options increases, defining precise, reproducible criteria for tumor unresectability remains a challenge and complicates interpretation of the literature. A patient with an unresectable tumor should be distinguished from a patient with disease that is clearly resectable but for whom there are medical contraindications to surgery (i.e., medically inoperable).

SURGERY OF THE NECK

Different types of neck surgery or dissection are used to address suspected or proven disease in the cervical lymph nodes. This is performed up front or after completion of chemoradiation, at the discretion of treating physicians. A comprehensive neck dissection involves the en bloc removal of all five lymph node levels (Fig. 9-2). Three important structures are potentially jeopardized by this procedure: the sternocleidomastoid muscle, the internal jugular vein, and the spinal accessory nerve. If none of these structures are spared, the procedure is considered a radical neck dissection, which is associated with the highest likelihood of postoperative shoulder pain and weakness. Different types of comprehensive neck procedures that spare one, two, or three of these structures (modified radical neck dissections) may be performed for selected patients, without compromising disease control. Comprehensive neck dissections generally are done with therapeutic intent, such as when cancerous lymph nodes are suspected or known to be present. In other settings, selective neck dissections are used, whereby fewer than five lymph node levels are removed. Selective procedures usually are performed electively in part to improve staging precision (such as when there are no palpable lymph nodes, but the estimated risk for occult metastases exceeds 15 to 20%, and negative findings on specimen analysis may obviate the need for postoperative radiation therapy).

PET imaging 3 months after treatment is useful in the assessment of patients with node-positive disease who were treated with chemoradiation therapy. Rather than all patients proceeding to adjuvant neck dissection, given the high negative predictive value of FDG-PET, observation can be considered for patients with non–FDG-avid neck lymph nodes measuring less than 1 cm. In a randomized study of patients with N2 or N3 neck disease, PET/CT-guided surveillance resulted in noninferior survival at 36 months as compared with up-front neck dissection, and these patients underwent fewer neck dissections.

KEY POINTS

- Function-conserving procedures are applicable for select patients in whom negative margins can be achieved with preservation of structures important for function.
- Conservative or debulking surgery is not part of routine clinical practice for head and neck cancer.
- Comprehensive neck dissections involve removal of all five lymph node levels and are usually performed with therapeutic intent. Selective neck dissections involve removal of fewer than all five levels and are generally done electively to improve staging precision.

PRINCIPLES OF RADIATION THERAPY

The curability of head and neck cancer with radiation therapy is inversely related to tumor bulk. The rate of disease control with radiation alone decreases with increasing T stage. This finding explains why radiation can be used as a single modality to treat early-stage disease but is generally applied as an adjunct to surgery or combined with chemotherapy for more advanced tumors.

RADIATION DOSE AND FRACTIONATION

The dose of radiation necessary to sterilize squamous cell cancer varies with the fractionation size and schedule used. Standard, once-daily fractionation consists of 2.0 Gy per day with a total dose of 70 Gy or greater to the primary site and gross adenopathy and 50 Gy or greater to uninvolved nodal stations at risk. When given postoperatively, the total dose to the primary site and involved nodal stations is 60 Gy or greater, and the dose to uninvolved nodal stations at risk is 50 Gy or greater. Postoperative radiation generally begins 4 to 6 weeks after surgery. The delivery of radiation requires careful treatment planning. In particular, the spinal cord must be blocked to prevent radiation-induced cervical myelopathy.

Potential improvements in the therapeutic index of radiation for head and neck cancer may be achieved by altering the radiation fractionation (more than one fraction per day, often with a change in the fraction size). The results of randomized trials have established the therapeutic benefits of an altered-fractionation strategy, particularly with regard to local–regional control. In one seminal study by the RTOG,[42] more than 1000 previously untreated patients with stage II, III, or IV HNSCC were randomly assigned to four different radiation-only treatment arms: standard fractionation, 2 Gy daily and 70 Gy for 7 weeks; hyperfractionation, 1.2 Gy twice daily and 81.6 Gy for 7 weeks; accelerated fractionation with a split, 1.6 Gy twice daily and 67.2 Gy for 6 weeks; and accelerated fractionation with a concomitant boost, 1.8 Gy daily, 1.5 Gy daily as a boost for the last 12 days only, and 72 Gy for 6 weeks.

With a median follow-up of 41.2 months among surviving patients, the hyperfractionation and concomitant boost arms yielded significantly improved local–regional control ($p = 0.045$ and $p = 0.050$, respectively), as well as a trend toward improved disease-free survival ($p = 0.067$ and $p = 0.054$). More acute toxicity, but no late effect, was seen in the three altered-fractionation groups. Although no significant differences in overall survival were demonstrated, the meta-analysis known as MARCH indicated a significant improvement in absolute survival at 5 years with altered-fractionation approaches (3.4%; HR, 0.92; 95% CI; 0.86, 0.97; $p = 0.003$). This

assessment included 15 randomized trials involving 6515 patients and compared conventional radiotherapy with hyperfractionated radiotherapy, accelerated radiotherapy, or both.[43] The benefit was significantly higher with hyperfractionated radiotherapy than with accelerated radiotherapy (8% vs. 2% at 5 years). Altered-fractionation programs are increasingly being incorporated into standard practice for patients who can tolerate the added local–regional toxicity and also are being investigated in combination with concomitant chemotherapy. In RTOG 0129, researchers investigated adding chemotherapy to different radiation delivery plans. Specifically, patients with locally advanced disease were treated with cisplatin plus accelerated fractionation with a concomitant boost or standard fractionation. With a median follow-up of 7.9 years, there were no significant differences between the standard fractionation group and the accelerated fractionation plus concomitant boost group in overall survival (HR, 0.96, p = 0.37; 5-year, 57% vs. 60%; 8-year estimate, 48% vs. 48%), progression-free survival (HR, 1.02; p = 0.52; 5-year, 49% vs. 50%; 8-year estimate, 42% vs. 41%), local–regional failure rate (HR, 1.08; p = 0.78; 5-year, 31% vs. 34%; 8-year estimate, 37% vs. 39%), or rate of distant metastases (HR, 0.83; p = 0.16; 5-year, 14.5% vs. 11.5%; 8-year estimate, 15% vs. 13%).[44]

With recent advances in technology, improved planning and delivery of radiotherapy has helped overcome some of the major side effects of conventional radiotherapy. One advancement is intensity-modulated radiotherapy, which is regularly used in the treatment of head and neck cancer. This therapy delivers therapeutic radiation doses specifically around the tumor and the at-risk lymph nodes with improved conformality, defined as the ratio of the dose to tumor relative to the dose to normal tissues. Increasingly, conformal plans are able to deliver the same dose to the tumor while sparing progressively more of the surrounding tissues. The advantages of this technique are that the surrounding normal tissue can be spared and that anatomic structures (e.g., the pharyngeal constrictor muscles necessary for swallowing and the salivary glands) can be preserved. In the randomized, phase III PARSPORT study, patients treated with intensity-modulated radiotherapy had less incidence of xerostomia compared with patients treated with conventional radiation therapy, albeit with higher rates of fatigue during treatment.[45] Another more recent advancement is the use of proton-beam therapy. Compared with typical photon therapy, in proton-beam therapy the physical properties of a proton allow the administration of lower doses of radiation beyond the tumor, leading to better conformality. However, definitive data that one method leads to better tumor control than the other in the management of head and neck cancer are lacking, and their relative side-effect profiles with and without the addition of systemic therapy are in the process of being better defined.

RADIATION-RELATED TOXICITY

Radiation at the doses outlined previously is associated with predictable acute mucosal and skin toxicities. More aggressive dosing and fractionation schedules and the addition of concomitant chemotherapy generally increase the severity of these acute toxicities. Depending on the amount of salivary tissue included in the radiation portal, xerostomia and loss of taste are common. Because adequate saliva is an important component of oral hygiene, careful dental assessment is necessary before the start of radiation therapy, followed by ongoing dental prophylaxis and fluoride treatments. Pain management, nutritional support, swallowing evaluation and therapy, and aggressive oral care are required. Other potential complications include hypothyroidism, especially for patients receiving treatment to the neck; Lhermitte syndrome, a self-limited, shocklike sensation extending down the spine and extremities with

neck flexion; long-term induration and fibrosis; and osteoradionecrosis of the mandible.

Some degree of xerostomia is common. Pilocarpine (a cholinomimetic, muscarinic agent), cevimeline (a parasympathomimetic and a muscarinic agonist), and amifostine (a thiol with chemoprotectant and radioprotectant properties) are used to treat dry mouth.[46-48] Amifostine is approved only for use with postoperative adjuvant radiotherapy and not in the definitive setting.

KEY POINTS

- Compared with standard schedules, altered-fractionation radiotherapy improves local–regional control of advanced tumors, albeit with increased acute local toxicity.
- Head and neck radiation commonly causes acute toxicities, including mucositis, edema, and xerostomia. Other potential toxicities include hypothyroidism, Lhermitte syndrome, long-term induration and fibrosis, and osteoradionecrosis of the mandible.
- Intensity-modulated radiotherapy is associated with less dry mouth after treatment than that seen with conventionally planned radiation therapy.
- Pilocarpine, cevimeline, and amifostine may ameliorate radiation-induced xerostomia.

PRINCIPLES OF CHEMOTHERAPY

A number of drugs have activity against HNSCC, including methotrexate, cisplatin, carboplatin, 5-fluorouracil, paclitaxel, docetaxel, and cetuximab. Gemcitabine (for nasopharynx cancer),[49,50] vinorelbine, bleomycin, ifosfamide, and irinotecan also are active but are used less frequently in current clinical practice. The reported response proportions vary with the setting (untreated or pretreated) and the drugs used (single agent or combination). Platinum-based regimens are most commonly used as first-line therapy. The anticipated major response rate in patients with previously untreated disease is 60 to 90%, with clinical complete responses in 20 to 50%. By contrast, the activity of platinum-based drug combination therapy in patients with recurrent disease is 30 to 40% and complete responses are rare. Rates of complete and partial responses from single-agent therapy are approximately half of those observed with combination chemotherapy.

The use of chemotherapy for patients with potentially curable, advanced, local–regional disease is generally distinguished from the treatment of patients with incurable, recurrent, metastatic disease. For patients with potentially curable cancer, the chemotherapy literature can be divided into the following four groups:

- induction or neoadjuvant chemotherapy administered for several cycles prior to definitive local therapy (surgery, radiation therapy, or chemoradiotherapy);
- chemoradiation in the setting of locally advanced, unresectable disease;
- local curative therapy (surgery) followed by adjuvant chemoradiation; and
- organ-preservation techniques for patients with resectable cancers of the oropharynx, larynx, and hypopharynx.

The goals of these multimodality approaches are to improve survival by reducing rates of local–regional recurrence and metastases as well as to achieve preservation of the organ and

its function without a decrement in the survival rates achievable with primary surgery. The latter specifically refers to preservation of the larynx for patients with primary cancers of the larynx or hypopharynx and preservation of structures in the oropharynx for speech and swallowing function, such as the tongue.

INDUCTION CHEMOTHERAPY

Studies evaluating the integration of induction chemotherapy with local–regional treatment dominated the literature of head and neck cancer during the 1980s and early 1990s. The results of randomized controlled trials evaluating two to four courses of cisplatin-based combination chemotherapy as induction followed by local therapy demonstrated a decrease in distant metastases in some trials, but no significant or consistent differences were observed in either local–regional control or overall survival when compared with the standard of care for most trials and meta-analyses.[39,51,52] This result was found despite the high major response rates seen after treatment with cisplatin-based combination chemotherapy in these previously untreated patients.

A meta-analysis of 63 randomized trials of local–regional treatment with or without chemotherapy was performed using updated patient data. This comprehensive review showed no significant survival benefit from the addition of induction chemotherapy (31 trials involving 5269 patients; HR, 0.95; 95% CI; 0.88, 1.01; p = 0.10). A subgroup analysis focusing on trials in which induction cisplatin/5-fluorouracil were used showed a significant survival benefit for this regimen (HR, 0.88; 95% CI; 0.79, 0.97; p = 0.05), but a similar subset analysis focusing on platinum-based concomitant therapy demonstrated an approximately 3-fold higher survival benefit.[52]

Taken collectively, these data did not support a role in standard clinical practice for induction chemotherapy in the setting of planned surgery and radiation (with improvement in overall survival as the endpoint).

The next phase of induction studies added taxanes to the backbone of previously tested cisplatin/5-fluorouracil. The results from three randomized controlled trials comparing three or four cycles of induction docetaxel/cisplatin/5-fluorouracil with standard cisplatin, 100 mg/m^2 plus 5-fluorouracil daily, and 1000 mg/m^2 per day by continuous infusion for 5 days are noteworthy.[53-55] The TAX 323 trial enrolled more than 300 patients with locally advanced unresectable disease. The control arm consisted of four cycles of the two-drug combination followed by radiotherapy, and the experimental arm consisted of four cycles of the three-drug combination (docetaxel, 75 mg/m^2; cisplatin, 75 mg/m^2; 5-fluorouracil, 750 mg/m^2 per day by continuous infusion for 5 days) followed by radiotherapy.[54] The response rate to the three-drug induction regimen was significantly higher than that of the two-drug regimen (68% vs. 54%; p = 0.006) as was overall survival (HR, 0.73; 95% CI; 0.57, 0.94; p = 0.016). There also was less nonhematologic toxicity with the three-drug combination than with the two-drug combination; however, hematologic toxicity was more common with the former. Similarly, the TAX 324 trial randomly assigned 501 patients with unresectable or resectable disease (all sites) to three cycles of standard cisplatin/5-fluorouracil or to combination docetaxel, 75 mg/m^2; cisplatin, 100 mg/m^2; 5-fluorouracil, 1000 mg/m^2 per day by continuous infusion for 4 days.[53] Definitive local therapy in both arms consisted of standard radiotherapy plus weekly carboplatin (area under the curve, 1.5). Overall survival was significantly improved for patients who received the three-drug therapy (HR, 0.70; 95% CI; 0.54, 0.90; p = 0.0058). The differences between groups persisted with longer follow-up. At a median follow-up of 72 months, median survival was 70.6

months (95% CI; 49.0, 89.0) in the triplet arm compared with 34.8 months (95% CI; 22.6, 48.0) in the doublet arm (p = 0.014).[56] The third trial was conducted by the GORTEC study group for organ preservation in patients with either locally advanced cancer of the larynx or hypopharynx.[55] A total of 220 patients were randomly assigned, and of these, just over half had a hypopharyngeal primary tumor. The stage of the primary tumor was T3 for the majority of patients. The two treatment arms were standard cisplatin/5-fluorouracil for three cycles (control) or combination docetaxel/cisplatin/5-fluorouracil for three cycles (dosing same as in TAX 323). After induction, patients with responsive disease received 70 Gy of standard radiation; patients whose disease did not respond to chemotherapy underwent total laryngectomy followed by radiotherapy with or without additional chemotherapy The three-drug therapy was shown to be statistically superior for the endpoints of response to the induction regimen (83% vs. 61%) and preservation of a functional larynx at 3 years (63% vs. 41%). More details of the patient population and outcomes are needed for interpretation of the results in the context of other larynx-preservation trials for these two primary sites.

These three trials demonstrate that combination of docetaxel/cisplatin/5-fluorouracil followed by radiotherapy alone or chemoradiation with carboplatin is superior to cisplatin/5-fluorouracil followed by the same definitive local therapy. Also, the three-drug regimen administered in TAX 323 seems to have an acceptable toxicity profile with lower rates of severe and life-threatening myelosuppression than those observed with the two-drug regimen. A fourth phase III trial has been published in final form.[57] This trial compared induction paclitaxel/cisplatin/5-fluorouracil with induction cisplatin/5-fluorouracil in a heterogeneous population of patients with resectable and those with unresectable disease. Chemoradiation was planned following induction chemotherapy, but the actual treatment was not uniform. The taxane-containing treatment group experienced a higher overall response rate (80% vs. 68%). However, the difference in overall survival was not significant, although the trend favored the paclitaxel-containing arm.

In addition to the trials reviewed earlier, a meta-analysis of five randomized trials representing 1772 patients comparing cisplatin/fluorouracil induction therapy with a taxane/cisplatin/5-fluorouracil regimen confirmed the superiority of the taxane-containing induction regimen, with a significant reduction in progression, local–regional failure, and distant failure compared with cisplatin/5-fluorouracil.[58]

These data provided the rationale for three phase III trials comparing induction chemotherapy with taxane/cisplatin/5-fluoruracil followed by chemoradiation therapy compared with chemoradiation therapy alone.[59-61] There was no evidence of a survival benefit in any of these three studies. The first was a phase III study that compared induction chemotherapy, including a docetaxel/cisplatin/5-fluorouracil induction arm, followed by chemoradiation therapy with chemoradiation therapy alone.[60] Next published was the PARADIGM study, which enrolled 145 patients with locally advanced head and neck cancer and randomly assigned them to docetaxel/cisplatin/5-fluorouracil induction therapy followed by chemoradiation therapy (with either docetaxel or carboplatin) or cisplatin-based chemoradiation therapy alone (with two cycles of bolus cisplatin).[61] After a median follow-up of 49 months, the 3-year overall survival was 73% in the induction chemotherapy therapy followed by chemoradiation therapy group and 78% in the chemoradiation-alone group (p = 0.77). More patients had febrile neutropenia on the induction therapy arm. In the DeCIDE trial, patients with N2/N3, locally advanced head and neck cancer were randomly assigned to receive two cycles of docetaxel/cisplatin/5-fluorouracil induction therapy followed by chemoradiation therapy or chemoradiation therapy alone. The concomitant therapy was similar in the two arms and consisted of cisplatin/5-fluorouracil/hydroxyurea. A total of 280 patients were enrolled. With a minimum follow-up of 30

months, the incidence of distant failure was higher in the chemoradiation-alone arm (29 vs. 17 in the induction therapy arm), but this difference was not statistically significant ($p = 0.11$); the overall survival was similar in the two arms at 72% in the induction arm and 69% in the chemoradiation-alone arm ($p = 0.69$). The incidence of grade 3 to 4 leukopenia and neutropenia was higher in the induction arm.[59]

Therefore, at this time, although induction chemotherapy with taxanes/cisplatin/5-fluorouracil followed by chemoradiation therapy remains an option, it cannot be concluded that it is superior to chemoradiation therapy alone in the management of locally advanced head and neck cancer. The role of induction chemotherapy followed by surgery and postoperative radiation therapy was investigated in a phase III trial that evaluated 256 patients with locally advanced (stages III and IVa) oral squamous cell cancers.[62] Patients received either two cycles of docetaxel/cisplatin/5-fluorouracil induction followed by surgery and postoperative radiation therapy or up-front surgery and postoperative radiation therapy. There was no increased perioperative morbidity noted with the induction arm. At a median follow-up of 30 months, there was no significant difference in overall survival between the two arms of the study. This approach of induction chemotherapy followed by surgery and postoperative therapy, therefore, cannot be considered as a standard treatment paradigm.

CONCOMITANT CHEMOTHERAPY AND RADIATION

The major role for chemotherapy in patients with nonmetastatic disease is its use as a radiation sensitizer. Therefore, the main focus has been on drugs that show activity against the disease and radiation-enhancement properties (e.g., cisplatin, cetuximab, and 5-fluorouracil). The two general strategies that can be identified amid a broad spectrum of approaches are

- concomitant single-agent or combination chemotherapy with continuous-course radiation, or
- combination chemotherapy with planned split-course radiation.

More recently, altered-fractionation approaches have become an added variable. Historically, the use of chemotherapy in this manner was applied to patients with unresectable disease and generally increased the severity of acute mucosal and skin toxicities but also improved local–regional control compared with radiation alone. These encouraging efficacy results led to studies of other patient groups (e.g., resectable, organ-preservation intent, and poor-risk adjuvant).

A study first reported in 1992 was the turning point for the growing interest in chemoradiation therapy for advanced head and neck cancer.[63] In this study, the investigators randomly assigned 157 patients with unresectable HNSCC to radiation alone (up to 70 Gy, conventional fractionation) or to a cisplatin/5-fluorouracil combination alternating with radiation (up to 60 Gy). The complete response rate (43%) and the survival rate (41%) in the group treated with chemoradiation therapy were significantly superior to those in the radiation alone group (22% and 23%, respectively; $p = 0.01$).

Another trial randomly assigned 295 patients with unresectable HNSCC to one of three treatment groups: radiation alone (70 Gy, 2 Gy daily); the same radiation with concomitant cisplatin (100 mg/m^2) on days 1, 22, and 43; or split-course radiation (60 Gy to 70 Gy, 2 Gy daily) with three cycles of concomitant bolus cisplatin/infusional 5-fluorouracil. In the third arm, the option existed to pursue surgical resection after the second cycle of chemotherapy, if possible; resection was available for all three groups if feasible after the completion of

treatment.[38] With a median follow-up of 41 months, there was a significant survival advantage at 3 years associated with chemoradiation compared with radiation alone (37% and 23%; p = 0.014). The split-course concomitant regimen offered no survival advantage over the control group (27%). Toxicity of grade 3 or higher was significantly more common with concomitant chemotherapy (52% with radiotherapy alone vs. 89% with chemoradiation therapy; p < 0.0001). This trial established chemoradiation with high-dose cisplatin as the standard of care for locally advanced unresectable head and neck cancer.

The meta-analysis by Pignon et al. that included the 1992 study highlights the favorable results seen with a chemoradiation approach in these early trials. Although significant heterogeneity among designs was noted, the chemoradiation regimen was associated with an 8% absolute benefit in survival at 5 years compared with radiation alone (HR, 0.81; 95% CI; 0.76, 0.88; p < 0.0001).[54] An updated analysis of 87 trials involving more than 16,000 patients showed the same absolute benefit for survival with concomitant treatment (HR, 0.81; p < 0.0001).[64]

Once-daily fractionation radiation therapy for 7 weeks with high-dose cisplatin (100 mg/m^2 on days 1, 22, and 43) was compared with accelerated boost radiation therapy (42 fractions for 6 weeks) in combination with two cycles of cisplatin (100 mg/m^2 on days 1 and 22) in the RTOG 0129 trial. There was no statistically significant difference in overall survival between the arms.[44]

The use of targeted therapies with radiotherapy is an area of great interest. Epidermal growth factor receptor (EGFR) is highly expressed in virtually all HNSCC, and expression is inversely associated with prognosis. Therefore, EGFR inhibitors have been the focus of most targeted therapy trials for head and neck cancer. Cetuximab was approved by the U.S. Food and Drug Administration (FDA) for use in combination with radiotherapy for patients with advanced head and neck cancer based on a multicenter trial published by Bonner and colleagues.[65] This important, proof-of-principle trial randomly assigned patients with locally advanced squamous cell cancers of the oropharynx, larynx, and hypopharynx to treatment with radiotherapy alone (standard or altered-fractionation schedules) or to the same radiotherapy with weekly cetuximab. Local–regional failure-free survival and overall survival rates were significantly improved with the addition of cetuximab. The updated median overall survival for patients treated with cetuximab and radiation was 49.0 months (95% CI; 32.8, 69.5) compared with 29.3 months (95% CI; 20.6, 41.4) in the radiotherapy-alone group (HR, 0.73; 95% CI 0.56, 0.95; p = 0.018). Five-year overall survival was 45.6% in the cetuximab and radiation group and 36.4% in the radiotherapy-alone group. Further, survival was improved in patients who experienced at least a grade 2 acneiform rash compared with patients with grade 0 or 1 rash (HR, 0.49; 95% CI; 0.34, 0.72; p = 0.002).[66] Cetuximab had no effect on distant metastases. In a retrospective evaluation, patients with oropharyngeal cancer demonstrated improved local–regional control, progression-free survival and overall survival with the addition of cetuximab to radiation, regardless of HPV/p16 status.[67] Whether this combination of radiotherapy plus a biologic therapy is as effective as the standard cisplatin-based chemoradiation is unknown; therefore, the exact role and indications for cetuximab with radiotherapy are not clear. More recently, the international phase II CONCERT-2 study, which randomly assigned patients with locally advanced HNSCC to standard radiation with either two cycles of cisplatin (100 mg/m^2) or three cycles of panitumumab (9 mg/kg), reported a 2-year local–regional control rate of 61% compared with 51%, respectively. The HR for progression-free survival was 1.73 (95% CI; 1.07, 2.81; p = 0.03), and no statistical difference in overall survival was reported.[68]

At present, the only indication for cetuximab with radiotherapy in lieu of platinum-based chemotherapy is for the treatment of patients in whom the use of cisplatin is precluded or there is patient preference because of concern for cisplatin-related side effects. Numerous trials are testing the addition of EGFR inhibition with monoclonal antibodies or small-molecule tyrosine kinase inhibitors (TKIs) to chemotherapy and radiation in various disease settings. One such trial, RTOG 0522, directly compared cisplatin and radiation with or without cetuximab.[69] After a median of 3.8 years, there was no statistically significant improvement in the 3-year progression-free survival (61.2% vs. 58.9%; p = 0.76) and overall survival (72.9% vs. 75.8%; p = 0.32) or distant metastasis (13.0% vs. 9.7%; p = 0.08) with the addition of cetuximab to cisplatin and radiation. In CONCERT-1, a randomized international phase II study in patients with locally advanced squamous cell, investigators compared three cycles of panitumumab (9 mg/kg) with cisplatin (75 mg/m^2) with standard three cycles of cisplatin (100 mg/m^2) and failed to show any benefit of adding panitumumab in local–regional control at 2 years.[70] Similarly, the addition of erlotinib, an oral small-molecule TKI acting on EGFR, failed to show any improvement compared with cisplatin and radiation alone in the management of locally advanced HNSCC.[71]

Given the favorable prognosis of HPV-related oropharyngeal cancer, recent efforts have focused on attempts to "deintensify" the definitive standard modalities of radiation and chemotherapy. The disease control rates for HPV-positive low-risk (N0-2a or N2b patients with ≤ 10 pack-year smoking history) were similar for radiation therapy alone and chemoradiation therapy in one retrospective series.[72] However, the rate of disease control was lower in the N2c subset managed by radiation therapy alone (73% vs. 92% for chemotherapy and radiation; p = 0.02). Besides T and N staging, stratification by smoking exposure may also help risk stratify these patients. These data are considered exploratory and at this time any deintensification approach, although attractive in reducing long-term toxicities, should be considered investigational.

In summary, chemoradiation therapy leads to improved disease control compared with radiation alone for patients with unresectable HNSCC and represents a standard treatment for patients who are able to tolerate the anticipated added treatment-related toxicity. There also is a role for this approach in the organ-preservation and larynx-preservation settings and for advanced local–regional nasopharyngeal cancer. The data showing improvement are best established for platinum-based chemoradiation therapy regimens; an advantage persists even when newer altered-fractionation approaches are employed.

ADJUVANT CHEMORADIATION

The results of two randomized controlled trials have clarified the role of chemotherapy and radiation in the postoperative adjuvant setting when compared with radiotherapy alone. These studies, conducted by the EORTC,[36] as well as the trial by the RTOG[35] addressed the question of whether the addition of cisplatin to standard postoperative radiotherapy (based on pathologic criteria) would improve the outcome for patients. The experimental arms of both studies consisted of standard fractionation radiation with concomitant cisplatin (100 mg/m^2) on days 1, 22, and 43. The 5-year results of the EORTC study indicated significant improvement in progression-free survival (47% vs. 36%; p = 0.04) and overall survival (53% vs. 40%; p = 0.02) in favor of chemoradiation therapy with cisplatin.[36] The findings of the RTOG study initially demonstrated a significant advantage with combined-modality adjuvant therapy for the first two outcomes, but not for overall survival (3-year survival, 56% vs. 47%; p = 0.09).[35] In both

studies, toxicity was greater with concomitant chemoradiation therapy.

Although the treatment was very similar in these two studies, the high-risk pathologic features were not uniform and the study populations differed. The entry criteria for the RTOG study were the presence of multiple positive nodes, an extracapsular extension of tumor, or a positive margin. In contrast, the EORTC trial defined *high risk* as a positive margin, an extracapsular extension of nodal disease, vascular embolism, or perineural disease; for oral cavity or oropharynx primary sites, *high risk* was defined as positive nodes at level IV or V. These differences may, in part, explain the variable outcome of the two trials. In an effort to reconcile the results of these two trials, a pooled analysis was performed, which indicated that the subsets of patients in both trials who experienced a significant benefit from cisplatin added to radiotherapy had either microscopically involved margins or extracapsular extension of disease in neck nodes.[73] Therefore, the presence of either or both of these risk factors is considered a definite indication for adjuvant chemotherapy and radiation. Since these initial analyses were performed, the RTOG trial has been reanalyzed with a median follow-up of 9.4 years, and data demonstrated a significant advantage for chemoradiation therapy in terms of improvement of local–regional control and disease-free survival in patients with either positive margins or extracapsular nodal extension, but only a trend for overall survival benefit ($p = 0.07$).[74]

COMBINED-MODALITY TREATMENT: ORGAN PRESERVATION

Initial organ-preservation studies were designed around the use of induction chemotherapy for patients with resectable disease and, subsequently, have focused on chemoradiation therapy. Avoidance of total laryngectomy received the greatest attention in these early studies.[75,76]

Larynx and Hypopharynx Organ Preservation

The U.S. Department of Veterans Affairs Laryngeal Cancer Study Group (VALCSG) conducted a seminal randomized trial in which induction cisplatin/5-fluorouracil infusion (three cycles) followed by radiation therapy (with surgery reserved for patients whose disease had an inadequate response, disease persistence, or relapse) was compared with total laryngectomy followed by radiation therapy.[75] All 332 patients had advanced, resectable, T2 to T4 laryngeal cancer. There was no significant difference in survival between the groups with more than 10 years of follow-up subsequent to the original publication; total laryngectomy was avoided for approximately two-thirds of survivors who received chemoradiation therapy. On multivariate analysis, T4 and N2 disease were both significant predictors of treatment failure, with 56% of T4 cases eventually requiring laryngectomy. The pattern of failure differed between the two treatment groups, with a significant reduction in distant failure but a higher rate of local failure for the patients randomly assigned to induction chemotherapy compared with those in the surgery control arm.

Long-term quality-of-life outcomes were also assessed. Among the 46 long-term survivors surveyed, those who received induction chemotherapy plus radiation had significantly better quality-of-life scores ($p < 0.05$), better pain scores, and less depression. After 2 years, communication (speech) scores favored the induction chemotherapy group, but at longer follow-up, the two treatment groups had similar speech scores.[77]

The EORTC performed a similar study involving patients with advanced, resectable (T2 to T4) cancer of the hypopharynx.[76] There was no difference in survival between the two groups; the 5-year estimate of successful larynx preservation (i.e., local control and no tracheostomy or

feeding tube) was 35%. The EORTC and VALCSG studies established induction cisplatin/infusional 5-fluorouracil followed by radiation (for the patients whose disease responded) as an alternative to initial surgical management. This combined-modality approach became a standard treatment option for patients with locally advanced, resectable laryngeal or hypopharyngeal cancer who sought to avoid total laryngectomy. Close monitoring for recurrence and timely integration of salvage surgery are important parts of these combined approaches and are necessary for survival to remain comparable with the survival rates associated with primary surgical management.

During the 1990s, the use of chemotherapy shifted from induction to concomitant use with radiation not only as definitive treatment for unresectable squamous cell cancers but also for patients with resectable disease who chose a nonsurgical organ-preservation approach. Multiple studies demonstrated that concurrent administration of chemotherapy with radiation resulted in improved tumor control compared with radiation alone or induction chemotherapy followed by radiation.

In one randomized study of patients with resectable stage III or IV squamous cell carcinoma of the head and neck, primary radiation therapy (68 to 72 Gy, 1.8 to 2 Gy daily) was compared with the same radiation regimen plus concomitant daily cisplatin (20 mg/m^2/day) and 5-fluorouracil (1000 mg/m^2/day) for 4 days starting on days 1 and 22.[78] Surgery was recommended for both groups if no response was evident at 50 to 55 Gy or for disease persistence or recurrence at the completion of treatment. Most of the 100 patients enrolled had primary lesions of the larynx, hypopharynx, or oropharynx. With a median follow-up of 5 years, overall survival was not significantly different between the two groups, but survival with successful primary-site preservation was superior in the chemotherapy and radiation group (laryngeal preservation at 5 years, 34% vs. 42%; $p = 0.004$), albeit at the expense of greater acute hematologic toxicity, mucositis, cutaneous reactions, weight loss, and the need for a feeding tube during treatment. The lack of a significant difference in overall survival was attributed to effective salvage surgery and competing causes of death.

Intergroup RTOG 91-11, a follow-up to the VALCSG study, addressed two questions unresolved in the prior trial, including the optimal sequencing of chemotherapy and radiotherapy (induction chemotherapy followed by radiation or concomitant chemotherapy and radiation) and the precise contribution of chemotherapy added to radiotherapy.[39] A total of 547 patients with T2 to low-volume T4, nonmetastatic, squamous cell cancer of the larynx were randomly assigned to one of three treatment arms: radiation alone (70 Gy, 35 fractions); concomitant cisplatin (100 mg/m^2), administered intravenously on days 1, 22, and 43, with the same radiation dose; or induction cisplatin/5-fluorouracil followed by radiation for patients who had a complete or partial disease response of the primary site. In all groups, laryngectomy was reserved for patients with insufficient response, suspected disease persistence, or local recurrence. A planned neck dissection was performed approximately 8 weeks after completion of radiation in patients who had N2 or N3 disease at initial staging. The results at 2 years showed significant improvement in the larynx-preservation rate for the concomitant-treatment arm (88%) compared with the induction arm (75%; $p = 0.005$) and the radiation-alone arm (70%; $p < 0.001$). Local–regional control also was significantly better with concomitant treatment compared with the other two treatments (78% vs. 61% and 56%, respectively). Chemotherapy suppressed distant metastases, with rates of 8%, 9%, and 16% for the concomitant, induction, and radiation-alone arms, respectively. Disease-free survival was significantly better in both the concomitant (61%) and the induction (52%) arms compared with

the radiation-alone arm (44%); however, the overall survival rates did not differ among the three groups. Chemotherapy-related toxicities (grades 3 to 4 mucositis in the concomitant arm and grades 3 to 4 myelosuppression in the induction arm) were more common in the combination-treatment groups than in the radiation-alone group, although rates for possible treatment-related deaths were not significantly different. Mature data (reported after a minimum follow-up of almost 5 years and, more recently, 10.8 years) for all patients confirmed these results (Table 9-6).[79] Laryngectomy-free survival is an endpoint that combines survival and a quality-of-life parameter and does not account for patients dying from other causes with an intact larynx. Although this would not be chosen as the primary endpoint in modern practice, laryngectomy-free survival was the endpoint used to generate the statistical hypothesis in 1990. In the initial 2-year data analysis of this endpoint, only the concomitant arm showed significant improvement when compared with radiation alone; however, in the mature analysis, both induction and concomitant arms reached statistical significance compared with radiation alone for laryngectomy-free survival. The importance of this finding for clinical practice is unclear because the larynx-preservation and local-control results were not different for patients treated with induction chemotherapy followed by radiotherapy or with radiotherapy alone; these results were significantly inferior to the results with concomitant cisplatin and radiotherapy. Late toxicity did not differ across the three arms of the study. It is intriguing, however, that overall survival favored the induction arm numerically, but not statistically, by 11%. The clinical relevance of this finding and its rationale remain unclear at this time.

Table 9-6 **RTOG 91-11 Results: 5- and 10-Year Outcomes**

Treatment Arm	Time (years)	LFS (%)	LP (%)	DM (%)	DFS (%)	OS 5-Year (%)
Cis/5-FU followed by RT	5	44	71	14.7	37.7	58.1
	10	29 ($p = 0.02$ as compared with CRT)	68	16.6	20.4	38.8
CRT	5	47	83.6	13.6	38	55.1
	10	24 ($p = 0.68$ as compared with induction; $p = 0.03$ as compared with RT alone)	81.7 ($p = 0.005$ as compared with induction; $p < 0.001$ as compared with RT alone)	16.1	21.6 ($p = 0.04$ as compared with RT alone)	27.5 ($p = 0.08$ as compared with induction; $p = 0.53$ as compared with RT alone)
RT alone	5	34	66	22	28	53.8
	10	17	64	24	14.8	31.5 ($p = 0.29$ as compared with induction)

Abbreviations: 5-FU, 5-fluorouracil; cis, cisplatin; CRT, concomitant chemoradiation; DFS, disease-free survival; DM, distant metastases; LFS, laryngectomy-free survival; LP, larynx preservation; OS, overall survival; RT, radiotherapy; RTOG, Radiation Therapy Oncology Group.

In summary, mature results from Intergroup RTOG 91-11 demonstrated that induction cisplatin/5-fluorouracil followed by radiation and chemoradiation with cisplatin demonstrate similar efficacy for the endpoint of laryngectomy-free survival. However, local–regional control and larynx preservation were significantly improved with concomitant chemoradiation compared with induction or radiation alone. Overall survival did not differ significantly across the three

arms. For patients who wish to preserve their larynx, 100 mg/m^2 of daily cisplatin administered on days 1, 22, and 43 during radiotherapy is the standard of care, with surgery reserved for patients with persistent or recurrent disease after treatment completion.

A randomized larynx-preservation trial for patients with locally advanced, resectable cancer of the larynx or the hypopharynx was completed by the EORTC; it compared induction cisplatin/5-fluorouracil chemotherapy followed by radiotherapy with an alternating schedule of chemotherapy and radiotherapy (four cycles of cisplatin/5-fluorouracil during weeks 1, 4, 7, and 10 with alternating weeks of radiotherapy with 20 Gy during the three 2-week intervals). In long-term follow-up, there was no difference in larynx preservation. The two arms performed equally in terms of survival with a larynx, overall survival, progression-free survival, and in severity of toxicities observed.[51]

Oropharynx Organ Preservation

Given the results of these larynx-preservation studies, the chemoradiation approach also has been of investigational interest for locally advanced, resectable tumors of other primary sites for which surgical management may lead to substantial cosmetic or functional morbidity. GORTEC reported a noteworthy site-specific trial in which 226 patients with stage III or IV squamous cell cancer of the oropharynx were randomly assigned to either radiotherapy alone (70 Gy, 35 fractions) or to the same radiation program with concomitant bolus doses of carboplatin (70 mg/m^2 daily for 4 days) and 5-fluorouracil (600 mg/m^2 as a daily 24-hour infusion for 4 days) starting on days 1, 22, and 43. Concomitant treatment yielded a better 3-year survival rate (51% vs. 31%; p = 0.02) and disease-free survival (42% vs. 20%; p = 0.04), albeit at the expense of greater toxicity. Mucositis, weight loss, and the need for a feeding tube, as well as hematologic toxicity, occurred more frequently in the chemoradiation therapy group. Therefore, this treatment approach is considered an evidence-based standard treatment option and is particularly applicable for the management of T3 to T4 or N2 to N3 disease located at the base of the tongue or tonsils.[41]

Available data indicate that chemoradiation therapy is feasible for oropharynx cancer, and disease-control outcomes compare favorably with those obtained historically with primary surgical management. However, a series of site-specific, direct, randomized comparisons with standard surgery and postoperative radiation therapy are lacking for this malignancy. Nonetheless, most head and neck oncologists believe that the evidence is sufficiently compelling to support the use of chemoradiation therapy in standard practice as initial management for advanced oropharyngeal cancer, even if it is resectable. For other sites of advanced resectable disease, especially the oral cavity (for which good reconstructive options exist), primary surgical management is better established and remains the standard of care.

In general, for patients with locally advanced squamous cell cancer of the larynx, hypopharynx, or oropharynx, chemoradiation therapy yields better disease control compared with radiation alone, albeit at the expense of greater acute toxicity. This is the preferred organ-preservation approach for cancer of the primary sites. It must be emphasized that successful application of a chemotherapy and radiation strategy for organ preservation requires a team approach that includes not only the head and neck surgeon, radiation oncologist, and medical oncologist but also a nutritionist, swallowing therapist, oncology nurses, advanced care practitioners (physician assistants and nurse practitioners), and social workers. Close monitoring with comprehensive head and neck examinations and timely integration of salvage surgery, when necessary, are part of the treatment plan and are necessary to avoid

compromising survival. The evaluation of functional and quality-of-life outcomes is another parameter for assessing the overall benefit of organ-preservation therapies and will be an important factor in comparing therapeutic approaches.

KEY POINTS

- Induction chemotherapy with the three-drug regimen docetaxel/cisplatin/5-fluorouracil improves disease control outcomes compared with cisplatin/5-fluorouracil alone.
- There are no definitive data that induction chemotherapy followed by chemoradiation therapy leads to better survival compared with chemoradiation alone.
- For patients with unresectable HNSCC, chemoradiation with high-dose cisplatin significantly improves survival compared with radiotherapy alone and is the standard of care.
- In locally advanced laryngeal cancer (T2 to low-volume T4), local-regional control and larynx preservation were significantly improved with concomitant cisplatin and radiation therapy compared with induction chemotherapy followed by radiation or radiation alone.
- Cetuximab added to radiation improves survival compared with radiation alone in locally advanced head and neck cancer, but there are insufficient data for it to replace chemoradiation with cisplatin therapy as the standard of care.
- Chemoradiation with high-dose cisplatin is the standard of care for postoperative adjuvant treatment for patients with positive resection margins or extracapsular extension of nodal disease.

NASOPHARYNGEAL CANCER

Cisplatin-based chemoradiation therapy is the cornerstone of therapy for newly diagnosed, advanced, local–regional nasopharyngeal cancer. Although this treatment is widely used, disagreements occur regarding the role of adjuvant chemotherapy in this setting. The clinical behavior of nasopharyngeal cancer varies somewhat according to its histologic subtype.

WHO type I (keratinizing squamous cell cancer) is more common in Western countries and has a local–regional behavior more similar to that of other smoking-related head and neck cancers. WHO types II (nonkeratinizing, differentiated) and III (undifferentiated cancer), both of which can occur with lymphoid stroma (lymphoepithelioma; Table 9-4), predominate in endemic areas (such as southern China and northern Africa) and have a higher propensity for distant metastases. There is also a category known as basaloid squamous cell carcinoma of the nasopharynx. WHO types II and III also are more responsive to radiotherapy and chemotherapy than the differentiated squamous histology, and more than 90% of cases are associated with EBV. Radiation is the historic mainstay of treatment for disease above the clavicle. The same drugs used in the management of squamous cell cancers arising from other sites in the head and neck, such as cisplatin, 5-fluorouracil, and the taxanes, also are active against nasopharyngeal cancer.

The management of locally advanced nasopharyngeal cancer was dramatically changed after the results of the Intergroup nasopharynx study were published.[37] In this trial, patients with

stage III or IV nasopharyngeal cancer were randomly assigned to either radiation alone (70 Gy, 35 fractions for 7 weeks) or to the same radiation schedule with three planned doses of concomitant cisplatin (100 mg/m^2) administered every 21 days, followed by three cycles of adjuvant cisplatin (80 mg/m^2) and 5-fluorouracil (1000 mg/m^2 per day for 4 days). Most patients (91%) had stage IV disease, and WHO type I histology was more common as compared with a series from endemic areas. With a minimum follow-up of 5 years, overall survival was significantly improved for patients who received combined-modality therapy that included the adjuvant chemotherapy (67% vs. 37%; $p < 0.001$), as was progression-free survival (58% vs. 29%; $p < 0.001$). This improvement in survival was observed even though only 63% of patients received all three planned cycles of cisplatin during radiation and only 55% received all three cycles of adjuvant cisplatin/5-fluorouracil.

The Intergroup study was criticized because the relative contributions of the concurrent cisplatin and the adjuvant therapies could not be determined, and the trial results may be less applicable to endemic areas where WHO type I histologic subtypes are infrequent. That being said, subsequent randomized trials[80,81] in endemic areas and two meta-analyses[82,83] have confirmed the significant survival advantage afforded by cisplatin chemotherapy concurrent with radiation as compared with radiation alone. By contrast, randomized trials of induction chemotherapy followed by radiation compared with radiation alone have shown no significant improvement in overall survival,[84,85] although some reported improved relapse-free survival. Three meta-analyses of trials that compared any sequence of chemotherapy and radiotherapy with radiotherapy alone have been published. The meta-analysis reported by Huncharek et al. was a pooled analysis of the published results of six randomized trials involving 1528 patients.[82] In this analysis, at 4 years, chemotherapy improved progression-free survival by 34% and overall survival by 20%. The second meta-analysis used updated individual patient data from eight randomized trials (1753 patients with locally advanced disease) conducted from 1966 to 2003.[83] The effect on overall survival of adding chemotherapy to radiotherapy was an absolute survival benefit of 6% or from 56 to 62% alive at 5 years (HR for death, 0.82; 95% CI; 0.71, 0.94; $p = 0.006$). The effect observed on event-free survival was an absolute benefit of 10% or from 42 to 52% alive at 5 years (HR for tumor failure [local, regional, or distant] or death, 0.76; 95% CI; 0.67, 0.86; $p < 0.0001$). A significant interaction between the timing of chemotherapy and overall survival was observed, with the highest benefit resulting from concomitant chemoradiation therapy ($p = 0.005$). In a third meta-analysis, Blanchard and colleagues pooled the data from 4806 patients treated across 19 studies and also confirmed that adding chemotherapy to radiotherapy significantly improved overall survival (HR, 0.79; 95% CI; 0.73, 0.86; $p < 0.0001$), with an absolute benefit at 5 years of 6.3%.[86] The interaction of timing of the chemotherapy with radiation and overall survival favored concomitant plus adjuvant therapy followed by concomitant without adjuvant therapy, but the benefit was not present for chemotherapy alone either as induction or adjuvant therapy.

Based on these data as a whole, the survival benefit from cisplatin-based chemoradiation seems clear and is the accepted standard of care for patients with locally advanced nasopharyngeal cancer. The benefit of adjuvant chemotherapy, theoretically used to suppress distant metastases common in nasopharyngeal cancer, is less widely accepted. An important study in that regard is the trial by Chen et al., which compared chemoradiation with or without adjuvant chemotherapy in 251 patients with nonmetastatic stage III or IV nasopharyngeal carcinoma.[85] The primary endpoint was failure-free survival. After a median follow-up of 37.8 months, the estimated 2-year failure-free survival rate was 86% in the chemoradiation plus adjuvant chemotherapy arm and 84% in the chemoradiation-only group ($p = 0.13$). This

controversial issue will hopefully be addressed by the results of an ongoing international study (NRG 001) that uses plasma EBV DNA to prognosticate which patients are at risk for recurrence following definitive chemoradiation. Patients who clear EBV DNA during definitive treatment are randomly assigned to observation or standard adjuvant treatment. In a second arm, patients with posttreatment EBV DNA in the blood are randomly assigned to two different adjuvant chemotherapy regimens. While awaiting further follow-up, National Comprehensive Cancer Network guidelines have been modified to include chemoradiation therapy alone without adjuvant chemotherapy as an acceptable option (category 2B). In the United States, the standard of care for treatment of patients with stages IIB, III, IVA (T4N0-2M0), and IVB (T1-4N3M0) nasopharyngeal cancer is radiotherapy (70 Gy) with chemoradiation therapy utilizing high-dose cisplatin on days 1, 22, and 43 followed by three courses of adjuvant cisplatin/infusional 5-fluorouracil.[37] Radiotherapy alone is indicated for stage I disease.

The general management of recurrent or metastatic nasopharyngeal carcinoma is a platinum-based doublet. In one randomized, phase III study, patients treated with gemcitabine/cisplatin experienced an improved median progression-free survival of 7.0 months (range, 4.4–10.9) compared to 5.6 months (range, 3.0–7.0) in patients receiving 5-fluorouracil/cisplatin (HR, 0.55; 95% CI; 0.44, 0.68, $p < 0.0001$).[87]

KEY POINTS

- WHO type I nasopharyngeal cancer (keratinizing) is more commonly found in the United States, whereas WHO types II (nonkeratinizing, differentiated cancer) and III (undifferentiated cancer) overwhelmingly predominate in endemic areas, such as southern China and northern Africa, and are associated with EBV.
- The standard of care (according to stage) is radiotherapy alone for stage I and chemoradiation therapy with cisplatin followed by three cycles of adjuvant cisplatin/5-fluorouracil for stages II to IVB nasopharyngeal cancer. However, results with regard to the benefits of adjuvant chemotherapy are inconclusive.
- Cisplatin/gemcitabine is an active combination therapy for the treatment of recurrent or metastatic nasopharyngeal cancer; it is more efficacious than treatment with cisplatin/5-fluorouracil.

INCURABLE RECURRENT OR DISTANT METASTATIC DISEASE

Systemic Therapy

Disease that cannot be resected and has been previously irradiated or involves distant organs is considered incurable. Cisplatin, carboplatin, docetaxel, paclitaxel, 5-fluorouracil, and methotrexate are the most commonly used cytotoxic agents to treat recurrent or metastatic HNSCC; cetuximab is an active targeted agent that is also commonly used. Activity also has been demonstrated for bleomycin, irinotecan, gemcitabine (in nasopharyngeal cancer), vinorelbine, capecitabine, oxaliplatin, ifosfamide, and pemetrexed. Randomized trials comparing combination chemotherapy and single-agent therapy show a near doubling of the response rate with platinum-based combinations, but unless a clinical complete response is achieved, the duration of response is brief (2 to 4 months) and does not have a significant effect on overall

survival.

Toxicity is generally greater when combination chemotherapy is used. As an example, one meta-analysis included all studies in which cisplatin/5-fluorouracil, the historical gold-standard combination regimen, was compared with single-agent therapy. A significant improvement in response was documented, which translated into only a 2-week difference in the median survival (odds ratio, 0.43; 95% CI; 0.29, 0.63). No formal quality-of-life data were available, but toxicity was greater for patients who received combination therapy. Numerous single agents have activity and can be used, but weekly methotrexate is the historical gold standard because of its ease of administration, toxicity profile, and relatively low cost.[88] Combination chemotherapy should be limited to patients with a good performance status (e.g., ECOG performance status of 0 to 1), who are better able to tolerate the added toxicity; for these patients, the higher response rate may translate into better palliation, although there are no objective quality-of-life data to support this notion. Factors associated with poor response in this population are well known and include poor performance status, the presence of comorbidities, bulky local–regional disease or high tumor volume, and prior treatment for recurrent disease.

It was hoped that the introduction of the taxanes in the 1990s would result in improved survival for patients with recurrent disease, but this has not occurred. Two different weekly schedules of paclitaxel offered no advantage compared with weekly single-agent methotrexate.[89] Results from another study showed that paclitaxel/cisplatin did not differ significantly from standard cisplatin/5-fluorouracil in terms of the median survival rate (9 vs. 8 months) and the 1-year survival rate (30% vs. 41%), although the paclitaxel regimen was generally better tolerated.[90]

Cetuximab is the only molecularly targeted drug to be approved for use in the United States for metastatic head and neck cancer; its indication is for platinum-refractory disease. Phase II trials of cetuximab alone or combined with cisplatin for patients who had experienced either stable or progressive disease as the best response to a standard platinum-based doublet were in the range of 10 to 13%.[91-93] In a randomized trial in which the combination of cisplatin/placebo was compared with cisplatin/cetuximab for 123 patients, no significant difference was found in median progression-free survival (2.7 vs. 4.2 months; $p = 0.27$), although the rate of major response (complete plus partial) was significantly higher for patients who received cisplatin/cetuximab (10% vs. 26%; $p = 0.03$).[94]

In the phase III EXTREME trial, 440 patients with recurrent or metastatic HNSCC were randomly assigned to either the intervention arm (cisplatin or carboplatin with 5-fluorouracil/cetuximab) or standard arm (cisplatin or carboplatin with 5-fluorouracil) as first-line treatment.[95] It was found that adding cetuximab to cisplatin/5-fluorouracil significantly prolonged the median overall survival from 7.4 months to 10.1 months (HR for death, 0.80; 95% CI; 0.64, 0.99; $p = 0.04$), significantly prolonged the median progression-free survival from 3.3 months to 5.6 months (HR for progression, 0.54; $p < 0.001$), and increased the response rate from 20% to 36% ($p < 0.001$). This is the first trial to show any improvement in overall survival when compared with the standard regimen of cisplatin/5-fluorouracil.

In a randomized, phase II study, patients with platinum-refractory disease were randomly assigned to treatment with single-agent afatinib, an oral small-molecule TKI that irreversibly inhibits EGFR and HER2, or cetuximab with crossover permitted at progression. Although both single-agent afatinib and cetuximab had modest activity, with a mean tumor shrinkage of 16.6% and 10.1%, respectively ($p = 0.30$), patients who progressed on either agent had clinical benefit after crossover, with disease control rates of 33.3% for afatinib and 18.8% for

cetuximab, suggesting a lack of cross-resistance between these agents.[96] In a randomized study comparing afatinib to single-agent methotrexate as a second-line treatment for recurrent/metastatic head and neck cancer, afatinib led to a statistically significant improvement in progression-free survival of 2.6 months, compared with 1.7 months for methotrexate ($p = 0.03$).[97] Other TKIs targeting EGFR have been studied, including gefitinib and erlotinib, which have modest activity in this setting (including responses for patients who received prior chemotherapy). However, a phase III study failed to show any overall survival benefit of either 250 mg or 500 mg of gefitinib daily compared to standard methotrexate therapy in recurrent metastatic head and neck cancer.[98]

Checkpoint Inhibitors

Pembrolizumab and nivolumab, monoclonal antibodies directed at programmed death 1 protein, were approved by the FDA for the treatment of platinum-refractory recurrent or metastatic HNSCC based on the results of three large clinical trials. In KEYNOTE-012, a nonrandomized study, 174 patients with platinum-refractory HNSCC were treated with pembrolizumab 10 mg/m^2 every 2 weeks or 200 mg flat dose every 3 weeks. A total of 28 patients (16%) experienced a tumor response, and the tumor response lasted for 6 months or longer in 23 (82%) of these and several have lasted for more than 2 years. [99] In KEYNOTE-055, a second nonrandomized study of pembrolizumab in patients with cetuximab- and cisplatin-refractory disease, a flat dose of 200 mg was administered every 3 weeks. Among the 171 patients treated, the overall response rate was 16% with a median duration of 8 months with three-fourths of responses continuing at time of publication.[100] The final approval is for a dose of 200 mg every 3 weeks. The approval for nivolumab treatment for HNSCC resulted from the positive results of a randomized, phase III study in which patients were randomly assigned 2:1 to nivolumab 3 mg/kg every 2 weeks or the physician's choice of weekly docetaxel, methotrexate, or cetuximab. Patients treated with nivolumab had improved median overall survival of 7.5 months (95% CI; 5.5, 9.1) versus 5.1 months (95% CI; 4.0, 6.0) in patients treated with standard treatment ($p = 0.01$). The response rate to nivolumab is 13.3%. At 1 year, 36.0% of patients in the nivolumab arm were alive compared to 16.6% of patients treated with standard therapy.[101] Though patients with HPV-positive (p16-positive) disease and those whose tumors expressed programmed death ligand 1 (PDL-1) performed somewhat better with nivolumab than with chemotherapy, those whose tumors did not express PDL-1 or were p16-negative, also attained benefit. Hence, PDL-1 expression is not required for administration of checkpoint inhibitors in the recurrent/metastatic setting.

Re-Irradiation for Second Primary or Recurrent Head and Neck Tumors

Repeat radiation therapy is increasingly feasible with the greater availability of conformal technology. Building on the improved disease control seen with concurrent chemoradiation for primary treatment, this approach also has been investigated in the recurrent disease setting. Phase II trials suggest that for a proportion of patients (up to 25% in some studies), disease control is more durable than what would be anticipated with chemotherapy alone. This re-irradiation approach may represent a good option for selected patients, but it requires special expertise in radiation planning. In one study, investigators reported the results with full-dose repeat radiation therapy with or without chemotherapy for 169 patients; 13 patients experienced complete remissions ranging from 12 months to 111 months.[102] Two successive phase II RTOG trials that used split-course radiation and twice-daily fractionation at a total

dose of 60 Gy have been completed.[103,104] The concurrent chemotherapy used in the first trial (RTOG 96-10) was 5-fluorouracil/hydroxyurea; the second trial (RTOG 96-11) utilized cisplatin/paclitaxel. At median follow-up of just under 2 years, the overall survival rates were 17%[103] and 25%,[104] respectively, suggesting that for a subset of patients, re-irradiation might provide a survival advantage compared with palliative chemotherapy alone. When analyzed for factors that predicted a favorable survival outcome, an interval of at least 3 years from the original radiation was seen in RTOG 96-10 but not in RTOG 96-11. However, a phase III trial (R04-21) comparing re-irradiation with chemotherapy to chemotherapy alone was terminated because of poor accrual. In another study, 130 patients with recurrent or new tumors within a previously irradiated field were randomly assigned after surgical resection to receive chemotherapy and radiation versus observation alone. This study found an improvement in disease-free survival but no difference between the two arms in overall survival.[105] Identifying which patients are most likely to benefit from the acute and potential long-term toxicities resulting from re-irradiation remains an important area of investigation.

KEY POINTS

- Combination chemotherapy leads to increased response rates compared with sequential single-agent therapy but has not demonstrated an improvement in survival and comes at the expense of increased toxicity.
- The exception is the combination of cetuximab/cisplatin/5-fluorouracil, which demonstrated a survival benefit compared with cisplatin/5-fluorouracil.
- Re-irradiation with or without concurrent chemotherapy may provide long-term survival for a select subset of patients.

CANCER OF UNKNOWN PRIMARY SITE

Although a malignant neck lymph node without a clear primary tumor is a common occurrence in the head and neck, for most patients the primary site will be found after comprehensive examination of the head and neck, assessment under anesthesia, and diagnostic imaging. The location of the lymph node in the neck directs the examiner toward the likely potential primary sites, and PET scanning may be helpful. In recent years, FDG-PET has become an effective diagnostic tool in identifying the primary site for patients who present with cervical lymph node metastases with an unknown primary site. A meta-analysis of 16 studies revealed an overall sensitivity of 88% and specificity 75%.[106] FDG-PET is now considered part of the standard evaluation for squamous cell carcinoma of unknown primary site.

Fine-needle aspiration of the lymph node is the first choice for initial biopsy. If negative, repeating fine-needle aspiration with consideration of a core needle biopsy, if feasible, is appropriate. Viral testing of the nodal specimen (HPV and EBV) may help suggest a particular primary site. If the histologic diagnosis remains inconclusive, subsequent excisional biopsy should be performed in such a way that the incision can be incorporated into an appropriate neck dissection. Open biopsy done inappropriately may contaminate the surgical field and create a larger problem.

If pathologic findings from the neck indicate a diagnosis of squamous cell cancer and a

primary lesion above the clavicle is suggested, especially if the lymph node is high in the neck, a comprehensive head and neck examination under anesthesia is the next step. Directed biopsies should be performed for suspicious mucosal areas as well as locations known to be a source of occult tumors, such as the hypopharynx, base of the tongue, and nasopharynx. In addition, a bilateral simple tonsillectomy is recommended based on the increasing incidence of tonsillar cancers associated with HPV.[5] Of note, the skin, upper part of the esophagus, and lung are other potential sources of squamous cell cancer spread to the neck. If the findings on biopsy of a cervical lymph node indicate an adenocarcinoma, the primary lesion sites, such as the thyroid gland, salivary gland, or sites below the clavicle, should be considered. Lymphoma is another important diagnostic possibility and may require a core needle biopsy for diagnostic purposes. Similarly, distinguishing lymphoma from anaplastic and undifferentiated or poorly differentiated cancers can be difficult on the basis of cytologic analysis alone and may require additional immunohistochemical studies or more tissue.

The choice of treatment of patients with squamous cell cancer in a neck node of unknown primary site is controversial and evolving. Historically, either surgery or radiation was used to treat patients with low-bulk disease in a single lymph node, whereas both modalities were necessary for patients with more advanced disease. The extent of radiation to the potential primary sites requires clinical judgment regarding the likely source of the tumor because a larger portal will increase the morbidity associated with treatment. Findings from clinical series indicate that with longitudinal follow-up, the primary site will ultimately be found for approximately 30% of patients. Long-term survival is better for patients in whom the primary lesion remains occult than for those in whom it does not. The mainstay of treatment is still neck dissection followed by radiation with concomitant cisplatin when extracapsular extension of nodal disease is present. However, integrated primary chemoradiation therapy is used increasingly for these patients based on the physician's impression of the likely primary site(s).

KEY POINTS

- The search for the primary site should include fused FDG-PET/CT imaging and an examination under anesthesia with directed biopsies of the base of the tongue, nasopharynx, and hypopharynx and ipsilateral tonsillectomy.
- Standard treatment consists of neck dissection followed by radiotherapy to include the likely primary sites, and concurrent chemotherapy is added if extracapsular extension of nodal disease is present.
- In selected patients, chemoradiation therapy is another treatment option.

MALIGNANT LESIONS OF THE SALIVARY GLANDS

Cancers of the major salivary glands (parotid, submandibular, sublingual) and the minor salivary glands are uncommon, accounting for fewer than 10% of epithelial head and neck tumors. Tobacco and alcohol use are not risk factors for tumors of the salivary glands, but there may be an association with prior exposure to radiation. The WHO classification lists 24 histologic subtypes of malignant epithelial salivary tumors. Their small numbers, as well as their histologic and prognostic heterogeneity, make them difficult to study; therefore, there are few adequately

tested histologic regimens to guide the medical oncologist.

The most common types of salivary gland cancers are adenoid cystic carcinoma and adenocarcinoma, which originate from the intercalated ducts, and mucoepidermoid carcinoma, which originates from the secretory ducts. A histologic reading of high-grade mucoepidermoid or adenocarcinoma correlates with aggressive behavior and greater likelihood of eventual metastasis, whereas low-grade cancers of these histologies are more likely to be cured with initial local therapies. Adenoid cystic cancer is the most common tumor found in the minor salivary glands, is prone to neurotropic spread, and has the highest propensity of the histologic subtypes for distant metastases, yet it can grow in a very indolent manner. Salivary duct carcinoma is an aggressive subtype of adenocarcinoma with a rapid appearance of metastases.

Surgery is the mainstay of treatment for all primary and recurrent resectable disease with adjuvant radiation, as indicated by the presence of adverse pathologic features.[107] There is a tendency among medical oncologists to recommend the addition of cisplatin or other chemotherapy as a radiosensitizer to improve local–regional control when poor-risk features are present (e.g., positive margins or extracapsular nodal spread) based on the experience with HNSCC, but there are no definitive data to support this addition. However, an ongoing cooperative group trial is attempting to answer this question.

Definitive radiation-based therapy is used for unresectable tumors. Neutron-beam therapy has shown promise in this setting, especially for adenoid cystic cancer, but toxicity is a concern and the RTOG-MRC randomized trial that suggested therapeutic benefit with neutron compared with photon therapy had significant methodologic limitations.[108] Concurrent chemotherapy with radiation is feasible—given the data from the management of squamous cell cancers of the upper aerodigestive tract—and not uncommonly applied for unresectable salivary gland tumors as an extrapolation of benefits seen with this strategy in several other primary tumors, although there are no randomized trial data in these less common tumors to demonstrate improved efficacy with this approach compared with radiation alone.

The available data regarding the activity of different chemotherapy agents are limited and commonly include mixed histologic subtypes; most older reports are case series rather than true clinical trials. A trial of single-agent paclitaxel showed activity for patients with mucoepidermoid carcinoma and adenocarcinoma but not for adenoid cystic carcinoma, emphasizing the importance of histology-specific trials.[109] The available data for other single agents and standard cytotoxic combinations were reviewed by Laurie and Licitra.[110] The most commonly used regimens include cyclophosphamide, doxorubicin, cisplatin, and 5-fluorouracil in various two- and three-drug combinations. Responses are reported across histologic types, but no one trial or case series includes enough patients with a given histology to yield statistical confidence.

Adenoid cystic carcinoma and selected other salivary gland cancer subtypes may be more indolent tumors; therefore, palliative chemotherapy should be attempted only for a symptomatic patient or when substantial tumor growth can be appreciated on serial imaging within a 6-month time frame. In this setting, doxorubicin, cisplatin, and 5-fluorouracil have been used as single agents; combination cyclophosphamide/doxorubicin/cisplatin is a regimen commonly used.[111] Even with combination chemotherapy, the rates of complete and partial responses will be low, and it is appropriate to consider investigational therapy. Epirubicin, mitoxantrone, and vinorelbine have demonstrated activity in adenoid cystic cancer,[112-114] but no such activity has been observed for paclitaxel.[109]

The search for molecular targets for which there are available therapies is the focus of

investigation. The *c-kit* target is expressed in approximately 80% of adenoid cystic cancers, whereas *EGFR* expression is quite variable; the hormone receptors and HER2 are rarely expressed. Imatinib has been evaluated in adenoid cystic carcinoma in a phase II trial with no objective responses observed.[110] Overexpression of *EGFR* is commonly seen in mucoepidermoid carcinoma, whereas *c-kit,* HER2, and hormone receptors are rarely expressed. In adenocarcinoma, *c-kit* is variably expressed depending on the histologic subtype; hormone receptor expression is rare, and *EGFR* expression is uncommon. With the proliferation of targeted agents, there is considerable interest in evaluating multitargeted agents, such as lapatinib (dual inhibitor of *EGFR* and HER2),[115] as well as agents that affect vascular endothelial cell proliferation, such as sorafenib and axitinib. Investigational agents for adenoid cystic carcinoma and the other salivary gland histologies are best evaluated in multicenter collaborations.

Microscopically, salivary duct carcinoma looks identical to ductal breast cancer, is commonly androgen receptor–positive, and may also overexpress *HER2* and *EGFR* on immunohistochemical analysis. Responses to antiandrogen therapy have been reported.[116]

KEY POINTS

- Metastatic adenoid cystic cancer and selected other salivary gland cancers are often characterized by an indolent natural history.
- Systemic treatment should be delayed until substantial tumor growth can be appreciated on serial imaging studies within a 6-month time frame or if disease is located such that symptom development is imminent (e.g., bronchial obstruction).
- The activity of chemotherapy may vary by histologic subtype.

THYROID CANCER

The American Cancer Society estimated 56,870 new cases of thyroid cancer in the United States and 2010 deaths from the disease in 2016.[1] The incidence of this cancer continues to increase in the United States, with a 2.4-fold increase in incidence noted between 1973 (3.6 cases per 100,000 people) and 2002 (8.7 cases per 100,000 people); however, the mortality rate is stable at 0.5 deaths per 100,000 people.[117] This change in incidence is accounted for by an increase in papillary thyroid cancer but not other histologic types. Nearly 90% of these cancers are subclinical or smaller than 2 cm, which suggests that earlier diagnosis may account for most of the observed change in incidence.

Thyroid cancers are classified on the basis of the two main parenchymal cells of origin: the follicular cells involved in thyroid hormone production and the parafollicular cells that produce calcitonin. The former give rise to well-differentiated thyroid cancer (which constitutes 90% of thyroid malignancies) and to anaplastic thyroid cancer (1 to 2% of thyroid cancers); the latter gives rise to medullary thyroid cancer (5 to 9% of thyroid cancers). The histologic subtypes within the well-differentiated thyroid cancer classification are papillary, mixed tumors with areas of papillary and follicular histologic features, follicular, follicular variant of papillary, and Hürthle cell, a follicular variant.

ETIOLOGY

The only well-documented etiologic factor for thyroid cancer is radiation exposure, with an inverse relationship between age at exposure and risk for development of a thyroid malignancy. The thyroid gland of children younger than age 10 is highly vulnerable to developing thyroid cancer if it is exposed to ionizing radiation. The risk for the development of thyroid cancer is much higher for individuals who have been exposed to radioactive iodine isotopes from nuclear reactor accidents and atomic bomb testing, as well as for children and young adults who have received external radiotherapy for other cancers (e.g., Hodgkin lymphoma, neuroblastoma, or Wilms tumor) compared with individuals irradiated during childhood for benign conditions (as was common until 1960). Data from Chernobyl show that nearly all thyroid cancers developing in children after exposure to radioiodine fallout were the well-differentiated papillary type but had a higher rate of local invasion and lymph node involvement than usually observed for this histology. More than 90% of well-differentiated thyroid cancers, however, are unrelated to radiation exposure. Familial syndromes should be suspected when there is a family history of thyroid cancer or a history of a familial syndrome associated with thyroid cancer. Approximately 5% of the differentiated thyroid cancers are associated with hereditary syndromes such as Gardner syndrome, familial adenomatous polyposis, Cowden syndrome, multiple endocrine neoplasia type 2A, familial medullary thyroid carcinoma, and Carney complex.

CLINICAL PRESENTATION AND WORKUP

The sporadic differentiated thyroid cancers are usually asymptomatic for long periods and present as a solitary nodule. The familial papillary thyroid cancers appear to be clinically more aggressive than the sporadic ones. The familial differentiated thyroid cancers are usually multifocal and bilateral and have a tendency to recur both local-regionally and in distant sites. Papillary thyroid cancer and its variants tend to recur locally in the regional lymph nodes, whereas follicular and Hürthle cell cancers tend to recur distantly, especially in bone and lung.

Various prognostic systems have been developed to assist in the risk classification of patients with differentiated thyroid cancer, with potential implications for management based on risk group. Several factors have been widely accepted as being associated with a poor prognosis: age older than 45 years, male sex, poorly differentiated histology, tumor size, and extrathyroidal extension at diagnosis. In contrast, involvement of the regional lymph nodes is associated with greater risk for nodal recurrence but does not confer a worse prognosis for survival.[118] Overall, the 10-year survival rate for differentiated thyroid cancer is excellent (90%). The median age at diagnosis is 45, and the median age at death is 75.[119]

Most thyroid cancers are detected as incidental thyroid nodules found on physical exam or by the patient presenting to the physician with a neck mass. The diagnostic evaluation should include high-resolution ultrasonography to aid in performing a fine-needle aspiration biopsy and to assess the number and characteristics of the nodules, including whether the nodules are solid or cystic. Fine-needle aspiration has high sensitivity and specificity and is the test of choice when evaluating solitary thyroid nodules.[120] Routine thyroid scanning with iodine-123 or technetium-99 is not recommended. This test provides information on whether a nodule is functional; however, the majority of benign and malignant nodules are “cold” or nonfunctioning, meaning that the test is nonspecific and not cost-effective. All patients with a thyroid nodule and suspected familial medullary thyroid cancer should have calcitonin level testing.

TREATMENT

Surgery

The mainstay of treatment is thyroid surgery; for differentiated thyroid cancer, levothyroxine suppression and administration of radioactive iodine are the standards. External-beam radiotherapy and chemotherapy are reserved for palliation of refractory or metastatic disease. The extent of initial surgical therapy is controversial. Many experts recommend removal of the entire thyroid, with the caveats that removal of only the affected lobe and the isthmus is necessary for patients with better risk (e.g., young patients with small tumors) and that total thyroidectomy is associated with a greater risk for complications, such as recurrent laryngeal nerve injury leading to vocal cord paralysis and hypocalcemia secondary to hypoparathyroidism.[121]

Radioactive Iodine

Although the practice is controversial, most U.S. physicians will administer a single dose of radioactive iodine to ablate any normal thyroid remnant and to destroy any microscopic deposits of the remaining thyroid cancer after a total thyroidectomy. It should be emphasized that recent use of iodinated contrast medium, an iodine-rich diet, and inadequate elevation of the level of thyroid-stimulating hormone (thyrotropin) can all undermine the effectiveness of radioactive iodine treatment. Human recombinant thyrotropin has replaced the need for a patient to be put into a hypothyroid state. Dosing strategies for radioactive iodine—ablative compared with higher therapeutic doses—are determined by the patient's prognostic risk, and they range from 50 mCi to 75 mCi for ablation of remnants after total thyroidectomy for low-risk patients, 100 mCi to 150 mCi for the treatment of local–regional lymph nodes, and 150 mCi to 250 mCi for the treatment of lung and bone metastases.

Ablation of remnants enables improved surveillance because normal thyroid cells are also removed, which could cause false-positive results on whole-body scans or false-positive elevations of serum thyroglobulin. In the absence of all normal thyroid tissue, the serum thyroglobulin is a highly sensitive and specific tumor marker.[122] After total thyroidectomy and ablation of remnants, the serum thyrotropin level generally should be suppressed to below normal levels with thyroxine because this hormone is a potential growth factor for microscopic cancer deposits.

Six to 12 months after initial therapy, measurement of the serum thyroglobulin should be performed while the patient is receiving suppressive doses of thyroxine. If the serum thyroglobulin is undetectable and the findings of ultrasound imaging of the neck are negative, an annual analysis of thyroglobulin levels and physical examination are sufficient for most low-risk patients. If there is no detectable level of serum thyroglobulin during treatment with suppressive doses of thyroxine at 1 year after surgery and ablation, the thyroglobulin level should be determined after two doses of recombinant human thyrotropin. If the level rises above 2 ng/mL, a search for remaining disease is warranted. Diagnostic whole-body imaging with iodine scanning should be performed. If this is negative, FDG-PET scanning has been shown to be helpful for localizing disease in more than 60% of such cases.[123]

If metastases develop, radioactive iodine is the treatment of choice. Complete response to treatment has been observed for 45% of patients with distant metastases, although a higher complete response rate has been noted for younger patients and those with small pulmonary metastases.[124] Following the approval of two TKIs for radioactive iodine–refractory thyroid cancers, chemotherapy plays a lesser role in the treatment of this disease. Some thyroid tumors grow very slowly, so a period of careful observation is reasonable before committing to

treatment.

MOLECULAR PATHWAYS IN THYROID CANCER

Interest in targeted therapies has been stimulated by the discovery of activating point mutations of the *BRAF* gene that occur early, are associated with more advanced disease at diagnosis,[125] and independently predict for recurrence. *RET/PTC* rearrangement is found in approximately 20% of adult sporadic papillary carcinomas.[126] Point mutations of the *BRAF* gene are found in 45% of thyroid papillary carcinomas.[127,128] *BRAF* serine–threonine kinase can lead to activation of the mitogen-activated protein kinase (*MAPK*) signaling pathway. Together, mutations involving one of these three genes (*RET/PTC, BRAF,* or *RAS*) are found in more than 70% of papillary carcinomas, and they rarely overlap in the same tumor. *PAX8-PPAR-gamma* is found in about 35% of follicular carcinomas and a small number of Hürthle cell carcinomas.[129]

Sorafenib, an orally active inhibitor of vascular endothelial growth factor (VEGF) receptors 1 to 3 and Raf kinases, was approved by the FDA for treatment of radioactive iodine–refractory thyroid cancer in 2013 based on the positive results of the phase III placebo-controlled DECISION trial.[130] A total of 417 patients, who had locally advanced or metastatic thyroid cancer that was refractory to radioactive iodine and had progression within the past 14 months, were randomly assigned to receive 400 mg of oral sorafenib twice daily or matching placebo. Patients receiving placebo were allowed to receive sorafenib open-label if they had progression. The primary endpoint was progression-free survival. Tumor histology was 57% papillary, 25% follicular, and 10% poorly differentiated; 96% of patients had metastatic disease. The most common site of metastatic disease was lung (86%), lymph nodes (about 50%), and bone (about 25%). Sorafenib was shown to extend the median progression-free survival of 5.8 months (placebo arm) compared with 10.8 months (sorafenib arm; $p < 0.0001$). Median overall survival had not been reached at the time of the presentation. The disease control rate (complete response + partial response + stable disease > 6 months) was 54% in the sorafenib arm, compared with 38% in the placebo arm ($p < 0.0001$). The majority of these responses were stable disease with no complete responses and 12% partial responses reported. Expected toxicities of sorafenib were reported. The most common grade 3 or 4 toxicities included hand–foot syndrome, hypertension, and hypocalcemia.

Lenvatinib, an oral, multitargeted TKI, was approved by the FDA for the treatment of radioactive iodine–refractory thyroid cancer in 2015 based on the positive results of the SELECT trial, a phase III placebo-controlled trial.[131] Lenvatinib inhibits VEGF receptors 1 to 3, fibroblast growth factor receptor 1-4, platelet-derived growth factor α, RET, and KIT. In a 2:1 design, 261 patients were randomly assigned to lenvatinib 24 mg daily and 131 patients were randomly assigned to placebo. The median progression-free survival was 18.3 months compared with 3.6 months, favoring lenvatinib with an HR for progression or death of 0.21 (95% CI; 0.14, 0.31; $p < 0.001$). The response rate to lenvatinib was 64.8%, with four complete responses and 165 partial responses. Treatment-related adverse events (grade 3 or higher) occurred in 75.9% of patients taking lenvatanib versus 9.9% in those taking placebo. The most common toxicities included hypertension, diarrhea, fatigue, anorexia, and weight loss.

Other TKIs are under evaluation in differentiated thyroid cancer. One drug with activity is axitinib (AG-013736), which targets VEGF receptors 1 to 3, platelet-derived growth factor receptor β, and c-kit. A multiinstitutional study assessed its safety and activity in 60 patients with radioactive iodine–resistant thyroid cancer of any histology. The drug was given at a dose of 5 mg twice daily. Partial responses were observed in 30% of patients, and stable disease

lasting at least 16 weeks was reported in another 38%. Median progression-free survival was more than 18 months.[132]

Pazopanib is a potent small-molecule TKI that targets all subtypes of VEGF receptor without activity against the RET receptor and has predominantly antiangiogenic activity. A phase II study with 37 evaluable patients with rapidly progressive, metastatic, radioiodine-refractory, differentiated thyroid cancer were treated with 800 mg of pazopanib administered once daily.[133] Partial response was seen in 49% (95% CI; 35, 68) and lasted longer than 1 year in 66% of the patients whose disease responded. Dose reduction was required in 43% of patients. The most common treatment-related adverse events were consistent with class effect, including hypertension, fatigue, diarrhea, bleeding tendencies, and skin and hair changes. Despite good clinical response, the effect on survival has not been determined and needs to be clarified by controlled trials.

ANAPLASTIC THYROID CANCER

Unlike the case with differentiated thyroid cancer, the anaplastic or “giant cell” variant is associated with an extremely poor prognosis, with the best available therapy producing a median survival of less than 1 year. An association with prior well-differentiated thyroid cancer or benign thyroid nodule disease is not uncommon. Patients are older, generally in their 60s or 70s, and the distribution between the sexes is balanced. Distinguishing the tumor from a large cell lymphoma of the thyroid is of fundamental importance. Clinically, anaplastic thyroid cancer is characterized by a rapidly growing mass in the thyroid that invades the trachea or larynx and causes symptoms of dysphagia, hoarseness, or hemoptysis. A total of 20 to 50% of patients have distant metastases at the time of presentation (most often pulmonary), and the remainder usually manifest metastases within 1 or 2 months of diagnosis. However, most deaths are a result of aggressive local–regional spread and upper airway respiratory failure. If resection is feasible, it should be pursued, although these tumors are typically unresectable at presentation, and the patient often requires an urgent tracheostomy. Initial external-beam radiation therapy, both for definitive treatment and as an adjuvant (often with doxorubicin sensitization),[134] is commonly used and considered the standard of care. Chemotherapy alone has limited efficacy. Doxorubicin/cisplatin is probably the most widely used combination.[135] Radioactive iodine generally plays no role in the treatment of these tumors. Combretastatin A4 phosphate is a novel drug whose precise mechanism of action is unknown; it has antitumor effects by binding tubulin and disrupting vascular supply within tumors. In a phase I trial, in combination with paclitaxel, a single patient with anaplastic thyroid cancer had a complete response that lasted more than 30 months after treatment.[136] A randomized, open-label, controlled, phase II/III multinational trial was done to assess the safety and efficacy of carboplatin and paclitaxel with or without combretastatin. A total of 80 patients were treated in the study, which was stopped early because of poor accrual. The median overall survival was 5.2 months (95% CI; 3.1, 9.0) in the experimental arm compared with 4.0 months (95% CI; 2.8, 6.2) in the control arm (HR, 0.72; 95% CI; 0.43, 1.20). The 1-year survival was 25.5% (95% CI; 15, 38) in the experimental arm compared with 8.7% in the control arm (95% CI; 2, 24). Deaths were primarily caused by disease progression.[137]

MEDULLARY THYROID CANCER

Medullary thyroid cancer is a neoplasm of the calcitonin-producing cells that reside in the thyroid. It constitutes approximately 5 to 9% of all thyroid cancers and is associated with a

mutation in the *RET* proto-oncogene. Both sporadic and familial types occur. The sporadic form is more common (60 to 70% of cases) and tends to occur in an older age group than the familial form (40 to 45 years vs. 15 to 25 years). Three distinct familial syndromes account for the remaining 30 to 40% of cases. The *RET* mutation is transmitted in the germline, and familial medullary thyroid cancer may be part of multiple endocrine neoplasia type 2A (medullary thyroid cancer, pheochromocytoma, and parathyroid hyperplasia) or type 2B (medullary thyroid cancer, pheochromocytoma, and intestinal and mucosal ganglioneuromatosis with characteristic marfanoid habitus); it also may be a familial form of medullary thyroid cancer not associated with multiple endocrine neoplasia.

The clinical presentation of the sporadic type of medullary thyroid cancer is usually a painless thyroid mass; however, high calcitonin levels may result in a watery secretory diarrhea as the primary symptom. The diagnosis is made on the basis of a constellation of a thyroid mass, a high calcitonin level, and a fine-needle aspiration specimen that stains positive for calcitonin. Screening for pheochromocytoma (catecholamine excess) is important in order to exclude a familial syndrome for a patient otherwise believed to have the sporadic type. CT and PET imaging are useful to detect metastases, but radioactive iodine scans are not useful. For the familial syndromes, a dominant inheritance pattern is recognized, and family members of patients with newly diagnosed cases of the disease should be screened for *RET* mutations because germline mutations are substantially higher than might be expected on the basis of family history alone. Total thyroidectomy often results in complete cures for young, at-risk family members (based on *RET* gene testing), even in the absence of clinically detectable thyroid abnormalities. Studies show that a minority of family members undergoing prophylactic thyroidectomy actually have histologically normal thyroid glands. More often, there is evidence of C-cell hyperplasia and microscopic or macroscopic medullary thyroid cancer, which underscores the importance of operating early.

The treatment of choice for medullary thyroid cancer is total thyroidectomy with bilateral central compartment node dissection and unilateral neck dissection (at the very least). The risk for multifocal disease is high for both familial and sporadic types. Radiation has disappointing efficacy for macroscopic disease, and postoperative radiation therapy is not routinely used. After resection of all disease in the neck, patients should be monitored with two tumor markers: calcitonin and carcinoembryonic antigen. The survival outcome has improved with genetic testing and prophylactic surgery. Ten-year survival rates are 70 to 80% for combined series of familial and sporadic types.[138]

Vandetanib is an oral inhibitor that targets VEGF receptor, RET, and EGFR and has clinically relevant antitumor activity in advanced medullary thyroid cancer with an acceptable safety profile.[139] In a randomized, phase III trial of 300 mg of vandetanib daily compared with placebo in 331 patients with advanced medullary thyroid cancer, a median follow-up of 24 months revealed a statistically significant difference favoring vandetanib with prolongation of progression-free survival when compared with placebo (HR, 0.46; 95% CI; 0.31, 0.69; $p < 0.001$). This study also revealed a statistically significant difference with objective response rate, disease control rate, and biochemical response favoring vandetanib when compared with placebo.[139] Common adverse events of any grade included diarrhea, rash, nausea, hypertension, and headache. Overall survival data has not yet been reported. Based on the results of this study, the FDA granted approval for vandetanib for the treatment of symptomatic or progressive medullary cancer in patients with unresectable, locally advanced, or metastatic disease in April 2011. QT prolongation, torsades de pointes, and sudden death are included in a boxed warning for this drug. Because of the risk of QT prolongation, vandetanib is available

only through the FDA Vandetanib Risk Evaluation and Mitigation Strategy program. The recommended daily dose of vandetanib is 300 mg orally. The starting dose should be reduced to 200 mg in patients with moderate or severe renal impairment.

Cabozantinib is an oral TKI that targets MET, VEGF receptor 2, and RET. In a randomized, phase III, double-blind, placebo-controlled, international trial, 330 patients with radiographic progression of metastatic medullary thyroid cancer were enrolled and randomly assigned (2:1) to cabozantinib (140 mg per day) or placebo.[140] The primary endpoint was progression-free survival. Patients assigned to cabozantinib therapy achieved a statistically significant improvement in progression-free survival of 11.2 months, compared with 4.0 months for the placebo arm ($p < 0.001$). Response rates were 28% for cabozantinib and 0% for placebo. Common adverse effects of cabozantinib included diarrhea, palmar–plantar erythrodysesthesia, decreased weight and appetite, nausea, and fatigue. Dose reductions were required in 79% of patients. On the basis of this study, the FDA approved cabozantinib for the treatment of progressive metastatic medullary thyroid cancer in November 2012. A black box warning for gastrointestinal perforations and fistula formation, occurring in 3% and 1% of patients, respectively, has been issued.

Local recurrences are usually treated surgically. Metastatic disease (commonly to the mediastinum, lung, bone, and liver) often follows an indolent course, and in this case, observation is reasonable. The newly approved agents vandetanib and cabozantinib have not been directly compared with each other and, although both agents have been shown to decrease carcinoembryonic antigen and calcitonin levels and improve progression-free survival, no overall survival benefit has been reported thus far. Therefore, the choice of agent may depend on expected side effects, and the indications for starting therapy will need to be individualized and balanced with toxicity profiles and quality-of-life outcomes. In an editorial, Haddad supported using certain parameters such as calcitonin doubling time and the presence of symptomatic disease as important considerations prior to initiating these currently approved therapies.[141]

Palliative surgery, including tumor debulking, or radiotherapy may be used as indicated for symptom control or to manage tumor encroachment on critical structures. Diphenoxylate, octreotide, and interferon alpha-2a may palliate the diarrhea that can occur. Doxorubicin, cisplatin, dacarbazine, 5-fluorouracil, streptozocin, and somatostatin analogs have some reported activity; however, medullary thyroid cancer generally is resistant to standard cytotoxic agents, making investigational therapy appropriate.

KEY POINTS

- For differentiated thyroid cancers, poor prognostic features include age older than 45 years, male sex, poorly differentiated histology, tumor size, and extrathyroidal extension at diagnosis. In contrast, involvement of the regional lymph nodes does not confer a worse prognosis for survival.
- Radioactive iodine is the treatment of choice for metastatic disease. Standard chemotherapy has disappointing activity. Radioactive iodine generally has no role in the treatment of anaplastic or medullary thyroid cancers.
- Sorafenib and lenvatinib are approved by the FDA for the treatment of locally recurrent or metastatic, progressive differentiated thyroid cancer that no longer responds to

radioactive iodine treatment.

- Screening for germline *RET* gene mutation in patients with medullary thyroid carcinoma should be considered because total thyroidectomy, based on the results of genetic testing, often results in complete cures for young, at-risk family members.
- Vandetanib and cabozantinib have been approved by the FDA for the treatment of symptomatic or progressive, locally advanced or metastatic medullary thyroid cancers.

MANAGEMENT OF DISEASE IN THE ELDERLY

Although head and neck cancer is mostly diagnosed in patients in their 50s/60s, with increasing lifespans, a substantial proportion of patients with head and neck cancer will be elderly. Elderly patients present with age-specific problems such as multiorgan dysfunction, depression, alteration of mental status, reduced nutritional status, and limited social support, all of which can interfere with the diagnosis and treatment of cancer. However, biologic age, not chronologic age, is more important and takes into account comorbid illnesses and performance status. In a large, single-institution study, the percentage of patients with head and neck cancer with moderate to severe comorbidity was 21%, and there was a significant relationship between severity of comorbidity and overall survival.[142] A comprehensive geriatric assessment can be used to evaluate functional status, mental status, medications, nutritional status, social support, and comorbid illnesses to provide physicians with a better sense of a patient's life expectancy and tolerance to different treatment modalities when making therapeutic decisions.[143-145]

A multidisciplinary team with both oncologic and nononcologic providers is needed to optimize a treatment strategy in elderly patients. Surgery remains an appropriate option for the management of head and neck cancer in elderly patients once a full risk assessment is completed and medical optimization is initiated. Postsurgical mortality is associated with older age, severity of comorbid illnesses, and length of the operation.[146] Given the concern about the time under anesthesia, reconstructive surgery with free flaps in elderly patients remains controversial.

Radiation is a potentially curative option for patients diagnosed with early-stage disease or those with nonmetastatic disease who are deemed ineligible for surgical resection. Radiation can be safely administered in an elderly population, and most patients are able to complete their planned treatment.[147] There are no data demonstrating poorer tolerance or need to reduce radiation dose because of age.[148,149] However, the functional consequences of toxicities may be more severe in a more frail or debilitated patient.

As discussed earlier, concurrent chemoradiation improves both local tumor control and overall survival by 8% at 5 years in patients with head and neck cancer with locally advanced disease when compared with radiation alone.[64] However, patients age 70 or older derived little or no incremental survival benefit from adding chemotherapy to radiation in the large meta-analysis.[47] Yet, the use of chemoradiation in patients older than age 65 has steadily increased during the past 15 years.[150] This trend has further increased with the use of cetuximab with radiation. However, even with this less toxic agent, overall survival benefit in an older patient population is not clear.[43] In some patients, the benefit of chemoradiation may be offset by acute, often severe, treatment-related toxicities, particularly among older patients and those with comorbid medical conditions or poor performance status. In a population-based study, older patients who received chemoradiation were more than twice as likely to experience severe acute toxic effects compared with patients who received radiation alone.[151] Older

patients can be more susceptible to the toxic effects of chemotherapy because of potential delayed clearance from renal or hepatic impairment, decreased bone marrow reserve, malnutrition, and cognitive impairment.[152]

SURVIVORSHIP

Survivorship is an important area that needs attention. Studies involving survivors of head and neck cancer have mainly focused on the social supports, tobacco and alcohol use, the risk for second primary cancers, functional status, and depression and how these factors influence quality of life.[13,153-156] Chronic pain, xerostomia, impairments of speech and swallowing, alterations of taste and smell, and poor cosmesis are some of the long-term sequelae associated with treatment for head and neck cancer. These variable long-term toxicities can have a profound psychosocial effect on cancer survivors and their families. Fortunately, advances in reconstructive techniques and organ-preservation strategies are having a positive effect on quality of life relative to the functional and cosmetic consequences of radical local therapies of the past. Nevertheless, quality-of-life and survivorship issues must be a focus of future research and an integral component of those efforts.[154]

KEY POINTS

- Older patients can safely be treated with radiation-based therapy for head and neck cancer but require additional attention for management of comordid illnesses.
- Measures of biologic rather than chronologic age are relevant when determining appropriate treatment for patients with locally advanced head and neck cancer.
- Survivors of head and neck cancer can experience issues with swallowing, breathing, pain, and neck mobility that require ongoing management.

GASTROINTESTINAL CANCERS

Manish A. Shah, MD

Recent Updates

Esophageal Cancer

- In patients who receive definitive chemoradiation for locally advanced esophageal cancer, delayed esophagectomy may be associated with increased operative morbidity including a significantly higher risk of esophageal anastomotic leaks. (Farinella E, *J Surg Oncol* 2016)

Gastric Cancer

- The phase III CRITICS study evaluating postoperative chemotherapy versus chemoradiotherapy in patients with locally advanced gastric cancer who received neoadjuvant epirubicin, platinum, fluoropyrimidine therapy failed to demonstrate improved patient survival with postoperative chemoradiation. (Verheij M, *J Clin Oncol* 2016)
- The three-drug combination of docetaxel/oxaliplatin/fluorouracil–leucovorin improved patient survival when compared with epirubicin/cisplatin/fluorouracil in the perioperative treatment of locally advanced gastric and gastroesophageal junction adenocarcinoma. (Al-Batran SE, *J Clin Oncol* 2017)
- The HELOISE study confirmed the standard dose of trastuzumab in combination with platinum/ fluorouracil as first-line therapy for HER2-positive gastric cancer. (Shah MA, *J Clin Oncol* 2017)
- The GATSBY study failed to demonstrate that second-line trastuzumab emtansine, the novel drug-antibody conjugate, is superior to taxane therapy in second-line treatment for HER2-positive gastric cancer. (Thuss-Patience PC, *Lancet Oncol* 2017)
- A series of studies evaluating mesenchymal-epithelial transition (MET) pathway antibody inhibition in combination with chemotherapy in advanced gastric cancer failed to improve patient survival in first-line treatment. (Shah MA, *JAMA Oncol* 2017; Cunningham D, *J Clin Oncol* 2015)

Pancreatic Cancer

- Although the phase II clinical trial in metastatic pancreatic cancer involving the Janus kinase 1/2 inhibitor ruxolitinib was encouraging, the phase III update of ruxolitinib and capecitabine in advanced pancreas cancer was negative. (Hurwitz H, *J Clin Oncol* 2017)
- The ESPAC-4 study demonstrated a survival advantage of gemcitabine with capecitabine in the adjuvant setting in advanced pancreatic cancer. (Neoptolemos JP, *Lancet* 2017)

Hepatocellular Carcinoma

- The RESORCE study confirmed the benefit of regorafenib in second-line treatment for advanced hepatocellular carcinoma. (Bruix J, *Lancet* 2017)

Colorectal Cancer

- There may be a role for vemurafenib in combination with irinotecan and cetuximab in BRAF V600E mutant colorectal cancer, according to the updated results of a random assignment phase II study. (Kopetz S, *J Clin Oncol* 2017)
- For tumors that are mismatch repair–deficient (e.g., microsatellite instability–high), the programmed death 1 inhibitor pembrolizumab demonstrated significant efficacy and was granted accelerated FDA approval. (Le DT, *N Engl J Med*

2015)

OVERVIEW

In 2017, approximately 310,440 new cancers of the digestive system will be diagnosed in the United States, making it the most common physiologic system afflicted by cancer and, importantly more common than breast cancer (255,180), lung and respiratory tract cancers (243,170), and genitourinary cancers (279,800).[1] About 157,700 patients will die of gastrointestinal malignancies, including 50,260 patients with colon cancer, 43,090 patients with pancreatic cancer, 28,920 patients with liver and intrahepatic bile duct cancers, and 26,650 patients with gastroesophageal cancers. The spectrum of diseases encountered in this field varies from rather indolent malignancies such as low-grade neuroendocrine tumors with overall survival measured in years to very aggressive and rapidly fatal cancers, such as pancreas and hepatocellular carcinomas, for which, in advanced stages, survival is measured in months. Several cancers of the digestive tract are linked to hereditary syndromes, which require genetic counseling of patients and family members. Medical oncologists are feeling significant pressure because of advances in the development of medical therapies, which now routinely include targeted agents beyond conventional chemotherapy in most gastrointestinal malignancies, as well as the identification of specific biomarkers, which allow tailoring medical therapy to subsets of patients with cancer. The complexity associated with the diagnosis and treatment of gastrointestinal cancers is further increased by the fact that most of these malignancies require multimodality management involving close interaction between gastroenterologists, interventional radiologists, surgeons, radiation oncologists, and medical oncologists. One of the medical oncologist's key roles is, therefore, to coordinate the multimodality team and counsel the patient on various potential, sometimes competing, treatment options for his or her disease.

ESOPHAGEAL CANCER

Esophageal cancers exhibit great variation in histology, geographic distribution, and incidence over time. Historically, the most common type of esophageal cancer was a squamous cell cancer of the upper to middle esophagus. However, during the past 3 to 4 decades, the incidence of squamous cell cancers has decreased, as the incidence of adenocarcinoma of the esophagus and gastroesophageal junction has continued to increase rapidly. In the United States, esophageal cancers represent the fifth most common gastrointestinal cancer (after colorectal, pancreas, liver, and gastric cancers) and rank among the 10 most common cancers worldwide.[2,3] Areas of high incidence include portions of Iran, Russia, and northern China where squamous cell cancers dominate.[4] In the United States, carcinoma of the esophagus is infrequent, constituting approximately 1% of all cancers and approximately 6% of gastrointestinal malignancies. During the past 3 decades, the incidence of adenocarcinoma of the distal esophagus and gastroesophageal junction has increased, paralleling the rise of gastroesophageal reflux disease (GERD) in the general population, most notably for patients with a high body mass index (BMI).[5,6] Squamous cell tumors are more likely to occur in patients who are black, and these tumors are associated with achalasia, caustic injury, tylosis, Plummer–Vinson syndrome, cigarette smoking, and excessive alcohol consumption. Patients with squamous cell carcinoma of the head and neck are at increased risk of a synchronous or metachronous esophageal cancer of the same histology.

Adenocarcinomas of the distal esophagus and gastroesophageal junction more typically arise

in metaplastic epithelium—a condition known as Barrett's esophagus.[6] This premalignant condition is characterized by the replacement of stratified squamous epithelium by columnar epithelium that develops as a consequence of chronic GERD. The incidence of Barret's esophagus is 10 to 20% among symptomatic patients who undergo endoscopy and 30 to 50% for patients with peptic strictures. Risk factors for Barrett's esophagus include GERD, white or Hispanic race, male sex, advanced age, smoking, and obesity.[6,7] Although it is associated with chronic reflux disease, the mechanism by which chronic irritation leads to epithelial changes is unknown. Approximately 60% of cases of distal esophageal or gastroesophageal adenocarcinomas have evidence of Barrett's esophagus. In a nationwide population study from Denmark, the relative risk of adenocarcinoma among patients with Barrett's esophagus was 11.3 (95% CI; 8.8, 14.4) compared with the risk in the general population.[8] The annual risk of esophageal adenocarcinoma was 0.12% (95% CI; 0.09, 0.15). Detection of low-grade dysplasia on the index endoscopy was associated with an incidence rate for adenocarcinoma of 5.1 cases per 1,000 person-years. In contrast, the incidence rate among patients without dysplasia was 1.0 case per 1000 person-years. Risk estimates for patients with high-grade dysplasia were slightly higher.

It is unclear whether rigorous medical management of reflux disease with long-term proton-pump inhibitors can affect the natural history of the disease or the development of malignancy. The typical treatment for patients with Barrett's esophagus is surveillance using upper endoscopy and biopsy to examine tissue for evidence of dysplasia.[7] High-grade dysplasia is an indication for more aggressive management, including surgical resection. Tumor markers, such as *TP53,* may be predictors of potential progression to malignant disease. There is an inverse association between *Helicobacter pylori (H. pylori)* infection and adenocarcinomas of the lower esophagus, presumably a result of the reduced acidity associated with atrophic gastritis.[9] On the other hand, infection with human papillomavirus (HPV) has been correlated with an increased incidence of squamous cell cancers of the upper esophagus.[10]

CLINICAL PRESENTATION AND DIAGNOSIS

The most common clinical presentation of esophageal cancer is dysphagia. Cachexia and substantial weight loss are complications of this presenting symptom, which cause many patients to be debilitated at the time of the diagnosis. Bleeding (hematemesis, tarry stools, anemia) can be present as well. Other symptoms include treatment-refractory heartburn, and patients with tracheobronchial invasion may present with laryngeal nerve paralysis, cough, and/or postobstructive pneumonia.[11]

An upper endoscopic examination should be performed to obtain a minimally invasive biopsy. Computed tomography (CT) of the thorax should be performed with tomographic slices through the liver to evaluate the extent of disease in the upper abdomen with special attention to potential liver metastases and celiac lymphadenopathy. A thorough clinical examination with careful attention paid to the lymph nodes in the supraclavicular and axillary regions is essential.

Endoscopic ultrasound (EUS) can accurately assess the depth of penetration in up to 90% of tumors and determine involvement of mediastinal lymph nodes in nearly all patients; it has become a standard component when evaluating patients with esophageal cancer eligible for local–regional therapy.[12] In addition, EUS allows the biopsy of suspicious lymph nodes to confirm the presence of lymph node metastases. Positron emission tomography (PET), preferably as a PET/CT scan, has become part of the routine pretreatment diagnostic workup for patients with esophageal cancers. PET allows for the determination of lymph node status

and the detection of occult sites of distant metastatic spread; therefore, it may spare the patient the morbidity of an aggressive local–regional treatment approach.[13,14]

TREATMENT

The treatment of choice for patients with esophageal cancer had long been controversial, but accumulating evidence from meta-analyses and clinical trials has led to a consensus regarding the practical management of esophageal cancers. The most frequently used initial treatment had long been primary surgical resection. However, the results of surgical resection alone have been discouraging, spawning a series of clinical trials to determine the efficacy of chemotherapy and radiation in addition to surgical resection.

Esophageal cancers limited to the mucosa (T1, T1a) may be managed with endoscopic mucosal resection. For lesions that have penetrated into the submucosa without lymph node involvement on staging studies (T1b), surgical resection with lymphadenectomy is recommended because of the risk of lymph node involvement. For any lymph node-positive disease and lesions T2 or greater amenable to surgical resection, multimodality management with chemotherapy and/or radiation therapy has become the standard.[11]

Surgery

The two most commonly used surgical techniques are transhiatal esophagectomy, which is generally reserved for patients with tumors of the lower esophagus, and a transthoracic approach (e.g., an Ivor-Lewis resection), which utilizes a combination of thoracotomy and laparotomy. The latter procedure is a more traditional operation for esophageal cancer. The results associated with the two approaches are similar.[15,16] Reports suggest a higher retrieval rate of lymph nodes with an Ivor-Lewis approach.[17,18] Operative mortality rates should be less than 5% when the operation is performed by an experienced surgeon. Historically, survival has been poor for patients treated with surgery only, with 5-year survival rates ranging from 5 to 34%.[11]

It is important to monitor and maintain patients' nutritional status in light of weight loss and continued difficulty with alimentation both before and during treatment. To palliate tumor-related esophageal obstruction, and alleviate local swallowing dysfunction, there has been a shift away from surgical resection in favor of newer techniques such as the use of esophageal stents, laser therapy, endoscopic dilation, and gastric/jejunal tube feeding.

Combined-Modality Neoadjuvant Treatment

The poor surgical outcome and the relatively advanced nature of disease at the time of diagnosis (stages II and III) in most cases, led to investigations regarding combined-modality approaches for the treatment of patients with esophageal cancer. Combined-modality treatment involves both chemotherapy and radiation therapy and has been the focus of most of the research for esophageal cancer over the past several decades. The addition of chemotherapy is designed to treat micro-metastases and enhance the local effects of radiation. An original landmark clinical trial, performed by Herskovic et al., was the first to demonstrate the benefit of combined-modality therapy.[19] In this trial, patients with locally advanced, unresectable esophageal cancer were randomly assigned to receive either radiation therapy alone or combined-modality radiation therapy and chemotherapy. More than 25% of patients were alive at 5 years in the group that received combined-modality therapy; none of the patients who

received radiation therapy alone were alive at 5 years. The median survival was 14 months for combined-modality therapy versus 9 months for radiation therapy alone.[20] Based on these data, radiation therapy alone is now reserved for palliative local–regional treatment. The results of the Herskovic study led to a series of trials designed to examine the role of chemoradiotherapy when combined with surgery (e.g., trimodality therapy) or when used instead of surgery (e.g., definitive therapy). The chemotherapy agents historically administered with radiation were fluorouracil (5-FU), a platinum drug (cisplatin or carboplatin), and/or mitomycin C.[21] With these combinations, the pathologic complete response (pCR) rate was approximately 20 to 25%.

Given the modest pCR rate with chemoradiation, definitive chemoradiotherapy is considered a standard option for patients with localized esophageal cancer who are not considered appropriate surgical candidates. Decisions regarding surgical appropriateness involve several factors, including, but not limited to, age, comorbidities, performance status, and need for laryngectomy (e.g., particularly for cancers located in the cervical esophagus). In addition, squamous cell cancers (mainly found in the middle and upper esophagus) are more sensitive to chemoradiation than adenocarcinomas and exhibit different tumor biology. Definitive chemoradiotherapy may therefore also be considered a viable option for squamous cell carcinoma of the esophagus.[22]

Preoperative chemotherapy prior to resection is not generally an accepted approach for patients with localized esophageal cancer, although this issue is controversial because of conflicting results from two large studies performed in the United Kingdom[23] and by the U.S. Intergroup.[24] Subsequently, the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial—which compared perioperative chemotherapy using epirubicin/cisplatin/continuously infused 5-FU (ECF) with surgery alone for patients with gastric, gastroesophageal, and esophageal cancers—yielded a significant improvement in overall survival for patients who received perioperative chemotherapy (see “Gastric Cancer” section for more on gastric and gastroesophageal junction cancers).[25] A total of 26% of the patients in this trial had esophageal and gastroesophageal junction cancers, and multivariate subgroup analyses indicated a survival benefit from perioperative chemotherapy for gastroesophageal junction cancers. The OE05 study compared four cycles of preoperative ECF to two cycles of preoperative cisplatin/continuously infused 5-FU (CF) in patients with localized esophageal cancer and demonstrated no difference in outcome, thereby putting into question the role of epirubicin in esophageal cancer.[26] Thus, based on these data, perioperative chemotherapy with a combination platinum/5-FU regimen may be considered for patients with gastroesophageal junction cancers who are not optimal candidates for chemoradiation. Trials comparing optimized perioperative chemotherapy with neoadjuvant chemoradiation are highly warranted.

Various randomized trials have been conducted to compare preoperative chemoradiation therapy with surgery alone, but results were conflicting. A meta-analysis, which included 18 randomized controlled trials with approximately 3000 patients, found that trimodality therapy significantly improved 2-year survival (hazard ratio [HR], 0.81; p = 0.002; 13% absolute difference) and reduced locoregional recurrence when compared with surgery alone.[27] In the absence of medical contraindications, most patients in the United States with localized esophageal cancers receive neoadjuvant combined-modality therapy followed by surgery. Data from a Dutch phase III trial confirmed the superiority of a neoadjuvant radiochemotherapy approach compared with surgery alone for patients with localized esophageal cancer.[28] In this study, 368 patients were randomly assigned to receive radiochemotherapy with weekly carboplatin/paclitaxel and a relatively low radiation dose of 41.4 Gy followed by surgery or surgery alone. The neoadjuvant treatment led to a pCR rate of 29%. The overall survival was

significantly better (p = 0.003) in the group of patients treated with chemoradiation (HR, 0.66; 95% CI; 0.50, 0.87). Median survival was 49 months in the neoadjuvant arm versus 24 months in the surgery-alone arm. Interestingly, patients with squamous cell carcinoma had a pCR rate of 49% with neoadjuvant chemoradiotherapy compared with 23% for patients with adenocarcinomas (p = 0.008). In a cross-trial comparison, the toxicity of the carboplatin/paclitaxel regimen was mild and appeared less severe than the toxicity seen with the 5-FU/platinum combination used in CALGB 9781.[29] These results add further support for the use of trimodality therapy as standard of care for patients with localized esophageal cancers. The ongoing RTOG 1010 study is evaluating the role of adding trastuzumab to carboplatin/paclitaxel combined with radiation therapy for patients as neoadjuvant treatment for locally advanced HER2-positive esophageal adenocarcinoma (NCT01196390).[30]

No convincing data justify the routine use of adjuvant chemotherapy following surgery.[32] Similarly, radiation therapy has no role as the sole postoperative modality. Finally, patients who have a pCR following chemoradiotherapy may choose not to proceed to resection immediately, opting to wait for local recurrence and progression in the hope of avoiding an esophagectomy altogether. This approach, of salvage esophagectomy, is associated with similar survival to proceeding directly to esophagectomy as planned, but possibly with higher surgical morbidity, including anastomotic leak of 25% (for salvage esophagectomy) versus 3% if performed shortly after completion of combined modality therapy.[33]

Treatment of Metastatic Disease

The intent of treatment for metastatic esophageal cancer is to control the disease and provide palliation. Many agents have demonstrated some activity in esophageal cancer, including fluoropyrimidines (fluorouracil and capecitabine), platinum agents, taxanes, irinotecan, mitomycin C, anthracyclines, and, to a lesser extent, methotrexate, vinorelbine, and gemcitabine.[34] Treatment commonly is administered as a combination of two or three drugs or, less frequently, as single-agent therapy, depending on the patient's performance status. The utility of treatment regimens is similar to the experience with gastric cancer, especially with regard to adenocarcinomas of the gastroesophageal junction. In most clinical trials of single-agent therapy, the response rate has ranged from 10 to 20%. Combination regimens have yielded response rates as high as 40 to 50%. Palliation of dysphagia and bleeding is important and is difficult to achieve. The liberal use of esophageal stents and local therapies, such as laser therapy and brachytherapy, as well as palliative radiation with or without chemotherapy can be very useful in this setting.

The activity of novel targeted agents has also been investigated in clinical trials. A phase III trial that investigated the role of bevacizumab in advanced gastroesophageal and gastric cancers failed to improve overall survival.[35] Epidermal growth factor receptor (EGFR) monoclonal antibodies added to chemotherapy do not improve patient survival.[36,79] In contrast, the vascular endothelial growth factor receptor 2 (VEGFR2) monoclonal antibody ramucirumab led to survival benefits when combined with paclitaxel versus paclitaxel alone and when used as a single agent versus best supportive care for patients with advanced gastroesophageal cancers who received first-line chemotherapy with a fluoropyrimidine and a platinum agent.[37,38] Trastuzumab added to standard chemotherapy in HER2-overexpressing gastric and gastroesophageal cancers also improved overall and progression-free survival (PFS) as well as response rates compared with chemotherapy alone.[39] These data on novel biologic agents are discussed in detail later in the section on "Gastric Cancer."

KEY POINTS

- In the United States, the incidence of esophageal squamous cell carcinoma is decreasing, and the incidence of adenocarcinomas is rising rapidly, likely as an effect of lifestyle changes.
- Combined-modality chemotherapy and radiation are standard neoadjuvant approaches to the treatment of esophageal cancer.
- Definitive chemoradiation (without surgery) can be a valid treatment option, in particular for patients with squamous cell cancers of the esophagus.
- After trimodality therapy (radiochemotherapy followed by surgery), adjuvant therapy is not the standard of care.

GASTRIC CANCER

EPIDEMIOLOGY AND ETIOLOGY

The incidence of gastric cancer has varied considerably during the past century. In the United States, where the incidence of gastric cancer has decreased approximately 75% during the past few decades, the incidence of gastroesophageal tumors has concomitantly increased.[6] Although gastric cancer rates have experienced a significant decline in incidence worldwide, it is still prevalent in regions of the world where the storage of fresh foods and the quality of water are poor and in some industrialized nations as well (e.g., Japan). Gastric cancer is a major health issue in both Japan and Korea, and both countries have nationwide screening programs. In both Japan and Korea, gastric cancer is associated with a better prognosis than in Western cultures. When controlling for baseline tumor characteristics, patient demographics, and surgical factors, there remains a difference in survival that remains unexplained.[40]

The lowest incidences for gastric cancer are in Western cultures and among people of higher socioeconomic status. Studies of migrant populations have supported evidence for the effect of environmental influences on the development of gastric cancer.[41] Together, these data support the concept that gastric cancer is strongly influenced by nutritional, socioeconomic, and medical factors rather than dominated by genetic predisposition. In the United States, gastric cancer is seen twice as often in men as in women and more frequently in black men as in white men, and its incidence increases with age starting at age 50.[42] The mortality rate associated with gastric cancer has decreased for white men, paralleling the overall decline in the incidence of gastric cancer in this population. As mentioned previously, determining the reason for the considerable rise in the incidence of adenocarcinoma of the proximal stomach and distal esophagus remains a challenge for epidemiologists. Possible reasons for this rise include the prevalence of obesity, elevated BMI with increased incidence of GERD, and increased calorie consumption.[43] The use of aspirin and other nonsteroidal anti-inflammatory agents has been associated with a lower risk of cancer of the gastroesophageal junction and other gastrointestinal tumors.[44]

Factors associated with an increased risk of gastric cancer include nutritional factors such as high salt and nitrate intake, a diet low in vitamins A and C, the consumption of large amounts of smoked or cured foods, lack of refrigerated foods, and poor-quality drinking water.[45] Occupational exposure to rubber and coal also increases the risk. Cigarette smoking, *H. pylori* infection, Epstein–Barr virus, radiation exposure, and prior gastric surgery for benign ulcer

disease also have been implicated as risk factors. Genetic risk factors include type A blood, pernicious anemia, a family history of gastric cancer, hereditary nonpolyposis colon cancer (HNPCC), Li–Fraumeni syndrome, and hereditary diffuse gastric cancer (HDGC) caused by mutations in the E-cadherin gene, *CDH1*. HDGC is a genetic predisposition syndrome characterized by a family history of diffuse gastric cancer, often with early onset of disease (generally below age 40). The cumulative risk of the development of diffuse gastric cancer by the age of 80 years for *CDH1* mutation carriers is 70% for men and 56% for women. Women are also at higher risk for the development of lobular breast cancer, with a cumulative risk of 42% by age 80.[46] It is recommended that individuals with a germline mutation in *CDH1* undergo a risk-reducing prophylactic gastrectomy to prevent the future development of diffuse gastric cancer.[47] Gastric cancer precursor lesions include adenomatous gastric polyps, dysplasia, chronic atrophic gastritis, and intestinal metaplasia. Results from several studies have demonstrated an increased likelihood of *H. pylori* infection in patients with gastric cancer, particularly cancer of the distal stomach.[48,49] Although cancer does not develop in most people with *H. pylori* infections, the increased risk for patients who are infected has raised the issue of whether treatment of *H. pylori* might decrease the risk of gastric cancer. Although the role of *H. pylori* in gastric carcinogenesis is well defined, no definitive evidence shows that mass eradication could reduce the incidence of gastric cancer.[50] A large Chinese study showed no benefit in the prevention of gastric cancer with the eradication of *H. pylori.*[51] By contrast, a meta-analysis suggested that eradication could indeed reduce the risk of gastric cancer.[52] At present, treatment of patients with this infection should be reserved for those with demonstrated ulcers, gastritis, or other symptoms.

CLINICAL PRESENTATION AND DIAGNOSIS

Common presenting symptoms for gastric cancer include bleeding, hematemesis, pain, anorexia, early satiety, and dyspepsia. Clinical symptoms often arise from infiltration of the tumor within the stomach wall (causing anorexia, stomach pain, early satiety) and metastatic spread of disease inside the peritoneal cavity, resulting in the formation of ascites and abdominal pain. The disease is commonly diagnosed by upper endoscopy and direct biopsy. It is important that a biopsy be performed for samples from any gastric ulcer because it is difficult to distinguish benign from malignant ulcers endoscopically. Staging includes CT scan of the chest, abdomen and pelvis to rule out metastasis and to determine surgical resectability. Endoscopic ultrasound for tumor staging has less accuracy for stomach cancer than esophageal cancer; however, it may be used to distinguish early-stage cancer from locally advanced disease.[53] PET scans are able to identify occult disease in as many as 10% of patients.[54] Laparoscopy can identify up to 20% of occult peritoneal metastases as well, and is considered a standard staging procedure as well.[54]

TREATMENT

The only potentially curative treatment approach for patients with gastric cancer is surgical resection. The type of surgery performed in Asia differs from the type of resection most commonly performed in the United States. D2 resection, the standard surgery in Japan, involves the meticulous resection of all regional lymph nodes, whereas in the United States, D1 resection (removal of only perigastric lymph nodes) has long been the standard. Retrospective data suggest that the outcome for D2 resection is better than that for D1; however, the disparity might well be caused by a fundamental difference in the disease process itself, rather

than the surgical technique. Randomized trials initially did not clearly demonstrate a survival benefit for patients undergoing a D2, versus a D1, dissection.[55,56] After 15-year follow-up of a randomized Dutch trial that included 1078 patients, however, D2 lymphadenectomy was associated with lower locoregional recurrence (12% vs. 22%) and gastric cancer–related death rates (37% vs. 48%) than D1 surgery.[57] Although D2 dissection was associated with higher operative morbidity, these data suggest that D2 lymphadenectomy should be considered the surgical standard of care.

Localized Disease

Patients with early-stage operable gastric cancer have a reasonable chance of being cured with surgery alone. Surgery cures early-stage node-negative disease in 75 to 80% of patients. However, for patients with stage III disease, the reported 5-year survival rates are 25% or less. Adjuvant therapy for resected gastric cancer became a standard approach following the report of the INT-0116 randomized, phase III trial, which examined adjuvant chemotherapy combined with radiation therapy.[58] Patients with stage I to III gastroesophageal or gastric cancer were randomly assigned to receive either surgery alone or surgery followed by bolus 5-FU/leucovorin (LV)–based chemotherapy (Mayo Clinic regimen) with sandwiched chemoradiation therapy (45 Gy) and bolus 5-FU/LV as a radiosensitizer. The results showed an approximate 20% improvement in survival for the group receiving the combined-modality therapy. The median overall survival in the surgery-only group was 27 months, as compared with 36 months in the chemoradiation group; the HR for death in the surgery-only arm was 1.35 (95% CI; 1.09, 1.66; $p = 0.005$); the HR for relapse was 1.52 (95% CI; 1.23, 1.86; $p < 0.001$). The study has been criticized for the very low rate of D1 (or D2) lymph node dissections. In fact, less than 50% of patients underwent a D1 or D2 resection, which was mandated per protocol. In addition, only the rate of local recurrence, not the rate of distant metastasis, was reduced in the adjuvant chemoradiation group, suggesting that the adjuvant therapy could have mainly compensated for inferior surgery. On the other hand, the survival benefit observed with postoperative therapy was maintained in all (preplanned) subgroup analyses. Although these trial results were met with skepticism elsewhere, they established a new standard of care for patients with this disease in the United States. A large CALGB-led Intergroup trial (C80101) demonstrated that the addition of ECF, a combination regimen of infusional 5-FU/cisplatin/epirubicin to 5-FU sensitized radiation did not improve patient survival.[59] These data suggest that more aggressive chemotherapy does not add benefit to chemoradiotherapy in the adjuvant setting in this disease.

Perioperative chemotherapy with the ECF regimen administered before and after surgery for resectable gastric cancer also has shown a significant overall survival benefit compared with surgery alone in the MAGIC trial.[25] As compared with the surgery group, the perioperative chemotherapy group had a higher likelihood of overall survival (HR for death, 0.75; 95% CI; 0.60, 0.93; $p = 0.009$; 5-year survival rate, 36% vs. 23%) and of PFS (HR for progression, 0.66; 95% CI; 0.53, 0.81; $p < 0.001$). At the 2017 ASCO Annual meeting, the FLOT regimen (fluorouracil/leucovorin/oxaliplatin/docetaxel (T)), was examined in the peri-operative treatment setting compared with perioperative ECX.[31] This phase III study enrolled 716 patients, and demonstrated a significant improvement in median overall survival (35 mo with ECF/ECX versus 50 months with FLOT), HR 0.77 ($p = 0.012$). The study demonstrated approximately equal toxicity in both arms, suggesting that FLOT may be a more effective three-drug chemotherapy regimen in the perioperative setting.

There are two large, well-performed studies that also suggest a benefit of postoperative chemotherapy. The Japanese phase III trial of tegafur/gimeracil/oteracil (also known as S-1), an oral fluoropyrimidine approved for use in Japan and Europe, as adjuvant therapy after D2 resection of stage II or III gastric cancer demonstrated an overall survival benefit, with a 3-year overall survival rate of 80.1% in the S-1 group and 70.1% in the surgery-only group (HR, 0.68; 95% CI; 0.52, 0.87; p = 0.003).[60] The improvement in overall survival was confirmed after 5-year follow-up.[61] The Korean phase III trial CLASSIC, which included 1035 patients with D2-resected stage II/III gastric cancer, identified adjuvant therapy with capecitabine plus oxaliplatin as superior to surgery alone, with significant improvement in 3-year disease-free survival (DFS; 73% vs. 61%; HR, 0.58; p < 0.0001). The 5-year overall survival was 78% in the chemotherapy arm compared with 69% in the observation arm (HR for death, 0.66; 95% CI; 0.51, 0.85).[62] In addition to these individual trials, a meta-analysis of 17 trials with 3838 patients confirmed that adjuvant chemotherapy without radiation after gastric cancer resection was associated with a significant survival benefit with an HR of 0.82 (95% CI; 0.79, 0.90, p < 0.001).[63]

Several trials are attempting to definitively establish the benefits of adjuvant radiation combined with chemotherapy after D2 resection. The Korean Adjuvant Chemoradiotherapy in Stomach Tumors (ARTIST) trial evaluated the addition of radiation therapy to adjuvant chemotherapy in patients who underwent gastrectomy with D2 lymph node dissection.[64] Patients were randomly assigned to one of two arms: (1) six cycles of chemotherapy with capecitabine/cisplatin (XP), or (2) two cycles of XP followed by chemoradiation (with capecitabine), followed by two more cycles of XP. Neither DFS nor overall survival was different between the two arms, but subsets of patients with node-positive disease and intestinal-type gastric cancer did have a significantly improved DFS with the addition of radiation therapy. The ongoing ARTIST2 trial will try to determine whether the addition of radiation therapy to adjuvant chemotherapy improves DFS in these subsets of patients at higher risk for recurrent disease (NCT01761461). The Dutch Trial of Neo-adjuvant Chemotherapy Followed by Surgery and Chemotherapy or by Surgery and Chemoradiotherapy in Resectable Gastric Cancer (CRITICS Study) attempted to answer the question of whether adjuvant chemoradiation therapy is superior to chemotherapy alone. In this large randomized study, 788 patients were randomly assigned to receive perioperative chemotherapy (either epirubicin, cisplatin, capecitabine or epirubicin, oxaliplatin, capecitabine) or preoperative chemotherapy and postoperative chemoradiotherapy (as per the MacDonald study[58]).[65] There was no difference in patient outcomes, suggesting that postoperative chemoradiotherapy does not improve patient survival compared to chemotherapy. The TOPGEAR study will evaluate whether chemoradiation therapy in addition to perioperative chemotherapy (via the MAGIC approach) will be superior to the MAGIC approach alone (NCT01924819).

Based on the aforementioned trials and meta-analyses, three different approaches to the management of localized gastric cancer are considered standard of care and are used with varying frequency based on regional preferences: postoperative chemoradiotherapy (United States), pre- and postoperative chemotherapy (United Kingdom, United States, and much of Europe), or adjuvant chemotherapy alone after D2 resection (Asia).

Advanced Disease

The medical treatment of metastatic gastric cancer is primarily palliative, but it is associated with improved survival and an improved quality of life over best supportive care. Multiple agents are active, including fluoropyrimidines (fluorouracil, capecitabine, and S-1), anthracyclines,

platinum agents, taxanes (paclitaxel and docetaxel), irinotecan, and targeted therapies, including trastuzumab for HER2-overexpressing gastric cancers and, most recently, ramucirumab, a VEGFR2 antibody.[37,38] Combination regimens are associated with higher response rates and, according to a meta-analysis, also are associated with increased overall survival when compared with single-agent therapies.[66] Combinations including cisplatin/fluorouracil in various schedules were long considered the standard of care, with epirubicin commonly added to form a triple-drug regimen, which was pioneered mainly in the United Kingdom.[67] However, based on cumulative evidence, and most recently, the OE05 study comparing ECF to CF in the preoperative setting for localized esophageal cancer,[26] epirubicin is not believed to add significant efficacy and may be omitted.[68] A phase III trial involving 445 patients with gastric cancer demonstrated superiority of the addition of docetaxel to cisplatin and fluorouracil (DCF) compared with cisplatin and fluorouracil alone, in terms of response rate (37% vs. 25%, $p = 0.01$), time to tumor progression (5.6 months vs. 3.7 months, $p < 0.001$), and overall survival (9.2 months vs. 8.6 months, $p = 0.02$).[69] However, the addition of docetaxel is associated with significant toxicities, most notably, a high rate of febrile neutropenia (30%); therefore, this regimen is not advisable for patients with gastric cancer who have a poor performance status. Modifications to the DCF have been examined, and one randomized, phase II study demonstrated that a reduced intensity schedule of 5-FU/LV given over 48 hours, along with docetaxel 40 mg/m^2 and cisplatin 40 mg/m^2 (mDCF) administered every other week was at least as effective as DCF but with reduced toxicity.[70] Another large randomized phase III trial including 1002 patients tried to improve the ECF regimen by substituting oral capecitabine (X) for continuous-infusion fluorouracil and by using the nonnephrotoxic compound oxaliplatin (O) instead of cisplatin (C).[71] The combination of epirubicin/oxaliplatin/capecitabine (EOX) was found to be less toxic and at least as active as the ECF combination, with all efficacy parameters trending toward superiority. Median survival times in the ECF (control arm), ECX, EOF, and EOX groups were 9.9 months, 9.9 months, 9.3 months, and 11.2 months, respectively; survival rates at 1 year were 37.7%, 40.8%, 40.4%, and 46.8%. In a secondary analysis, overall survival was longer with EOX than with ECF, with an HR for death of 0.80 in the EOX group (95% CI; 0.66, 0.97; $p = 0.02$). PFS and response rates did not differ significantly between the regimens.

A third phase III trial compared cisplatin/5-FU with irinotecan/5-FU in 333 patients with advanced gastric cancer. No difference in outcome measures (response rate, PFS, and overall survival) could be found, but the irinotecan-based regimen was found to be less toxic and thus could be an alternative for patients who are not considered candidates for a platinum-based treatment regimen.[72] Based on these trial data, a combination regimen with a platinum agent (cisplatin or oxaliplatin) plus fluoropyrimidine as a backbone, with or without the addition of docetaxel, can be considered first-line standard of care in the palliative treatment of advanced gastric cancer. Irinotecan has clearly demonstrated activity and could be integrated in a sequential treatment approach.

The role of targeted agents, in particular drugs targeting the VEGF and EGFR/HER2 system, has been investigated in several clinical trials. The first targeted agent with documented efficacy in advanced gastric and gastroesophageal junction cancer was trastuzumab, the humanized monoclonal antibody against HER2. Based on the preclinical observations that about 20% of gastric cancers (and about 30% of gastroesophageal adenocarcinomas) overexpress HER2,[73] the phase III ToGA (Trastuzumab in GAstric cancer) trial investigated whether the addition of trastuzumab to standard chemotherapy would extend survival of patients with advanced adenocarcinoma of the stomach or gastroesophageal

junction.[39] Of the 3807 tumors from patients with gastric cancer tested, 810 (22.1%) were positive for HER2 overexpression using immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH) analysis. Eventually, 584 patients were randomly assigned to receive a fluoropyrimidine (5-FU 800 mg/m^2/day on days 1 to 5 or capecitabine 1000 mg/m^2 twice daily on days 1 to 14 based on physician choice) plus cisplatin 80 mg/m^2 on day 1 with or without trastuzumab (8 mg/kg loading dose followed by 6 mg/kg) on day 1. Cycles were repeated every 3 weeks for six cycles, and trastuzumab was subsequently continued every 3 weeks until disease progression. In the study, 55% of patients were from Asia and 18% of patients had tumors originating in the gastroesophageal junction. The addition of trastuzumab to cisplatin/fluoropyrimidine increased median overall survival from 11.1 months to 13.8 months (HR, 0.74; 95% CI; 0.60, 0.91; p = 0.0046). In addition, secondary endpoints such as PFS (6.7 months vs. 5.5 months, p = 0.0002) and overall response rate (47.3% vs. 34.5%, p = 0.0017) were also improved in the trastuzumab arm. There were no significant differences in toxicity between the two treatment arms. An asymptomatic decrease in ejection fraction occurred in 4.6% and 1.1% in the trastuzumab and chemotherapy-alone arms, respectively. As a result of the ToGA trial, trastuzumab added to standard chemotherapy is the standard of care in patients with metastatic, HER2-overexpressing gastric and gastroesophageal cancers. The HELOISE study examined the dose of trastuzumab in gastric cancer by randomly assigning 248 patients to receive cisplatin/capecitabine chemotherapy with either standard-dose or high-dose trastuzumab (8 mg/kg load followed by 10 mg/kg every 3 weeks).[74] Although a higher dose of trastuzumab did successfully increase trastuzumab trough concentrations, there was no improvement in survival when compared to standard trastuzumab dosing combined with chemotherapy (median overall survival, 12.5 months with standard trastuzumab vs. 10.6 months with high-dose trastuzumab).[74] These data firmly establish the standard dose of trastuzumab in gastric cancer.

In contrast with the positive results for trastuzumab in HER2-overexpressing gastric cancers, two phase III trials of lapatinib, an oral HER2/EGFR kinase inhibitor, added to chemotherapy in first-line (LOGIC) and second-line (TyTAN) treatment failed to meet their primary endpoints.[75,76] In the second-line treatment trial, however, the subgroup of patients with high HER2 expression (3+ on IHC testing) exhibited a survival benefit with the addition of lapatinib to paclitaxel versus placebo. It is unclear though whether lapatinib will be further developed in gastric cancer given the fact that trastuzumab has become the standard of care for HER2-positive gastroesophageal cancers. Finally, TDM-1, a novel antibody-drug conjugate combining trastuzumab with the drug emtansine, which acts on microtubules was examined in a phase III study in second-line gastric cancer and failed to show an improved survival compared with taxane therapy.[77] Together, the results of these studies demonstrate no evidence to support continuing HER2 blockade beyond progression in gastric cancer, providing yet another distinction among HER2-positive diseases.

Antibodies targeting the EGFR, a member of the HER family of receptor tyrosine kinases, such as cetuximab and panitumumab, have also been tested in randomized, phase III trials; unfortunately, the results were negative. The EXPAND trial randomly assigned over 900 patients with advanced gastroesophageal adenocarcinoma to receive capecitabine/cisplatin with or without cetuximab.[78] Although the toxicity was increased in the cetuximab arm, no benefit in any outcome parameter was noted. The REAL-3 trial investigated the addition of panitumumab to EOX in 553 patients.[79] The dose of EOX had to be reduced after an interim toxicity analysis, and the trial was eventually stopped when an interim efficacy analysis documented a detrimental effect in overall survival for the panitumumab-containing combination

compared with the standard arm. The consistently negative data from these two large phase III trials confirm that there is no role for the use of EGFR monoclonal antibodies in advanced gastroesophageal adenocarcinoma.

Results of a trial investigating angiogenesis inhibitors in gastric and esophageal cancers have been inconsistent. In the first phase III trial (AVAGAST), bevacizumab failed to demonstrate an overall survival benefit when added to cisplatin/fluoropyrimidine in patients with gastroesophageal junction and gastric adenocarcinomas.[35] Both median PFS (6.7 vs. 5.3 months; HR, 0.80; 95% CI; 0.68, 0.93; p = 0.0037) and overall response rate (46.0% vs. 37.4%; p = 0.0315) were significantly improved with bevacizumab versus placebo. However, the study failed to meet its primary endpoint of improving overall survival: median overall survival was 12.1 months with bevacizumab plus cisplatin/fluoropyrimidine and 10.1 months with placebo plus cisplatin/fluoropyrimidine (HR, 0.87; 95% CI; 0.73, 1.03; p = 0.10). Preplanned subgroup analyses revealed regional differences in efficacy outcomes with a survival benefit for Pan-American patients but not for patients from Asia, who, as expected, constituted the largest regional group. It has long been speculated that the biology of gastric cancers and the treatment approach to these tumors differs greatly between Asian and non-Asian countries. Thus, one would have to be careful with the interpretation of global trials in this disease, which will invariably include a substantial number of patients from Asia.

A second set of trials investigated ramucirumab, a VEGFR2 monoclonal antibody, in the second-line treatment setting of advanced gastroesophageal cancer. The REGARD trial randomly assigned 472 patients after first-line fluoropyrimidine/platinum therapy in a 2:1 ratio to receive single-agent ramucirumab or placebo.[37] Median overall survival was 5.2 months for the ramucirumab group and 3.8 months for the placebo group (HR, 0.776; 95% CI; 0.603, 0.998; p = 0.047). Aside from a higher rate of hypertension, no relevant differences were seen in recorded side effects between ramucirumab and placebo. In comparison with the AVAGAST bevacizumab trial, REGARD enrolled fewer patients from Asian countries (15% vs. 49%) and included a higher percentage of gastroesophageal junction cancers (25% vs. 14%). Concerns have been raised regarding the placebo control arm in the REGARD study, given the convincing documentation of a survival benefit associated with second-line chemotherapy. The RAINBOW trial was an international phase III study including 665 patients that compared paclitaxel plus placebo to paclitaxel plus ramucirumab as second-line therapy for those in whom disease progressed after exposure to a platinum/fluoropyrimidine–based regimen.[38] Overall survival was 9.6 months in the ramucirumab arm compared with 7.4 months with paclitaxel alone (HR, 0.807; 95% CI; 0.678, 0.962; p = 0.017). Patients in the ramucirumab arm had a significantly higher response rate (28% vs. 16%, p = 0.001) and improved PFS (4.4 months vs. 2.9 months, p < 0.0001) than patients in the paclitaxel alone arm. In the RAINBOW trial, overall survival was not significantly increased among Asian patients compared with non-Asian patients. Despite the activity of ramucirumab seen in the above second-line trials, a randomized phase II study did not show benefit to adding ramucirumab to mFOLFOX6 as first-line treatment for advanced gastroesophageal tumors.[80]

The usefulness of second-line chemotherapy in the palliative management of gastric cancer had long been questioned. Eventually, three randomized trials of chemotherapy versus best supportive care clearly demonstrated improvement in overall survival with the use of second-line chemotherapy with either irinotecan or taxane after failure of first-line fluoropyrimidine/platinum therapy.[81-83] A head-to-head comparison between two commonly used second-line therapies, paclitaxel and irinotecan, demonstrated similar efficacy for these approaches.[84]

Radiation therapy can be effective for metastatic disease (e.g., metastasis to bony

structures for symptom control) and perhaps for unresectable, bleeding tumors in conjunction with chemotherapy, but it is rarely used to treat primary advanced unresectable gastric cancer.

Several novel agents are currently being investigated in advanced gastric cancer. One of the most promising of these is the anti–programmed death 1 (PD-1) monoclonal antibody pembrolizumab. The KEYNOTE-012 trial evaluated pembrolizumab in patients with programmed death ligand 1 (PD-L1)–positive tumors.[85] Two-thirds of patients had undergone two or more prior systemic therapies. This 39-patient trial demonstrated impressive activity in this heavily pretreated population. The overall response rate was 22%, and the median overall survival was 11.4 months, which compares very favorably to the 5.2-month overall survival seen in the second-line REGARD study. In addition, a subset of patients had prolonged response to pembrolizumab, with a median response duration of 40 weeks (range, 20 to 48). In one phase III study of 493 patients with advanced gastric or gastroesophageal junction cancer whose disease has progressed on two or more lines of therapy, nivolumab, an anti–PD-1 monoclonal antibody, demonstrated significant efficacy over best supportive care, with a median OS of 5.3 months versus 4.14 months with best supportive care (HR, 0.63; 95% CI; 0.5, 0.78).[86] These studies suggest that immuno-oncology agents do have modest activity in gastric cancer, and studies to define their role are ongoing.

Antibody inhibitors of the mesenchymal-epithelial transition (MET) pathway also initially showed promise for advanced gastric cancers, particularly in patients whose tumors express the MET receptor (e.g., hepatocyte-growth factor receptor). A randomized, phase II trial, however, did not show an improvement in PFS with onartuzumab, a MET antibody, when combined with 5-FU/oxaliplatin (mFOLFOX).[87] Subsequent phase III studies evaluating the MET antibody, onartuzumab,[88] as well as the antibody to the hepatocyte growth factor, rilotumumab (also targeting the MET pathway), were also negative, confirming lack of efficacy of this strategy in advanced gastric cancer.[89]

In contrast, the multikinase inhibitor regorafenib did show an improvement in PFS compared with placebo (2.6 months vs. 0.9 months; $p < 0.0001$) in a randomized, phase II study (INTEGRATE) for chemotherapy-refractory advanced metastatic gastric and gastroesophageal junction tumors, demonstrating promise as salvage therapy for this patient population.[90]

KEY POINTS

- The incidence of gastric cancer correlates with socioeconomic status and is clearly dependent on environmental factors. The worldwide incidence of gastric cancer is in decline; however, there is an increase in more proximal and gastroesophageal cancers.
- Controversy surrounds the question of the best operation for gastric cancer, with data from Japanese studies suggesting a better result using a more aggressive, extensive lymph node dissection.
- Individuals who carry a germline *CDH1* mutation are at significant lifetime risk for the development of gastric cancer and should undergo risk-reducing prophylactic gastrectomy as early as their 20s.
- Randomized trials have demonstrated a survival benefit from adjuvant chemoradiotherapy, pre-operative and postoperative chemotherapy, or adjuvant chemotherapy without radiation for stages I to III gastric cancer resulting in several

standard-of-care options.

- Combination chemotherapy regimens have become more widely used for advanced disease, with some evidence that supports its benefit over single-agent therapy.
- The addition of trastuzumab to chemotherapy is standard of care in HER2-overexpressing metastatic gastric and gastroesophageal cancers. The standard dose of trastuzumab in gastric and gastroesophageal junction cancer has been defined in phase III evaluation.
- The VEGFR antibody ramucirumab has shown efficacy in second-line phase III trials in advanced gastric cancer and is now a standard care option either alone or with paclitaxel therapy.

PANCREAS CANCER

EPIDEMIOLOGY AND ETIOLOGY

Cancer of the exocrine pancreas is a substantial health problem in the United States, with an annual incidence of 53,670 cases and an annual mortality of 43,090 patients in the United States, with virtually all of those patients dying within 2 years of diagnosis.[1] It is estimated that more than about 270,000 patients die of pancreas cancer each year worldwide.[3] The incidence of pancreas cancer increased until the late 1970s and then plateaued. The risk factors for pancreas cancer are largely unknown, although there is some suggestion of a link to tobacco exposure.[91,92] Data regarding coffee and excess alcohol consumption are conflicting; therefore, they cannot be considered true etiologic factors. There is an association between pancreas cancer and diabetes; however, it is more likely that diabetes is an early manifestation of cancer and not necessarily a predisposing factor.[91,93] Chronic pancreatitis also may be a predisposing factor. Selective mutations of *BRCA2,* and to a lesser degree, *BRCA1* have been associated with familial pancreas cancer. Other less common genetic syndromes have been linked to pancreas cancer (e.g., hereditary pancreatitis, HNPCC, *p16* mutations, Peutz–Jeghers syndrome, ataxia telangiectasia).[94]

Approximately 10 to 20% of patients are thought to have a familial predisposition. There is no standard surveillance or screening for this disease. Most pancreas cancers harbor activating genetic mutations of the oncogene *KRAS,* which is integrated in signaling pathways of various receptor kinases such as EGFR and the insulin-like growth factor receptor I (IGFR-I). In addition, most pancreas cancers show mutations in several tumor suppressor genes, such as *p53, DPC4, p16,* and *BRCA2.*[95,96] A whole-genome sequencing study in 24 pancreas cancers identified an average of 63 genetic alterations per cancer, the majority of which were point mutations.[97] Pancreatic adenocarcinomas arise from ductal epithelial cells. Pancreatic intraepithelial neoplasia, which are microscopic lesions of the pancreas, and intraductal papillary mucinous neoplasms and mucinous cystic neoplasms, which are both macroscopic lesions, are thought to be precursors of invasive pancreatic cancer.[95,96]

CLINICAL PRESENTATION AND DIAGNOSIS

Symptoms associated with pancreas cancer at the time of presentation commonly include abdominal pain, weight loss, and/or jaundice. The classic description is midepigastric abdominal pain with bandlike radiation to the back. The disease typically is not diagnosed for several

months after the initial presentation with vague abdominal symptoms or back pain. Ultimately, the diagnosis is most often made with a CT scan, magnetic resonance imaging (MRI), or ultrasound. When evaluating patients with adult-onset diabetes without other risk factors, physicians should consider pancreas cancer as a possible diagnosis.[98] The most common diagnostic tests used for pancreas cancer are CT scan, MRI, EUS, and endoscopic retrograde cholangiopancreatography. Other tests, such as PET/CT and EUS, may play a role in distinguishing cancer from other abnormalities and are used to adequately stage the disease but do not replace biopsy as a definitive diagnostic test.

TREATMENT

The treatment for resectable pancreas cancer is primarily surgery, although neoadjuvant treatment strategies with either radiochemotherapy or chemotherapy alone have made inroads into clinical practice. For patients with tumors that appear resectable, which includes only approximately 20% of all pancreas cancers, surgery remains the only potentially curative treatment option. Tools such as EUS, MRI, and PET have improved the ability to determine which patients are candidates for surgery. To determine the resectability of a pancreas mass, a detailed evaluation of its spatial relationship to critical vascular structures—in particular, the superior mesenteric artery and celiac axis—must be performed. Most patients with pancreas cancer are found to have unresectable disease either because of a locally advanced disease (involvement of critical vascular structures) or obvious metastatic disease (liver, peritoneal involvement) at the time of diagnosis. The 5-year survival rate for the minority of patients who are able to undergo resection is 5 to 25%.[99]

Adjuvant Therapy

The optimal adjuvant therapy after pancreas cancer resection is controversial, particularly with regard to the value of radiation therapy. A small randomized study (43 patients) conducted in the United States over 30 years ago showed that a significantly larger number of patients in the combined-modality group were alive at 1 year compared with the surgery-alone group. On the basis of these findings, postoperative radiochemotherapy with bolus fluorouracil became the standard of care in the United States.[100] Since then, the role of radiation in this context has been repeatedly challenged by European investigators,[101] culminating in a trial suggesting that the use of radiation conferred an adverse outcome compared with patients who received adjuvant chemotherapy alone (ESPAC-1).[102,103] The complex study design, concerns about the radiation protocol, and the questionable randomization strategy used in ESPAC-1 limited acceptance of chemotherapy alone as a standard of care in the United States.

More recently, clinical trials have set somewhat competing standards for the adjuvant medical therapy of pancreas cancer. A German phase III trial (CONKO-1) including 364 patients demonstrated the superiority of adjuvant chemotherapy with gemcitabine compared with surgery alone for patients with resected pancreas cancer, regardless of whether a tumor-free resection margin could be obtained.[104,105] An update of this study demonstrated a significant improvement in 5-year overall survival of 20.7% (95% CI; 14.7, 26.6) compared with 10.4% (95% CI; 5.9, 15.0), for gemcitabine compared with surgery alone, and 10-year overall survival of 12.2% (95% CI; 7.3, 17.2) compared with 7.7% (95% CI; 3.6, 11.8).[106]

A large phase III trial conducted mainly in the United Kingdom, the European Study Group for Pancreatic Cancer (ESPAC)-3 trial, compared weekly gemcitabine to bolus 5-FU/LV (Mayo Clinic regimen) as adjuvant therapy in 1088 patients with resected pancreas cancer.[107] Median

survival was almost identical in the two groups (5-FU/LV, 23.0 months; gemcitabine, 23.6 months; p = 0.39). More mucositis/stomatitis and diarrhea were seen with bolus 5-FU/LV; patients taking gemcitabine had more thrombocytopenia. Since survival was equivalent, but a significantly higher rate of grade 3 and greater adverse events occurred in the 5-FU/LV arm (14% vs. 7.5%; p < 0.001), gemcitabine is the preferred standard option for adjuvant chemotherapy for resected pancreatic cancer.

The ESPAC-4 study compared adjuvant gemcitabine to gemcitabine/capecitabine in a large phase III study of 732 patients.[108] This study did demonstrate a modest improvement in survival with the combination adjuvant therapy; the median survival was 28.0 months, versus 25.5 months with gemcitabine alone (HR, 0.82; 95% CI; 0.68, 0.98, p = 0.032).

The randomized, phase III comparison of gemcitabine with S-1 in 385 patients with resected pancreas cancer were reported.[109] Although S-1 and gemcitabine had previously shown similar results in the advanced setting,[110] adjuvant S-1 was found to be superior to gemcitabine (HR, 0.57; 95% CI; 0.44, 0.72, p < 0.0001), with a 5-year estimated survival with gemcitabine of 24.4%, versus 44.1% with S-1. In Japan, S-1 has since emerged as the standard of care in adjuvant therapy for pancreas cancer.

A meta-analysis of nine large phase III clinical trials, reported in 10 articles, mostly support the role of adjuvant chemotherapy in pancreatic cancer, with an HR for death of 0.65 with adjuvant fluorouracil and of 0.59 with adjuvant gemcitabine.[111] Based on these studies and the meta-analysis of them, the combination of gemcitabine/capecitabine, gemcitabine alone, or S-1 in Asia are appropriate adjuvant options in patients with resected pancreatic cancer.

To expand on the potential role of radiation therapy, a U.S. trial (RTOG 9704) involving 451 patients documented an improved outcome for patients with cancers of the pancreas head (but not with cancers of the pancreas body or tail) who received adjuvant gemcitabine followed by radiochemotherapy with continuous infusion of fluorouracil (50.4 Gy, 5-FU at 250 mg/m^2/day) and subsequent gemcitabine monotherapy compared with postoperative fluorouracil-based radiochemotherapy.[112] In this updated analysis, patients with pancreas head tumors (388 patients) had a median survival of 20.5 months and a 5-year overall survival of 22% in the gemcitabine group compared with a median survival of 17.1 months and a 5-year survival of 18% in the fluorouracil group (p = 0.08).[112] This trial was designed to verify the role of adjuvant radiation therapy in resected pancreas cancer. Thus, for the foreseeable future, the standards of care might differ between the United States and Europe, with adjuvant gemcitabine-based chemotherapy without radiation favored in Europe and combined-modality approaches favored in the United States. The ongoing RTOG Intergroup phase III trial 0848 is currently evaluating the value of radiation therapy as adjuvant therapy for resected pancreas cancer (NCT01013649).

Based on the convincing results in advanced pancreas cancer, a phase III trial investigating the efficacy of mFOLFIRINOX (see “Treatment of Metastatic Pancreas Cancer” section) compared with gemcitabine as adjuvant therapy has been activated in France and Canada (NCT01526135). Similarly, the ongoing Adjuvant Therapy for Patients with Resected Pancreatic Cancer (APACT) study is a phase III trial comparing gemcitabine to gemcitabine plus nab-paclitaxel in the adjuvant setting (NCT01964430).

Chemotherapy and Radiation for Locally Advanced Pancreas Cancers

Preoperative chemotherapy and radiation are used in some centers in a neoadjuvant fashion in up-front resectable pancreas cancers, and results of phase II trials regarding this treatment

approach have been published.[113] For patients with initially unresectable cancers, a “conversion approach” of chemotherapy with or without radiation is attempted, with occasional adequate tumor responses allowing subsequent surgical resection. No randomized trial has been conducted yet, so it is unclear whether this approach is associated with a survival advantage. In addition, no clear definition of “borderline resectable” pancreas cancer has been established yet, although most surgeons consider abutment of major upper abdominal blood vessels the main criterion.[114]

For patients with locally advanced, unresectable disease, the two treatment strategies include primary radiochemotherapy and systemic chemotherapy. Most patients in the United States are currently treated with a combination of radiation therapy and chemotherapy. The standard regimen is infusional fluorouracil and radiation therapy, but the role of contemporary chemotherapy agents, including low-dose gemcitabine, capecitabine (an oral fluorouracil substitute), and targeted agents in combination with radiation therapy is now being explored. This approach may improve pain and prevent gastric or biliary obstruction. A randomized trial (E4201) validated this approach with a better outcome for patients receiving gemcitabine in combination with radiation therapy versus gemcitabine alone in patients with localized, unresectable pancreas cancer.[115] The primary endpoint of the trial was survival, which was 11.1 months (95% CI; 7.6, 15.5) and 9.2 months (95% CI; 7.9, 11.4) for chemoradiation and gemcitabine alone, respectively (one-sided $p = 0.017$). However, this trial enrolled only 74 of the planned 316 patients with unresectable pancreas cancer, so the results are not necessarily definitive.

The other feasible strategy is to initiate systemic chemotherapy as primary therapy because the clinical benefit of gemcitabine-based therapy in this setting is well documented, even in the absence of significant tumor shrinkage. This approach has been found to be superior in a European phase III trial including 119 patients, which compared induction chemoradiotherapy (60 Gy, infusional 5-FU and intermittent cisplatin) followed by maintenance gemcitabine with gemcitabine alone for locally advanced unresectable pancreas cancer.[116] Interestingly, median overall survival was shorter in the chemoradiation arm compared with gemcitabine-alone arm (8.6 months vs. 13 months, $p = 0.03$).

The role of radiation therapy as a component of the management of locally advanced pancreas cancers was further investigated by the international LAP07 phase III trial.[117] In this trial, patients with locally advanced, unresectable pancreatic cancer were initially randomly assigned to gemcitabine with or without erlotinib. Patients with at least stable disease after 4 months underwent a second randomization to either continue with the same chemotherapy as in the first phase or to proceed to chemoradiation with capecitabine as a radiation sensitizer. This study closed at the first planned interim analysis because of lack of efficacy. A total of 449 patients were randomly selected up front, 269 patients (61% of the initial study cohort) were eligible for the second randomization. One of the key findings of this study was that the addition of erlotinib to gemcitabine in this setting did not provide any benefit in overall survival. In fact, the overall survival trended toward a detrimental effect in the erlotinib arm. Secondly, no survival benefit was observed with the switch from chemotherapy to consolidating radiochemotherapy; the arms showed no difference in PFS and OS. A subsequent analysis to evaluate the effect of radiation therapy on locoregional tumor control found that patients in the radiation arm had significantly less local tumor progression (34% vs. 65%, $p < 0.0001$) and a longer time prior to reintroduction of chemotherapy (159 vs. 96 days, $p = 0.05$).[118] In conclusion, there appears to be no role for erlotinib in the management of locally advanced pancreas cancers. Chemoradiation after an induction chemotherapy phase can be considered

in select patients. Even though no survival benefit could be documented with this approach, it may provide local tumor control and allow patients a longer break from treatment of their advanced disease.

Based on the available data, radiochemotherapy or chemotherapy alone can be used as initial treatment for patients with unresectable pancreas cancer without distant metastases. Chemoradiation might be preferred for patients with poorly controlled pain from local tumor invasion in view of the well-documented analgesic effect of radiation therapy. Whether the high antitumor activity of FOLFIRINOX (see "Treatment of Metastatic Pancreas Cancer" section) with documented response rates above 30%[119] or gemcitabine plus nab-paclitaxel can emerge as the preferred neoadjuvant treatment for select patients is the focus of ongoing studies.

Other palliative means to treat patients in this setting include biliary stenting, intraoperative or external-beam radiation therapy, and celiac axis nerve blocks. Aggressive management of symptoms such as pain, anorexia, and obstruction should be the primary focus. Some patients require the placement of a duodenal stent for relieving gastric-outlet obstruction.[120] It is noteworthy in this context that the routine preoperative placement of biliary stents in patients with biliary obstruction and operable pancreas head cancers was associated with an increase in surgical complications when compared with up-front surgery without prior biliary drainage.[121] Thus, routine preoperative biliary drainage in patients undergoing subsequent surgery for cancer of the pancreas head should be considered only after close consultation with the surgeon and if it can be performed by an experienced interventional gastrointestinal team familiar with the placement of preoperative biliary stents.

Treatment of Metastatic Pancreas Cancer

Regarding advanced metastatic disease, several agents, such as fluoropyrimidines, gemcitabine, irinotecan, platinum compounds, and taxanes, have minor to moderate single-agent activity in pancreas cancer. In the mid-1990s, gemcitabine was tested in a randomized clinical trial with 126 patients against single-agent intravenous fluorouracil (administered without LV as short-term infusion, and thus not optimally administered).[122] Gemcitabine was found to be superior to fluorouracil with regard to clinical benefit, with more patients (24% vs. 5%) experiencing a reduction of pain as well as improvements in appetite and weight. There were few clinical responses in either arm (less than 10%), but the median survival (5.65 months vs. 4.4 months, $p = 0.0025$) and the 1-year survival rate (18% vs. 2%) were better for patients treated with gemcitabine. Subsequently, a plethora of clinical trials have tried to outperform gemcitabine monotherapy, with all studying gemcitabine compared with gemcitabine plus another agent. In phase III trials, agents added to gemcitabine consisted of several conventional chemotherapy drugs, such as fluorouracil, cisplatin, oxaliplatin, irinotecan, or pemetrexed. Novel biologic agents also were used, such as matrix metalloproteinase inhibitors, farnesyl-transferase inhibitors, or the VEGF-inhibitor bevacizumab and the EGFR antibody cetuximab. All of these trials failed to lead to improvements in overall survival.[123]

Subsequently, two phase III trials showed modest survival benefits of similar magnitude when another agent was used in combination with gemcitabine. In the first trial, the combination of gemcitabine with erlotinib, an EGFR tyrosine kinase inhibitor, was found to significantly increase PFS (HR, 0.77; 95% CI; 0.64, 0.92; $p = 0.004$) and overall survival (HR, 0.82; 95% CI; 0.69, 0.99; $p = 0.038$), albeit with a median overall survival improvement of only roughly 2 weeks.[124] No increase in response rate was noted. Nevertheless, based on these data, erlotinib obtained approval from the U.S. Food and Drug Administration (FDA) for the treatment of

advanced pancreas cancer in conjunction with gemcitabine. The second trial, a phase III trial comparing gemcitabine with or without capecitabine, initially demonstrated moderate benefits regarding response rates as well as PFS and overall survival.[125] However, in a combined analysis of two similar trials, the addition of capecitabine to gemcitabine was found to be associated with improved overall survival (HR, 0.86; 95% CI; 0.75, 0.98; p = 0.02).[125] A meta-analysis of 15 randomized trials involving 4465 patients that compared gemcitabine alone with gemcitabine plus either a platinum compound or fluoropyrimidine demonstrated a survival benefit for patients with good performance status who received combination chemotherapy (HR, 0.76; 95% CI; 0.67, 0.87; p < 0.0001). By contrast, application of combination chemotherapy to patients with an initially poor performance status appeared to be ineffective (HR, 1.08; 95% CI; 0.90, 1.29; p = 0.40).[126]

A new standard of care in the palliative therapy of pancreas cancer was defined by the results of a French study of 342 patients comparing gemcitabine with FOLFIRINOX, a combination of standard modified FOLFOX6—a well-known regimen established in colorectal cancer—with full-dose irinotecan (180 mg/m^2) in an every-2-week schedule.[119] The median overall survival was an unprecedented 11.1 months in the FOLFIRINOX group as compared with 6.8 months in the gemcitabine group (HR, 0.57; 95% CI; 0.45, 0.73; p < 0.001). Median PFS was 6.4 months in the FOLFIRINOX group and 3.3 months in the gemcitabine group (HR, 0.47; 95% CI; 0.37, 0.59; p < 0.001). The objective response rate was 31.6% for FOLFIRINOX compared with 9.4% for the gemcitabine group (p < 0.001). More adverse events were noted in the FOLFIRINOX group; 5.4% of patients in this group had febrile neutropenia. These results established FOLFIRINOX as the new standard of care for patients with advanced pancreas cancer, age less than 75, with good performance status, absence of biliary obstruction, and no infectious complications. The usefulness of FOLFIRINOX as adjuvant and neoadjuvant therapy as well as a backbone for the addition of targeted agents is currently being investigated in clinical trials.

Another standard first-line therapy for advanced pancreatic cancer was established when the addition of nab-paclitaxel to gemcitabine was found to be superior to gemcitabine alone in a phase III trial.[127] This study included 861 patients with metastatic pancreas cancer. The median OS was 8.5 months in the nab-paclitaxel/gemcitabine group, compared with 6.7 months in the gemcitabine-alone group (HR, 0.72; 95% CI; 0.62,0.83; p < 0.001). The median PFS was 5.5 months in the nab-paclitaxel/gemcitabine group, compared with 3.7 months in the gemcitabine-alone group (HR, 0.69; 95% CI; 0.58, 0.82; p < 0.001); the response rate according to independent review was 23% compared with 7% (p < 0.001). Neutropenia, febrile neutropenia (3% vs. 1%), neuropathy, and fatigue were significantly higher in the nab-paclitaxel arm. Subsequently, nab-paclitaxel received regulatory approval as a component of the gemcitabine-based first-line therapy of pancreas cancer.

Based on these studies, several first-line regimens can be considered appropriate treatment options for patients with metastatic pancreas cancer. With all caveats surrounding cross-trial comparisons, the outcomes data associated with FOLFIRINOX appear to be stronger than the nab-paclitaxel/gemcitabine results. On the other hand, the side-effect profile seems to favor the nab-paclitaxel/gemcitabine combination. It is unlikely that a direct head-to-head comparison between these two regimens will ever be performed, so that the available data will need to suffice to inform clinical practice. It could be reasonable to establish a three-tier approach toward metastatic pancreas cancer: otherwise healthy, younger patients in good performance status could preferentially be treated with FOLFIRINOX as first-line therapy and potentially nab-paclitaxel/gemcitabine as second-line therapy. Patients with poor performance status,

advanced age, and significant comorbidities could still be considered candidates for single-agent gemcitabine therapy. In between these extremes lies a group of patients who could be considered for nab-paclitaxel/gemcitabine as first-line therapy. It will be interesting to see how these treatment standards will be adopted into clinical practice in the future.

Second-line treatment options should be considered for patients with good performance status after progression on first-line therapy. In view of the commonly rapid progression of disease and deterioration of patients' performance status, randomized trials in second-line therapy are difficult to conduct. A German phase III trial randomly assigned 46 patients with advanced pancreas cancer who had received first-line gemcitabine to weekly infusional 5-FU/LV with biweekly oxaliplatin or best supportive care. The oxaliplatin-based therapy was able to confer a significant overall survival benefit (4.8 months vs. 2.3 months; HR, 0.45; p = 0.008).[128]

The recently reported NAnoliPOsomaL Irinotecan (NAPOLI)-1 trial evaluated nanoliposomal irinotecan (MM-398; nal-IRI) in patients with metastatic pancreatic cancer refractory to gemcitabine.[129] This trial randomly assigned 417 patients in a 1:1:1 fashion to receive nal-IRI alone, 5-FU/LV, or combination nal-IRI plus 5-FU/LV. Patients in the combination nal-IRI plus 5-FU/LV arm had a significantly improved overall survival compared with the 5-FU/LV arm—6.1 months compared with 4.2 months (HR, 0.67; p = 0.012) in the intention-to-treat population and 8.9 months compared with 5.1 months (HR, 0.57; p = 0.011) in the per-protocol population.[130] PFS was also improved (3.1 months vs. 1.5 months; HR, 0.56; p < 0.001). nal-IRI alone provided no survival benefit over 5-FU/LV. nal-IRI plus 5-FU/LV may provide another second-line treatment option for those in whom disease progressed on gemcitabine-based therapy but are not candidates for FOLFIRINOX. In October 2015, nanoliposomal irinotecan obtained FDA approval for use in combination with fluorouracil and LV in patients with metastatic pancreas cancer who have previously received gemcitabine-based therapy.

So far, agents targeting the VEGF system (bevacizumab) and the EGFR system (cetuximab) have failed to demonstrate activity in metastatic pancreas cancer.[131-133] Studies utilizing other targeted agents, including hedgehog inhibitors and IGFR inhibitors, have also not lived up to their initial promise. Other agents of interest currently undergoing investigation in clinical trials include *JAK2* inhibitors, *PI3K*, *MEK*, and *BRAF* inhibitors, as well as immune modulators and vaccines. In a randomized phase II study comparing the *JAK1/2* inhibitor ruxolitinib plus capecitabine with placebo plus capecitabine, a nonsignificant improvement was seen in median OS (137 vs. 130 days, p = 0.25).[134] However, in a subset of patients with very high levels of circulating inflammation (C-reactive protein > 13 mg/L), the survival advantage was 2.7 months (83 days) in the ruxolitinib plus capecitabine group compared with 1.8 months (55 days) in the placebo group (HR, 0.47; 95% CI; 0.26, 0.85; p = 0.011). Two phase III trials investigating the combination of ruxolitinib/capecitabine versus placebo with capecitabine in second-line treatment have been reported, having failed to show an improvement in survival.[135] Results of the combination of GVAX, an irradiated granulocyte macrophage colony-stimulating factor–secreting vaccine and CRS-207, a live-attenuated, mesothelin-expressing *Listeria monocytogenes* vaccine, also show promise in advanced pancreas cancer.[136] This trial included patients who received one or more prior lines of therapy and demonstrated an overall survival of 6.1 months for the combination GVAX/CRS-207 compared with 3.9 months for those who received GVAX alone (HR, 0.54; p = 0.011). Ongoing studies are evaluating this combination further in patients with advanced pancreatic cancer (NCT02004262).

AMPULLARY CARCINOMA

Ampullary cancers (also known as periampullary cancers) arise from the area known as the ampulla of Vater, which is a junction located adjacent to the pancreas, common bile duct, and duodenum. As such, tumors from this area are histologically divided into intestinal and pancreatobiliary subtypes. Genomic analyses suggest that *WNT* pathway alterations are more common in intestinal-type ampullary cancer, whereas *RAS* pathway alterations are more prevalent in the pancreatobiliary subtype.[137,138] Both studies identified *ELF3*, a member of the ETS transcription factor family, as a potential driver for ampullary carcinoma. Historically, these tumors have been thought to carry a relatively favorable prognosis, known for their high rates of resectability and good prognosis following pancreatoduodenectomy. In one series of 152 patients, the 5-year disease-free survival rate was 47.1%,[139] highlighting the better survival than true pancreatic cancers. Because ampullary cancers are rare, and difficult to isolate, there are few studies that specifically enroll ampullary cancers alone. Treatment of ampullary cancers generally follows the histology type; for example, intestinal-type ampullary cancers are preferentially treated as cancers of the small and large bowel, whereas pancreatobiliary ampullary cancers adopt a pancreatic or bile duct treatment paradigm.[140]

KEY POINTS

- Diagnostic tests, such as PET and EUS, do not replace the need for a biopsy to prove the diagnosis of pancreatic and ampullary cancers.
- The best approach to adjuvant therapy (especially the role of radiation) is controversial; however, it is clear that additional therapy beyond surgery alone is appropriate for most patients with stage I–III resected disease. Options include adjuvant gemcitabine, gemcitabine plus capecitabine, S-1, and possibly the inclusion of postoperative combined chemoradiotherapy.
- Both FOLFIRINOX and nab-paclitaxel with gemcitabine are superior combination regimens compared to gemcitabine monotherapy for patients with advanced pancreatic cancer who are considered candidates for more aggressive therapy.
- Ampullary carcinomas are tumors arising around and/or involving the ampulla of Vater; they can be of either the intestinal or the pancreatobiliary type, and they commonly carry a more favorable prognosis than pancreatic or bile duct cancers.
- Although there is no consensus, treatment of ampullary cancers generally follow the treatment of their histologic subtype.

CANCERS OF THE LIVER AND BILIARY TREE

EPIDEMIOLOGY AND ETIOLOGY

Primary hepatobiliary cancers, which include hepatocellular cancers, cholangiocarcinomas, and gallbladder cancers, represent the highest global incidence of solid organ tumors and are responsible for about 1 million deaths annually, although they are uncommon in Western cultures (particularly hepatocellular cancers).[3] The risk factors for hepatocellular cancer are well known (Table 10-1). Hepatitis B virus infection accounts for about 60% of the total liver cancer in developing countries and for about 23% of liver cancer in developed countries; the

corresponding percentages for hepatitis C virus infection are 33% in developing countries and 20% in developed countries.[141] In the United States and several other low-risk Western countries, alcohol-related cirrhosis and possibly nonalcoholic fatty liver disease, associated with obesity, are thought to account for the majority of liver cancers.[142]

Table 10-1 **Risk Factors for Hepatocellular Cancer**
Hepatitis B and C
Excessive alcohol consumption
Autoimmune hepatitis
Primary biliary cirrhosis
Androgenic steroids
Aflatoxins
Tobacco
Nitrosylated compounds
Thorotrast
Hemochromatosis
Alpha-1 antitrypsin deficiency
Wilson disease
Porphyria
Glycogen storage disease

HEPATOCELLULAR CANCER

Clinical Presentation and Diagnosis

Hepatocellular carcinoma is graded as well differentiated, moderately well differentiated, and poorly differentiated. The most important pathologic issue is the distinction between the fibrolamellar variant and the more traditional hepatocellular cancer. Fibrolamellar cancer is generally seen in younger patients, is much more likely to be resectable, and is less commonly associated with infection or cirrhosis.[143] In contrast, traditional hepatocellular cancer is found more often in men older than age 65. Less than 25% of the tumors are resectable, often because of underlying liver disease and inadequate hepatic reserve.[144] The predominant reason for nonresectability is the multifocal nature of the disease in the liver and detection late in the disease course, the latter of which is because of the long asymptomatic latency until diagnosis. Patients at high risk for the disease, such as patients with chronic hepatitis, are often monitored with imaging tests, which are often not very useful because of the similarity in appearance between cirrhotic and cancerous livers. Frequently, biopsies are required to distinguish cancer from cirrhosis. Likewise, the alpha-fetoprotein (AFP) tumor marker is not always helpful in distinguishing between the two diseases. Data suggest that an elevated subfraction of AFP, the lens culinaris agglutinin-reactive fraction of alpha-fetoprotein (AFP-L3%), is a more reliable indicator of the presence of a hepatocellular carcinoma in patients with hepatitis C–related cirrhosis than is the total AFP.[145]

Treatment

The treatment of choice for patients with hepatocellular cancer is surgical resection or transplantation. However, resection is not possible in most cases, and transplantation is limited by organ availability. Attempts at administration of systemic chemotherapy have been unsuccessful in generating radiographic responses, with virtually no suggestion of improvement in survival in patients with localized disease. Nonetheless, hepatic arterial infusions of chemotherapy as well as chemoembolization (transcatheter arterial chemoembolization) have proved to be useful and have been associated with improved outcome in randomized trials.[146] Local ablative treatments are generally reserved for unresectable, localized disease. These approaches include alcohol injection and radiofrequency ablation. Percutaneous ablation achieves complete remission (CR) in more than 80% of tumors smaller than 3 cm in diameter, but in only 50% of tumors of 3 to 5 cm in size.[147] Although these response rates are high, it is unclear whether these techniques result in a survival benefit. A pooled analysis of eight comparative studies suggested that radiofrequency ablation was superior to other locally percutaneous ablative techniques.[148]

For the subset of patients who are able to undergo surgical resection or ablation with curative intent, there is currently no benefit to adjuvant systemic therapy. Based on the benefits of sorafenib, an oral inhibitor of VEGFR and *Raf*, in the advanced setting, the STORM trial tested whether patients would benefit from sorafenib after resection or ablation. A total of 1114 patients were randomly assigned to receive sorafenib 400 mg twice daily or placebo. There were no differences in recurrence-free or overall survival.[149]

Liver transplantation represents the ultimate local therapy for unresectable hepatocellular cancer. For patients with substantial cirrhosis, liver transplantation provides an excellent option for early-stage tumors because the procedure is therapeutic for both the cancer and for the underlying pathology. Once patients have passed the high-risk peritransplantation phase, the prognosis is similar to that for patients who have had resection of more localized disease.[150] Patients with known extrahepatic disease are not candidates for liver transplantation.

Repeated unfavorable outcomes have resulted in no standard systemic chemotherapy for advanced unresectable disease. Single-agent anthracyclines and fluoropyrimidines have been most widely used in clinical trials and clinical practice, but reported response rates and times to tumor progression vary considerably.[151] Combination regimens are associated with higher response rates but do not necessarily translate into better overall outcomes. A Chinese phase III trial that compared standard doxorubicin to FOLFOX4 noted a benefit in PFS and a trend toward improved outcome in overall survival with FOLFOX4 (median OS, 6.40 months vs. 4.97 months; HR, 0.80; 95% CI; 4.23, 6.03; p = 0.07), but the overall results were disappointing.[152]

Current trials are focusing on targeted therapies, such as angiogenesis and signal transduction inhibitors, either as single agents or in combination with chemotherapy or with other biologic agents, in particular, since sorafenib was established as standard first-line therapy. Sorafenib was compared with placebo in a phase III trial (SHARP) of 602 patients with unresectable hepatocellular cancer.[153] In this trial, the use of sorafenib was associated with significant prolongation of time to radiologic tumor progression (5.5 months vs. 2.8 months, p = 0.000007) and of OS (10.7 months vs. 7.9 months, p = 0.00058). Based on these data, sorafenib has emerged as new standard therapy for advanced, unresectable hepatocellular carcinoma and has received approval by regulatory agencies. It is unclear at this point whether the observed efficacy of sorafenib is more related to its VEGFR- or its *Raf*-inhibitory capacity. Interestingly, in a large phase III trial comparing sunitinib, another oral multikinase inhibitor with significant antiangiogenic activity, clearly demonstrated the superiority of sorafenib over

sunitinib.[154] The superiority was especially pronounced in patients with hepatitis C–associated hepatocellular carcinoma. Since the SHARP trial included only patients with Child–Pugh A (Table 10-2), questions regarding the activity and tolerability of sorafenib in patients with more severe liver dysfunction have been raised. In clinical practice, only patients with Child–Pugh A and perhaps B7 scores should be routinely considered for sorafenib therapy.

Clinical trials using VEGF and other kinase inhibitors (e.g., hepatocyte growth factor [HGF]/c-Met targeting agents) for hepatocellular cancer with or without other targeted agents or chemotherapy are underway, even though several studies with initially promising agents such as the bFGF/VEGF inhibitor brivanib have already showed negative results. The REACH study evaluated the efficacy of ramucirumab in patients with hepatocellular carcinoma that progressed on prior sorafenib therapy.[155] In the intention-to-treat population, the median overall survival was improved with ramucirumab compared with placebo, but the difference was not statistically significant (9.2 months vs. 7.6 months, p = 0.1391).[156] However, a prespecified subset analysis demonstrated a significant median OS benefit for patients with an AFP level of 400 ng/mL or greater of 7.8 months for ramucirumab compared with 4.2 months for placebo (HR, 0.67; 95% CI; 0.51, 0.90; p = 0.0059). Thus, the AFP level may serve as a marker for the benefit of ramucirumab in second-line treatment for advanced hepatocellular carcinoma. Regorafenib was examined against best supportive care in second-line treatment for patients with advanced hepatocellular carcinoma that progressed or were intolerant to sorafenib.[157] In this study, 573 patients were randomly assigned (2:1) to receive regorafenib 160 mg or placebo daily. Patients who received regorafenib experienced a median survival of 10.6 months, versus 7.8 months with placebo (HR, 0.63; 95% CI; 0.5, 0.79; p < 0.0001).[157]

Table 10-2 Child–Pugh Scoring System

The score employs five clinical measures of liver disease.
Each measure is scored 1 to 3, with 3 indicating the most severe derangement.

Measure	1 point	2 points	3 points
Total bilirubin, pmol/l (mg/dL)	< 34 (< 2)	34–50 (2-3)	> 50 (> 3)
Serum albumin, g/dL	> 3.5	2.8–3.5	< 2.8
PT INR	< 1.7	1.71–2.30	> 2.30
Ascites	None	Mild	Moderate to severe
Hepatic encephalopathy	None	Grades I to II (or suppressed with medication)	Grades III to IV (or refractory)

Chronic liver disease is classified into Child–Pugh class A to C, by adding the points: A = 5 to 6, B = 7 to 9, C = 10 to 15. Abbreviation: PT INR, prothrombin time international normalized ratio.

A potential treatment algorithm for hepatocellular carcinoma is outlined in Fig. 10-1.[144]

BILIARY CANCERS

Cancers of the extrahepatic bile duct and gallbladder are relatively rare, with only 11,740 cases diagnosed annually in the United States, resulting in approximately 3830 deaths annually.[1] The low mortality for biliary cancers overall can be explained by the fact that about 50% of gallbladder cancers are incidental findings on cholecystectomy, which—commonly diagnosed in an early stage—can have an excellent prognosis (3-year OS, 70 to 100%). It is important to note, though, that when a gallbladder cancer is found after laparoscopic cholecystectomy, re-resection of the adjacent liver segment and lymphadenectomy are indicated for all disease

stages except stage I.[158,159]

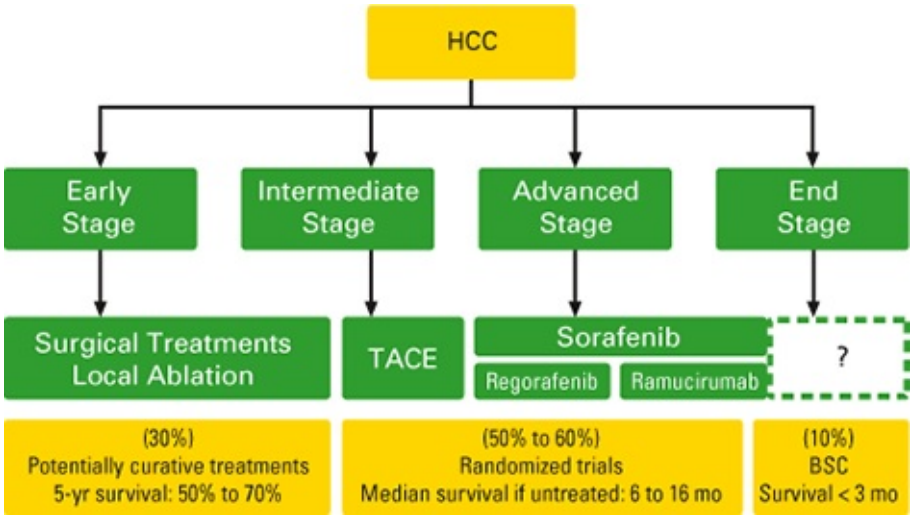

Fig. 10-1 Hepatocellular cancer (HCC) treatment algorithm.

Unfortunately, American statistics do not give specific numbers for intrahepatic cholangiocarcinomas but subcategorize them under “hepatobiliary tumors,” so that the actual incidence of biliary cancers is definitely higher, perhaps approaching the incidence of esophageal cancers, with about 15,000 cases per year.[160] Because of the location of these tumors, they are frequently difficult to resect; therefore, specialized surgical intervention should always be sought. Cholangiocarcinoma is most common in female patients older than age 50, and long-term survival is highly dependent on the effectiveness of surgical therapy. Conditions that are associated with an increased risk include primary sclerosing cholangitis (with an increased incidence among patients with inflammatory bowel disease), choledochal cysts, and other hepatic infections.[161] Gallstones also increase the risk of cancers of the gallbladder.

Clinical Presentation, Diagnosis, and Treatment

Cholangiocarcinomas typically present with jaundice or with a mass evident on CT or ultrasound or are visualized endoscopically. The primary treatment is surgical resection, if possible. The cure rate for patients with early-stage disease ranges from 60 to 70%; however, for patients with more advanced disease, the 5-year survival rate is only 10 to 25%.[162,163] Thus, the role of either preoperative or postoperative radiation and chemotherapy may be important. Although the role of radiation therapy—either alone or in combination with chemotherapy—has been evaluated in several studies, no substantial benefit has been seen.[164,165] Adjuvant therapy is often used for patients with positive margins (chemoradiation) or for patients with positive lymph nodes (chemoradiation and/or chemotherapy). This practice is supported by a meta-analysis, which demonstrated that the greatest benefit for adjuvant therapy was in patients with biliary cancers who had lymph node–positive disease (odds ratio [OR], 0.49; $p = 0.004$) and in those who had a positive microscopic resection margin (OR, 0.36; $p = 0.002$).[166] Based on Surveillance, Epidemiology, and End Results data for patients with resected gallbladder cancer between 1995 and 2005, a web-based nomogram predicting the benefit of adjuvant chemoradiation was developed for this patient group, which can serve as a guideline in the

absence of definitive phase III data in this setting.[167]

The effectiveness of systemic chemotherapy alone in advanced cancers is poor, with response rates ranging from 10 to 40% for both single-agent and combination chemotherapy regimens.[162] Although the surgical approaches for intra- and extrahepatic cholangiocarcinomas and gallbladder cancers differ, systemic chemotherapy does not currently distinguish between these cancers. Most of the regimens used are gemcitabine- or fluoropyrimidine-based and follow treatment strategies established in pancreas cancer. A pooled analysis of clinical trials in biliary cancers documented higher response rates and longer time to tumor progression for gemcitabine-based combination regimens with fluoropyrimidines and with platinum agents than for gemcitabine alone.[162]

The results of this pooled analysis were confirmed by a standard-setting phase III trial that randomly assigned 410 patients with advanced biliary tract cancers to receive gemcitabine 1000 mg/m^2 on days 1, 8, and 15 every 4 weeks for six cycles or gemcitabine 1000 mg/m^2 plus cisplatin 25 mg/m^2 on days 1 and 8 every 3 weeks for eight cycles.[168] The addition of low-dose cisplatin did not result in significant differences in grade 3 or 4 toxicities. The PFS was 8.4 months in the gemcitabine/cisplatin arm and 6.5 months in the gemcitabine-only arm (HR, 0.72; 95% CI; 0.57, 0.90; p = 0.003). This translated into an overall survival benefit of 11.7 months in the gemcitabine/cisplatin arm compared with 8.3 months in the gemcitabine-only arm (HR, 0.70; 95% CI; 0.54, 0.89; p = 0.002). This trial established a new standard of care in the treatment of advanced biliary cancers, gemcitabine/cisplatin, which can now serve as the backbone for the addition of targeted agents in future trials.

The role of photodynamic therapy for superficial, hilar cholangiocarcinomas is not well defined, but sustained palliation of biliary drainage has been reported.[169] Chemoembolization or radioembolization techniques have been used for unresectable cholangiocarcinomas with dominating liver involvement, but they should not yet be considered standard of care because of the paucity of available data.[170]

KEY POINTS

- Hepatocellular carcinoma is an important cancer whose global incidence can be reduced by vaccination against hepatitis B.
- Resection, when feasible, is the mainstay of treatment for this family of tumors.
- Locally ablative procedures and chemoembolization are components of a standard treatment algorithm for hepatocellular carcinomas without distant metastasis.
- Sorafenib has emerged as standard systemic palliative therapy for advanced hepatocellular carcinoma.
- Regorafenib is a standard second-line option in patients whose disease has progressed or who are intolerant of sorafenib.
- The combination of gemcitabine/cisplatin is a standard of care treatment option for patients with advanced biliary tree cancers.

COLORECTAL CANCER

EPIDEMIOLOGY AND ETIOLOGY

Colorectal cancer affects approximately 135,430 patients in the United States every year. Among all cancers, it is the second leading cause of death in the United States, with about 50,260 deaths, affecting both men and women equally (second only to lung cancer, which results in 155,870 deaths annually).[1] Colorectal cancer is both sporadic and familial. The incidence of colorectal cancer is higher in developed countries than in developing countries. In the past decade, there has been a decrease in the incidence and mortality of colorectal cancer in the United States.[1] Findings from epidemiologic studies indicate that during the past 2 decades, the anatomic distribution of colorectal cancer may have shifted from the distal to the proximal colon. These results indicate strong environmental associations for colorectal cancer. The amount of fat intake relative to dietary fiber has long been believed to have an effect on colorectal cancer. Findings from case–control studies demonstrate that intake of fiber-rich foods (at least 13 g per day of dietary fiber) is strongly associated with a low risk of colorectal cancer. Other etiologic factors include the content and quality of bile acids, as well as vitamin and mineral intake, with calcium appearing to play a critical role. Folate has long been thought to work as a chemoprotectant against colorectal cancer, but data from a prospective study failed to demonstrate a protective effect against the development of colorectal adenomas.[171] In general, however, data from prospective, interventional studies indicate that the association among dietary fiber, calcium, fat intake, and colorectal cancer is not clear.[172,173] Additional environmental factors include the intake of alcohol and tobacco, hormone replacement in women (protective), total calorie consumption, and physical activity as it relates to obesity.[174-177] Interestingly, there has been an increased recognition that the regular use of nonsteroidal anti-inflammatory agents, including aspirin and cyclooxygenase-2 inhibitors such as celecoxib, may have a protective effect against colorectal adenomas and colorectal cancer.[44,178-181] Initial studies on the chemoprotective effect of aspirin in the context of nonpolyposis familial predisposition, such as Lynch syndrome, were negative,[182] but a prospective, randomized trial in 861 carriers of Lynch syndrome taking aspirin compared with placebo demonstrated that 600 mg of aspirin per day for a mean of 25 months substantially reduced cancer incidence after 55.7 months (HR, 0.56; 95% CI; 0.32, 0.99; p = 0.05).[183]

FAMILIAL SYNDROMES:

The two most common inherited forms of colorectal cancer are HNPCC and the familial adenomatous polyposis (FAP) syndrome (Table 10-3). These two recognized genetic syndromes are distinct in molecular biology and in clinical characteristics.

The first syndrome to be recognized was FAP, which is caused by an inherited mutation in the adenomatous polyposis coli (*APC*) gene, a key regulator of the Wnt-signaling pathway. Mutations of the *APC* gene lead to the formation of a dysfunctional protein, which prevents it from binding beta-catenin so that beta-catenin can then activate the transcription of various oncogenes. Patients with mutated *APC* have hundreds to thousands of colonic polyps, predisposing them to malignant tumors at a young age. Although FAP represents a small percentage (approximately 0.5 to 1%) of the overall number of cases of colorectal cancer, *APC* (or beta-catenin) mutations activating the Wnt-signaling pathway have been found in the vast majority (80 to 85%) of sporadic colorectal cancers. Further gene expression studies along the adenoma–carcinoma sequence have provided an important genetic model in which specific genetic mutations, leading to invasive colorectal cancers, have been clearly elucidated (Fig. 10-2).[184]

Table 10-3 **Factors That Increase the Risk of Colon Cancer**
Polyposis Syndromes
■ Familial polyposis

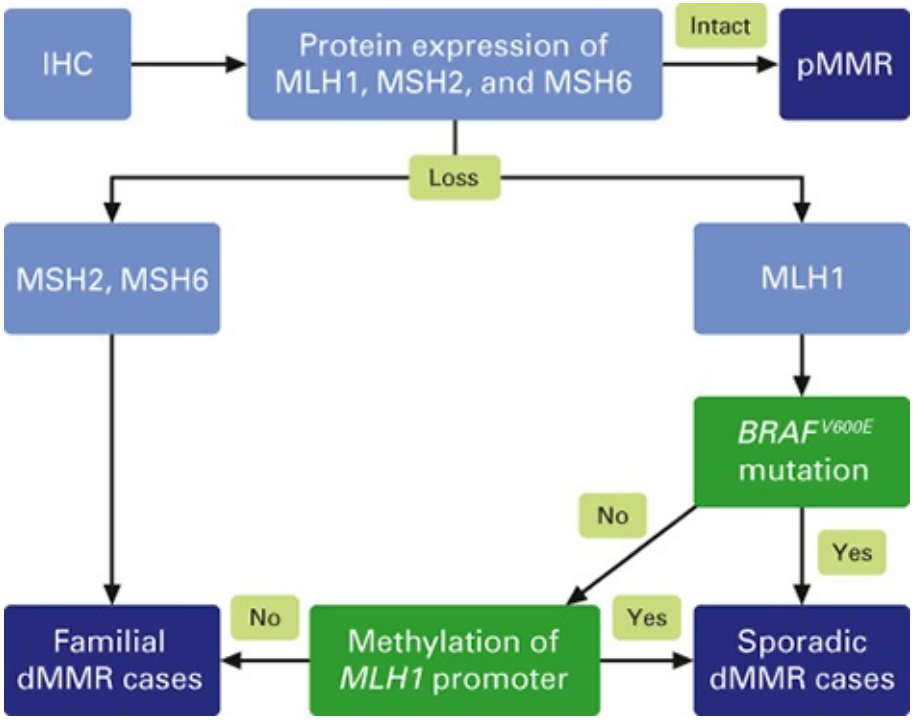

Fig. 10-3 Flow diagram to distinguish between patients with sporadic and familial mismatch repair–deficient (dMMR) colorectal cancers.[189]

Abbreviation: pMMR, proficient mismatch repair.

HNPCC is an inherited autosomal-dominant disease with high penetrance; it is the most common hereditary colorectal syndrome, accounting for approximately 5% of colorectal cancers. Colorectal cancer generally develops at an early age in these patients (median age, 45), commonly located in the proximal colon. Other associated malignancies with the genetic syndrome include ovarian, pancreas, breast, biliary, endometrial, gastric, genitourinary, and small bowel primary cancers. The Amsterdam Criteria and Bethesda Criteria are used to identify patients who should be considered for genetic testing (Table 10-4). The genetic abnormality of microsatellite instability (MSI) is common in HNPCC cancers and is caused by mutations in a group of genes that code for DNA mismatch repair enzymes, including *MSH-2, MLH-1, PMS-2,* and *MSH-6.*[185] The defect in mismatch repair allows spontaneous genetic mutations to accumulate in the colonic mucosa, which predisposes for the development of dysplasia and, eventually, for invasive cancers. MSI denotes that with reduced or absent DNA repair activity, the length of repetitive DNA sequences varies (becomes unstable) upon DNA replication. Approximately 10 to 15% of sporadic colon cancers also have aberrations in the mismatch repair enzymes,[186] generally caused by epigenetic silencing of MLH1,[187] and are thus characterized as having MSI. A panel of microsatellite markers is used to test for microsatellite instability, and tissue is classified as MSI-high (MSI-H) if two or more of five core markers show instability. The prevalence of MSI-H is about 15% in stage II, 8% in stage III, and 4 to 5% in stage IV colorectal cancers. Depending on how much the DNA repair capacity is affected in standardized polymerase chain reaction tests, MSI-high or MSI-low (as well as microsatellite-stable [MSS] tumors) are distinguished. IHC for protein products hMLH1 and hMSH2 provides a rapid, cost-effective, sensitive (92.3%), and specific (100%) method for screening for DNA mismatch repair defects. In a comparative study, the predictive value of normal IHC for an MSS (e.g., MSI-low, MSI-L) phenotype was 96.7%, and the predictive value of abnormal IHC was 100% for an MSI-H phenotype.[188] In terms of nomenclature, MSI-H is synonymous with deficient mismatch repair (dMMR), MSS is synonymous with proficient mismatch repair

(pMMR). Figure 10-3 shows a flow diagram to distinguish between patients with sporadic and familial mismatch repair deficient (dMMR) colorectal cancers.[189] HNPCC is clinically associated with an early age at onset, a proximal tumor location, a mucinous histology, and a higher grade at the time of diagnosis. Interestingly, the prognosis for patients with this type of cancer is better in stage II colon cancer, when compared with that for patients with MSS tumors. The improvement is seen despite an apparent lower responsiveness to fluorouracil-based chemotherapy.[186,190-194] MSI-H tumors are also characterized by strong lymphocytic infiltration and have recently been characterized as “hypermutated” with the potential for the generation of a large number of neoantigens, which could lead to an activation of the immune system.[195] This fact could make these tumors a target for the treatment with immune checkpoint inhibitors.[196] Other polyposis and colorectal cancer syndromes also exist (Table 10-5). The identification of Lynch syndrome in patients with colorectal cancer has significant implications for the choice of therapy and for screening recommendation for family members; therefore, universal testing of all patients with colorectal cancer using MSI analysis of IHC for mismatch repair enzyme expression in tumor tissue has been recommended.[195] Current guidelines published by the National Comprehensive Cancer Network (NCCN; www.nccn.org, Colon 2016.v1) suggest that Lynch syndrome screening should be considered for patients with colorectal cancer at age 70 or younger and also those older than 70 who meet the Bethesda guidelines. The Ohio Collaborative study showed that 16% of patients with newly diagnosed colorectal cancer who were under age 50 had identifiable germline mutations, suggesting that genetic counseling for all patients under age 50 who have colorectal cancers is also reasonable.[197]

Table 10-4 **Clinical Criteria to Determine Likelihood of Hereditary Nonpolyposis Colorectal Cancer (HNPCC)**
Amsterdam II Criteria (All criteria must be met.)
■ At least three relatives with an HNPCC-associated cancer (colorectal, cancer of the endometrium, small bowel, ureter, or renal pelvis).
■ One relative should be a first-degree relative of the other two.
■ Malignancies should include at least two successive generations.
■ At least one family member should be diagnosed before age 50.
■ Familial adenomatous polyposis is excluded.
■ Tumors should be verified by pathologic examination.
Revised Bethesda Criteria to identify colorectal cancer patients who should undergo pathologic examination for HNPCC (Any criterion is sufficient.)
■ Colorectal cancer in a patient under age 50.
■ Synchronous or metachronous colorectal cancer, or associated with another HNPCC-associated tumor (i.e., endometrial, stomach, small intestine, ovarian, pancreatic, biliary tract, ureter or renal pelvis, brain, sebaceous gland adenoma, or keratoacanthoma)
■ Pathologic features of a MSI-high cancer (e.g., tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, medullary growth pattern) in a patient under age 60
■ Development of colorectal cancer in an individual who has a first-degree relative with colorectal cancer and/or HNPCC-related extracolonic cancer and/or colorectal adenoma, with one of the cancers diagnosed before age 50 or an adenoma diagnosed before age 40
■ Colorectal cancer in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age

Inflammatory bowel disease, particularly ulcerative colitis, is associated with an increased risk for colon cancer, estimated to be 5 to 10% by 20 years after the time of diagnosis; it also is associated with a high incidence of synchronous cancers, affecting 10 to 20% of cases.[198] Crohn's disease also may have a role in the increasing risk for colorectal cancer, particularly cancer in the ileocolic region. However, in the absence of colonic involvement by Crohn's disease, there is no increased risk of colon cancer. The risk for the development of a subsequent cancer is 3% for patients with a history of adenomatous polyps.

COLORECTAL CANCER GENETIC ABERRATIONS

In 2012, the Cancer Genome Atlas published their analysis of genomic alterations in 224 tumor

and normal pairs, revealing the most prevalent genomic alterations in colorectal cancer. Hypermutated tumors (defined as > 12 mutations/10^6 base-pairs [bp]), representing ~15% of cases were separated from the ~85% nonhypermutated tumors (those with < 8 mutations/10^6 bp). Among the nonhypermutated tumors, there were 17 somatic recurrently mutated genes, the most common being *APC, TP53, KRAS, PIK3CA, FBXW7, SMAD4, TCF7L2,* and *NRAS.*[195] Another prevalent colorectal cancer subtype involves aberrant CpG methylation.[200] Characterized by global hypomethylation with regional hypermethylation commonly at CpG islands, the CpG island methylator phenotype (CIMP) represents ~20% of colorectal cancer. CIMP-positive tumors are associated with right-sided tumors, female sex, and *BRAF* V600E mutations.[200-202] Table 10-6 provides the frequencies of the most prevalent colorectal cancer molecular alterations.

Table 10-5 Polyposis and Colorectal Cancer Syndromes

Syndrome	Characteristic Polyp Features	Inheritance Pattern	Extracolonic Manifestations
Familial adenomatous polyposis	> 100, diffuse polyposis	Autosomal dominant	Small-bowel adenoma and adenocarcinoma, gastric adenoma and cancer, fundic gland polyps, adrenal adenomas and cancers, thyroid cancer, and desmoid tumor
Gardner syndrome	> 100, diffuse polyposis	Autosomal dominant (phenotypic variant of FAP)	Epidermoid cysts, desmoid tumors, osteomas, and fibromas
Turcot syndrome	> 100, diffuse polyposis	Autosomal dominant (phenotypic variant of FAP)	Brain tumors
Flat adenoma syndrome	1 to 100, right-sided polyps		Fundic gland polyps and periampullary cancer
MUTYH-associated polyposis	Includes conventional adenomas, serrated adenomas, and hyperplastic polyps.	Autosomal recessive	? others
Hereditary nonpolyposis colon cancer	1 to 10 polyps	Autosomal recessive	Cancers of the endometrium, stomach, biliary tree, and small bowel; transitional cell cancer of the ureter and renal pelvis
Peutz–Jeghers syndrome	1 to hundreds, diffuse	Autosomal dominant	Ovarian and testicular tumors

Abbreviation: MUTYH, mutY Homolog (*E. coli*).

SCREENING

The screening tests for colorectal cancer include digital rectal examination, fecal occult blood testing (FOBT), fecal immunochemical test (FIT), sigmoidoscopy, colonoscopy, and air-contrast barium enema. The FIT is performed essentially the same way as the traditional guaiac FOBT, but it does not require drug or dietary restrictions. The newest technique, virtual CT colonography, is a tool to reliably visualize polyps and cancer in a nonendoscopic way, which still requires a standard bowel preparation.[204] Each of these tools, with the exceptions of digital rectal examinations and virtual CT colonography (for paucity of prospective data), has been shown to have a positive effect on colorectal cancer–related mortality. However, there is still a poor compliance rate with these tests, with less than 50% of patients ever undergoing any screening procedures. For many years, the guidelines for standard screening options varied according to different medical societies, with a general shift away from emphasizing

sigmoidoscopy in favor of colonoscopy, particularly in light of the observed shift toward more proximal colon cancers. The obvious advantages of colonoscopic screening are that the entire large bowel and distal ileum can be assessed and that immediate intervention, such as biopsy and polypectomy, is possible. The results of studies have demonstrated that although sigmoidoscopy in conjunction with annual FOBT[205] is an effective means of reducing the mortality related to colon cancer, approximately 8% of distal cancers and all proximal cancers (approximately 40 to 50% of all colorectal cancers) will be missed. Therefore, the most common recommendation from various organizations is for colonoscopy to be performed every 5 to 10 years for a patient with average risk, starting at age 50. (See Chapter 1: "Epidemiology and Prevention" for more information.) In March 2008, the American Cancer Society, the American College of Radiology, and the U.S. Multi-Society Task Force on Colorectal Cancer (a group that comprises representatives from the American College of Gastroenterology, American Gastroenterological Association, and American Society for Gastrointestinal Endoscopy) released the first-ever joint consensus guidelines for colorectal cancer screening.[206] The guidelines added two new tests to the list of recommended options—stool DNA and CT colonography and, for the first time, included a preference for screening tests that can not only detect cancer early but also detect precancerous polyps; these tests provide a greater potential for cancer prevention through polyp removal. Two studies confirmed the long-term reduction in colorectal cancer mortality by population screening with either FOBT or endoscopy.[207,208] The first DNA-based stool test received FDA approval in 2014 based on a prospective, randomized study that compared a multitarget DNA stool test including quantitative molecular assays for *KRAS* mutations, aberrant *NDRG4* and *BMP3* methylation, and beta-actin, plus a hemoglobin immunoassay against standard FIT in 9989 participants from a population cohort.[209] The sensitivity for detecting colorectal cancer was 92.3% with DNA testing and 73.8% with FIT ($p = 0.002$). The sensitivity for detecting advanced precancerous lesions was 42.4% with DNA testing and 23.8% with FIT ($p < 0.001$). The Centers for Disease Control and Prevention includes the stool DNA test as part of their screening recommendations (http://www.cdc.gov/cancer/colorectal/basic_info/screening/tests.htm). Table 10-7 lists the recommendations of the joint task forces.

Table 10-6 **Selected Common Genetic Aberrations in Colorectal Cancer**

Gene	Function	Molecular Lesion	Frequency
APC	Regulates WNT signaling pathway	Inactivating mutations	40–70%
TP53	Regulates cell-cycle progression, DNA repair, and apoptosis	Inactivating mutation	~50%
KRAS	Regulates intracellular signaling via MAPK	Activating mutations (codons 12, 13, 61, 117, 146)	40%
NRAS	Regulates intracellular signaling via MAPK	Activating mutations	~10%
BRAF	Regulates MAPK pathway	Activating mutation (V600E)	8–20%
PIK3CA	Regulates PI3–AKT pathway	Mutation (exon 20 and 9)	~20%
SMAD4	Regulates the TGFβ and BMP pathways	Inactivating mutations and deletions	25%
TGFBR2	Regulates the TGFβ pathway	Inactivating mutations	20%
PTEN	Regulates PI3–AKT pathway	Mutation or loss of expression	10% mutation / 30% loss
Other Molecular Alterations			
Chromosome instability		Aneuploidy	70%
CpG island methylator phenotype		Methylation > 40% of loci	20%
Microsatellite instability		Unstable microsatellite repeats	15%

Abbreviations: MAPK, mitogen-activated protein kinase; PI3/AKT, phophatidylinositol-3 kinase/serine-threonine kinase.
Modified from Kuipers et al.[203]

Screening should be more regular for patients at high risk, including those with inherited syndromes, inflammatory bowel disease, and previous adenomatous polyps or colorectal cancer. Individuals with HNPCC should have screening by total colonoscopy every 1 to 3 years beginning between ages 20 and 25 because of the lack of a visible premalignant lesion in this population and the higher risk for right-sided colon cancers.[210] Individuals with FAP should start screening colonoscopies as early as age 10. If a colon cancer or severe dysplasia is found in patients with inflammatory bowel disease, the general recommendation is for a near-total or a subtotal colectomy because of the high incidence of synchronous and metachronous cancers in this population.[211] Surgery can be less extensive for patients with sporadic cancers. For patients with type II HNPCC, a more extensive surgery can be recommended, particularly for women beyond childbearing age, for whom hysterectomy and oophorectomy should be considered.

TREATMENT FOR COLORECTAL CANCER

Early-Stage Colon Cancer (Stages 0, I, II, and III)

Nearly all patients with stage 0 disease (carcinoma in situ or intramucosal cancer) are cured by endoscopic resection alone, recognizing that the lymph nodes are not adequately assessed by this technique. The primary treatment for virtually all invasive nonmetastatic colorectal cancers is surgery. Studies indicate that laparoscopic-assisted surgery for colon cancer provides the same outcomes for overall survival and rate of recurrence as open laparotomy.[212] Studies prospectively evaluating the role of laparoscopic-assisted surgery in rectal cancer are ongoing. Early outcome parameters of a large, 1103-patient European study did not demonstrate a difference between open and laparoscopic surgery for rectal cancer.[213]

Surgery alone is curative for more than 85% of patients who have stage I or early stage II disease. For patients with more advanced stage II disease, the 5-year survival rate is

approximately 80% for T4aN0 cancers but drops to around 60% for T4bN0 tumors.[214] For stage III disease (positive lymph nodes), the 5-year survival rate is 30 to 50% with surgical resection alone.

Prognostic and Predictive Factors. Factors other than stage (Table 10-8) that adversely affect outcome include male sex, extent of local invasion (T4), undifferentiated histology (outside of the context of MSI-H tumors), mucinous features, signet-ring features, lymphovascular and perineural invasion, and elevated levels of carcinoembryonic antigen (preoperatively).[216] Another important prognostic factor is the number of lymph nodes identified in the resected specimen; a minimum of 12 lymph nodes is necessary for adequate staging. The prognosis for colon cancer for patients with HNPCC (and cancers with the defective mismatch repair phenotype in general) in stage II is better than the prognosis for patients with sporadic tumors (or a proficient mismatch repair phenotype), perhaps because the accumulation of genetic mutations in tumor cells do not allow for metastatic spread and potentially because of an activation of the host's immune system. Interestingly, though, the prognosis of patients with MSI-H and MSS cancers in stage III is quite similar. Mutations in *KRAS* and *BRAF* have been shown to have a negative prognostic impact on recurrence-free survival and postrecurrence overall survival in patients with stage III colon cancers, although the prognostic implication of *KRAS* mutations has not been confirmed in all studies.[217,218] Following a genomewide or a candidate-gene screening approach, gene signatures for colorectal cancer are currently being developed that could identify prognostic and predictive markers for the usefulness of adjuvant chemotherapy in patients with borderline indications.[219,220]

Table 10-7 Screening Guidelines for Colon and Rectal Cancer[132]

Beginning at age 50, both men and women at average risk for the development of colorectal cancer should use one of the screening tests below. The tests that are designed to find both early cancer and polyps are preferred if these tests are available and the person is willing to have one of these more invasive tests.
Tests that find polyps and cancer
■ Flexible sigmoidoscopy every 5 years*
■ Colonoscopy every 10 years
■ Double-contrast barium enema every 5 years*
■ CT colonography (virtual colonoscopy) every 5 years*
Tests that mainly find cancer
■ Fecal occult blood test (FOBT) every year*†
■ Fecal immunochemical test (FIT) every year*†
■ Stool DNA test (sDNA), interval uncertain*
People should talk to their doctor about starting colorectal cancer screening earlier and/or being screened more often if they have any of the following colorectal cancer risk factors:
■ A personal history of colorectal cancer or adenomatous polyps
■ A personal history of chronic inflammatory bowel disease (Crohn's disease or ulcerative colitis)
■ A strong family history of colorectal cancer or polyps (cancer or polyps in a first-degree relative [parent, sibling, or child] younger than age 60 or in two or more first-degree relatives of any age)
■ A known family history of hereditary colorectal cancer syndromes such as familial adenomatous polyposis (FAP) or hereditary nonpolyposis colon cancer (HNPCC)

*Colonoscopy should be done if test results are positive.
†For FOBT or FIT used as a screening test, the take-home multiple sample method should be used. A FOBT or FIT done during a digital rectal exam in the doctor's office is not adequate for screening.

Adjuvant Chemotherapy. The initial trial presented in the early 1990s that established adjuvant chemotherapy as standard of care in stage III colon cancer used a combination of fluorouracil and levamisole administered for 12 months.[221] A 10 to 20% absolute improvement in 5-year survival was documented for patients receiving postoperative adjuvant fluorouracil-based chemotherapy. Evidence from subsequent trials demonstrated that fluorouracil combined with LV provides a superior outcome, with 6 months of therapy being adequate to achieve this survival benefit.[222] For more than a decade, the standard in adjuvant therapy remained unchanged because of the lack of novel agents with relevant activity in colorectal cancer. This changed when oxaliplatin, irinotecan, and the oral fluorouracil prodrug capecitabine were utilized for the treatment of advanced colorectal cancer, with combination regimens of infusional fluorouracil plus either irinotecan or oxaliplatin demonstrating high antitumor efficacy.

Worldwide, six phase III trials were conducted to evaluate the value of these three novel chemotherapeutic agents in the adjuvant setting. To set the stage for the conduct and interpretation of these trials and their results, a large retrospective meta-analysis confirmed that, for adjuvant colon cancer, 3-year DFS can serve as an definitive surrogate marker for 5-year overall survival.[223] This finding had a major effect on clinical trial design and endpoint definition in subsequent studies of adjuvant colon cancer. Based on these findings, the FDA recognized 3-year DFS as an appropriate endpoint for full approval of a regimen for adjuvant colon cancer. Oxaliplatin was approved as part of adjuvant treatment for stage III colon cancer in 2004 on the basis of this endpoint. One trial established 6 months of oral capecitabine as a safe and at least equally effective alternative to conventional intravenous bolus fluorouracil with LV (Mayo Clinic regimen) for stage III colon cancer.[224] Two other trials confirmed the value of oxaliplatin as a component of adjuvant chemotherapy for stages II and III colon cancer.[225,226] The results of the pivotal Multicenter International Study of Oxaliplatin/5-FU/Leucovorin in the Adjuvant Treatment of Colon Cancer trial clearly demonstrated that oxaliplatin plus infusional fluorouracil and LV (FOLFOX) is superior to fluorouracil with LV in terms of 3-year DFS.[225] In a subgroup analysis, only the increase in DFS for patients with stage III disease was statistically significant, providing an absolute benefit of approximately 8 to 10% (HR, 0.76; 95% CI; 0.62, 0.92). In unselected patients with stage II disease, the DFS benefit for FOLFOX compared with fluorouracil and LV alone was approximately 3.5%, but it exceeded 5% for patients with stage II tumors with clinical high-risk features (undifferentiated tumors, T4, perforation, obstruction, fewer than 10 lymph nodes identified, and angiolymphatic invasion). An update demonstrated a significant improvement in 6-year (not 5-year) overall survival for patients with stage III, but not for patients with stage II, colon cancer when an oxaliplatin-based regimen was used as adjuvant therapy.[227] Results of the National Surgical Adjuvant Breast and Bowel Project C-07 trial further strengthened the role of oxaliplatin plus fluorouracil-based regimens in the adjuvant therapy of colon cancer.[226,228]

The third phase III trial in the sequence of studies comparing 5-FU/LV to a fluoropyrimidine/oxaliplatin combination as adjuvant therapy, the XELOXA trial (oxaliplatin/capecitabine [XELOX] vs. bolus 5-FU/LV), confirmed the role of oxaliplatin as a component of adjuvant therapy in stage III colon cancer with significant improvements in DFS (HR, 0.80; 95% CI; 0.69; 0.93; p = 0.0045) and a trend toward improved overall survival at 5 years.[229] As in the MOSAIC trial, longer follow-up is likely needed to demonstrate improved overall survival because of the available active treatment options upon tumor recurrence, which shift overall survival differences to a later time point.

Although irinotecan- and oxaliplatin-based regimens are thought to be equally effective as palliative therapy for advanced colorectal cancer, for unknown reasons, none of the three phase III trials using combination regimens of irinotecan/fluorouracil/LV demonstrated significantly superior efficacy regarding 3-year DFS when compared with fluorouracil and LV alone.[230-232]

Table 10-8 **Staging, Incidence per Stage, and Treatment Recommendations for Invasive Colon Cancer**

	Stage I	Stage II	Stage III	Stage IV
Staging	T1, N0, M0	A: T3, N0, M0	A: T1-2, N1/N1c, M0; T1, N2a, M0	A: Any T, Any N, M1a
	T2, N0, M0	B: T4a, N0, M0	B: T3-4a, N1/N1c, M0; T2/3, N2a, M0; T1-2, N2b, M0	B: Any T, Any N, M1b
		C: T4b, N0, M0	C: T4a, N2a, M0; T3-4a, N2b, M0; T4b, N1-2, M0	
Definition	Invades submucosa (T1) or muscular propria (T2)	Invades subserosa, nonperitonealized pericolic/perirectal tissues (T3) or penetrates to the surface of the visceral peritoneum (T4a) or directly invades into or is adherent to other organs or structures (T4b)	Involves 1-3 (N1-N1a: 1, N1b: 2 to 3) or more (N2-N2a: 4-6, N2b: > 6) lymph nodes; N1c for tumor deposits in subserosa, mesentery, or pericolic/perirectal tissue without lymph node metastasis	M1a: distant metastasis confined to one organ or site M1b: distant metastasis in more than one organ or site
Incidence	15%	25%	35%	25%
Usual treatment	Surgery	Surgery with or without chemotherapy	Surgery with chemotherapy	Chemotherapy with or without surgery

Based on these results, the standard adjuvant chemotherapy for stage III colon cancer is an oxaliplatin-containing regimen (FOLFOX, XELOX, or bolus fluorouracil/folinic acid/oxaliplatin [FLOX]) administered for 6 months. Capecitabine or fluorouracil and LV should be reserved for patients who are not considered optimal candidates for oxaliplatin.

To mitigate the long-term neurotoxic side effects of oxaliplatin-based adjuvant therapy, the International Duration Evaluation of Adjuvant chemotherapy (IDEA) collaboration was established to prospectively combine and analyze data from six randomized trials conducted around the world to answer the question of whether a 3-month course of oxaliplatin-based adjuvant therapy is noninferior to the current standard 6-month treatment for patients with stage III colon cancer. The final analysis, reported at the ASCO meeting in 2017, included 12,834 patients from 12 countries. There was significant heterogeneity, including varying treatments (FOLFOX and XELOX), tumor heterogeneity (pT4 varied from 12 to 29% across studies), and varying follow-up (35–62 months).[233] The primary analysis suggests that 3 months of oxaliplatin-based chemotherapy is not noninferior to 6 months with disease-free survival (HR, 1.07; 95% CI; 1.0, 1.15) because the upper bound of the 95% CI crossed the prespecified threshold of 1.12. Subgroup analyses suggest that 3 months may be noninferior for lower-risk patients (e.g., pT1–3N1), where the DFS HR was 1.01 (95% CI; 0.9, 1.12). However, for higher risk patients (T4 or N2+), the DFS HR was 1.12 (95% CI; 1.03, 1.24). Thus, for high-risk stage III colorectal cancer, the standard of care remains 6 months of adjuvant oxaliplatin-based therapy. However, for low-risk stage III patients, there is a suggestion that 3 months of oxaliplatin-based adjuvant therapy may be acceptable because of the complexity of the study and the heterogeneity of the study population; this recommendation remains controversial.

For patients with stage II disease, the role of adjuvant chemotherapy remains controversial; the results from a series of clinical trials demonstrated a trend toward improved recurrence-free survival and overall survival (HR, 0.80; 95% CI; 0.56, 1.15). Findings from two pooled retrospective analyses showed conflicting results.[234,235] One analysis suggested a 30% risk reduction, translating into an approximate 8% absolute reduction in mortality, whereas a similar

pooled data set showed no benefit from adjuvant chemotherapy. An analysis of Medicare data revealed that more than 50% of patients in the United States with stage II colon cancer receive postoperative adjuvant chemotherapy.[236] In view of these data, and the UK QUick And Simple And Reliable (QUASAR) trial, it appears that unselected patients with stage II colon cancer (i.e., not distinguished between high-risk and low-risk stage II) will have a 3% benefit in 3-year DFS and overall survival with fluorouracil and LV as adjuvant chemotherapy.[237] It has to be kept in mind, though, that the quality of lymph node assessment in the QUASAR trial did not meet our current standards, with more than 60% of patients having less than 12 lymph nodes identified in resected specimens; so the inclusion of a certain percentage of stage III cancers in this analysis seems likely.[238] Current ASCO recommendations dating back to 2004 suggest that not all patients with stage II tumors should receive adjuvant chemotherapy, but that a discussion should be led with patients about their individual benefit/risk ratio when utilizing adjuvant chemotherapy in stage II colon cancer.[239] Efforts have been made to individualize the baseline prognosis and to predict the benefits of chemotherapy for patients with resected colon cancer.[240] As a result, two web-based tools are now available to provide data of this type (an adjuvant therapy calculator developed by the Mayo Clinic[241] and Adjuvant! Online[242]). These tools can provide helpful information for clinical decision-making.[243,244]

The identification of prognostic factors might help distinguish patients at high risk for relapse and identify high-risk stage II patients who may more likely benefit from adjuvant treatment. Apart from the clinical risk factors listed previously, molecular determinants of poor prognosis, such as microsatellite stability and *LOH18q,* are being evaluated in prospective clinical trials. Remarkably consistent results from retrospective analyses of large adjuvant trials and pooled data sets have confirmed that patients with stage II colon cancer and MSI-high tumors, which represent tumors of the deficient mismatch repair phenotype (MMR-D), have excellent prognosis and do not need to be treated with adjuvant chemotherapy.[223,238,245,246] Efforts are underway to develop a molecular profile of prognostic variables that could potentially guide adjuvant treatment decisions in stage II colon cancer.[238,247,248] These tests include gene expression signatures such as the Oncotype DX Colon[238] and ColoPrint,[248] as well as molecular detection assays of micrometastasis in morphologically unaffected lymph nodes.[247] At this time, none of these assays is routinely recommended for use in clinical practice as a decision tool for adjuvant therapy in stage II colon cancer.

The role of novel targeted agents with clear efficacy in advanced colorectal cancer, such as bevacizumab (an antibody against VEGF) and cetuximab (an antibody against EGFR) have been investigated in the adjuvant setting in ongoing large phase II trials. The first trial in a human malignancy to test bevacizumab in the adjuvant setting, NSABP C-08 randomly assigned 2710 patients with stage II (25%) and stage III (75%) colon cancer to receive modified FOLFOX6 every 2 weeks for 12 cycles, or mFOLFOX6 using the same schedule plus bevacizumab given every 2 weeks on day 1 for a total of 1 year, meaning bevacizumab was continued for 6 months beyond the planned completion of chemotherapy.[249] After a median follow-up of 35.6 months, 3-year DFS, the primary endpoint, was 77.4% for mFOLFOX6 alone and 75.5% in the bevacizumab arm. These results were not statistically significant (HR, 0.89; $p = 0.15$). A transient reduction in the rate of tumor recurrences was observed at 1 year, coinciding with the extended duration of bevacizumab in the experimental arm, but this effect was lost after discontinuation of the VEGF inhibitor. Almost identical observations were made in the international three-arm phase III AVANT trial, which included a capecitabine/oxaliplatin plus bevacizumab experimental arm.[250] At this time, bevacizumab plays no role in the adjuvant therapy of colon cancer outside of clinical trials.

The EGFR antibody cetuximab has also been tested as a component of adjuvant therapy in stage III colon cancer added to a modified FOLFOX 6 backbone.[251] Initially conceived as a phase III trial of FOLFOX with or without cetuximab in all patients with resected stage III colon cancer, the trial was eventually amended to enroll only patients with *KRAS* wild-type cancers.[252] Unfortunately, even in this preselected patient group, which has shown to benefit from EGFR antibodies in the palliative setting, cetuximab failed to improve outcome measures. Indeed, it even showed a trend toward a detrimental effect, particularly in patients with *KRAS*-mutated cancers.[249] A similar European adjuvant study with cetuximab (PETACC-8) confirmed the lack of efficacy of cetuximab in the adjuvant setting when added to FOLFOX in *KRAS* wild-type colon cancers, although this trial did not suggest a detrimental effect.[253] The body of evidence confirms that EGFR antibodies do not enhance the efficacy of FOLFOX in the adjuvant setting.

After completion of adjuvant therapy, lifestyle changes should be discussed with the patient, as there is growing evidence that certain interventions can improve outcomes in patients with resected early-stage colorectal cancer.[254] Increased exercise after diagnosis and avoidance of a Western pattern diet are associated with a reduced risk of cancer recurrence and improved overall survival. Patients with classes II and III obesity (BMI > 35) have a modestly increased risk of recurrence. Regular use of aspirin or cyclooxygenase-2 inhibitors decreases recurrence rates. Lower serum vitamin D levels have been associated with an increased risk of recurrence, but prospective studies are lacking to show that increasing vitamin D to normal levels can improve outcomes. In contrast, change of weight after diagnosis or smoking status (never, past, or current) are not associated with outcomes after diagnosis. The role of aspirin in this setting deserves particular attention. Data from a large population cohort study[255] and an analysis of a prospective trial[256] demonstrated a profound effect of aspirin as secondary prophylaxis in patients with resected colorectal cancer harboring *PIK3CA* mutations (exons 9 and 20). *PIK3CA* mutations are found in about 12% of colorectal cancers, and aspirin could emerge as a key component of postresection therapy in these patients. Randomized trials are underway to evaluate aspirin (in Asia and the United Kingdom) and celecoxib (in the United States and Canada) as adjunctive therapy with standard surgery and adjuvant therapy for early-stage colon cancer.

Advanced Colorectal Cancer (Stage IV)

The prognosis for patients with stage IV disease without specific therapy is poor, with a median survival of 5 to 6 months. However, a subset of patients with isolated sites of metastases is potentially curable with surgery (see “Limited Hepatic or Pulmonary Metastasis” section). Nevertheless, for the majority of patients with metastatic disease, the goal of therapy is palliation using systemic medical therapy. For decades, standard first-line therapy consisted of fluorouracil/LV, with response rates of approximately 20% and a median survival of approximately 1 year. In the late 1990s and early 2000s, the addition of oxaliplatin/irinotecan to the backbone of fluorouracil/LV resulted in an improvement in median survival to nearly 24 months when patients received active first-line and second-line therapy. The introduction of biologic agents, such as bevacizumab, cetuximab, and panitumumab, have further enhanced the efficacy of systemic medical therapy.[257] The emphasis of current advances in medical therapy is on the development of predictive biomarker signatures, which can help guide treatment decisions for specific patient subpopulations.

The availability of various active agents for the treatment of metastatic colorectal cancer has resulted in an abundance of therapeutic options that now demand a goal-oriented, strategic

approach to therapy in order to maximize patient benefit. When treating a patient with metastatic colon cancer, the first determination is whether stage IV disease is potentially curable by a surgical resection of metastases either at the time of diagnosis or after downsizing initially unresectable metastases by neoadjuvant chemotherapy.[257] This will guide the choice and timing of chemotherapy because, in this scenario, the most appropriate treatment is conceivably the one that generates the highest response rates and carries the greatest potential to downsize metastases. If the patient's disease does not appear curable, the main goals of systemic chemotherapy are to extend the duration of a patient's life and to maintain quality of life for as long as possible. In this scenario, treatment regimens that offer the longest PFS and overall survival, as well as a favorable toxicity profile, are preferred.

Fluorouracil. Until 2000, standard first-line therapy for metastatic colon cancer was the fluoropyrimidine analog fluorouracil plus LV as biomodulator and activator. LV forms a complex with fluorouracil that permits prolonged inhibition of the enzyme thymidylate synthase, a key factor in DNA synthesis. Response rates of fluorouracil/LV are in the range of 15 to 25%. Over time, fluorouracil has been given with LV in varying schedules and doses. The most commonly used regimens in the United States included the Mayo Clinic regimen (425 mg/m^2 of fluorouracil and 20 mg/m^2 for LV on days 1 to 5 every 4 to 5 weeks)[258] and the Roswell Park regimen (500 mg/m^2 of fluorouracil and 500 mg/m^2 of LV administered weekly for 6 out of 8 weeks).[259] Although these regimens used fluorouracil exclusively as bolus administration, European protocols preferred to use fluorouracil in the form of protracted infusions (e.g., for 2 days in the French biweekly LV5FU2 regimen or for 24 hours in the German weekly Arbeitsgemeinschaft Internistische Onkologie regimen).[260,261] The incorporation of the novel cytotoxic agents irinotecan and oxaliplatin into fluorouracil-based regimens has resulted in significantly improved efficacy. This has shifted the paradigm for front-line treatment from fluorouracil and LV alone to combination regimens incorporating these newer cytotoxic agents.

Capecitabine. Capecitabine is an oral fluoropyrimidine, a prodrug of fluorouracil, which is metabolized to its active form in three enzymatic steps. Its efficacy is similar to that of bolus fluorouracil and LV, with slightly higher response rates.[262] Common side effects of this drug include diarrhea and hand–foot syndrome. Capecitabine has been used as a backbone of combination regimens with both oxaliplatin and irinotecan, but overlapping toxicities (diarrhea) make a combination with irinotecan more difficult to tolerate than oxaliplatin. Other oral fluoropyrimidines, which have not been approved in the United States, include tegafur/uracil, S-1 (a prodrug of 5-FU), gimeracil (5-chloro-2,4-dihydropyridine), which inhibits dihydropyrimidine dehydrogenase enzyme activity, and oteracil (potassium oxonate). Although capecitabine has never been directly compared with infusional 5-FU/LV, oxaliplatin-based combination regimens with either capecitabine (CAPOX or XELOX) versus infusional 5-FU/LV (FOLFOX) have been shown to have similar efficacy in the treatment of advanced colorectal cancer.[263-265] It is notable, though, that patients in the United States do not tolerate the capecitabine doses used in European or Asian trials, presumably because of the higher nutritional folate intake in the United States.[266,267] Reducing the dose of capecitabine by about 20% in combination regimens with oxaliplatin, however, does not appear to decrease the treatment efficacy, but it greatly improves the side-effect profile of the treatment.[268]

Irinotecan. The first chemotherapy agent other than fluorouracil that improved survival for metastatic colon cancer—initially in second-line and later in first-line therapy—was irinotecan.[269-272] This compound has single-agent activity, which yields approximately a 15% response rate for patients with metastatic colon cancer refractory to fluorouracil.[269,271,272] In a

landmark clinical trial, patients with fluorouracil-refractory metastatic colon cancer were randomly selected to receive either best supportive care or single-agent irinotecan. The results of the trial demonstrated that irinotecan offers an approximate 3-month survival advantage as well as an improvement in quality of life.[269] A second trial in the same second-line patient population found irinotecan superior to infusional 5-FU.[271] Following this, three key trials were conducted to test the role of irinotecan in first-line treatment. In the United States, a three-arm trial was conducted to compare three treatment regimens: weekly bolus 5-FU/LV (Roswell Park regimen); weekly bolus 5-FU/LV plus irinotecan (IFL); and irinotecan alone.[272] The results of the trial revealed a survival advantage of longer than 2 months (14.8 months vs. 12.6 months, $p = 0.04$) and an almost doubling of the response rate (39% vs. 21%, $p < 0.001$) for patients receiving the three-drug regimen compared with those receiving the bolus 5-FU/LV regimen. This study established the three-drug regimen as the standard of care in the United States at that time.

In Europe, two phase III trials were conducted, in which fluorouracil was given as an infusion in combination with irinotecan, to form the FOLFIRI regimen. The results demonstrated a similar significant increase in response rate and time to disease progression for the three-drug regimen.[270-274] However, only the trial reported by Douillard et al.[270] demonstrated significant prolongation of overall survival (17.4 months vs. 14.1 months, $p = 0.031$), likely because of the limited availability of active second-line and third-line treatment options compared with the second European trial conducted later.[274] The main side effects of irinotecan are diarrhea, myelosuppression, and alopecia.

Oxaliplatin. Although oxaliplatin has very limited activity in colorectal cancer as a single agent (single-agent response rate, 24.1%[275]), it shows enhanced clinical efficacy in combination with fluoropyrimidines, in particular with infusional fluorouracil and LV. In three European phase III trials, combination protocols of infusional fluorouracil/LV/oxaliplatin (biweekly FOLFOX or weekly FUFOX) were compared with 5-FU/LV as first-line therapy for patients with advanced colorectal cancer.[276-278] In all three studies, a higher antitumor activity was noted for the combination regimens, with response rates of approximately 50% and PFS in the range of 8 to 9 months. However, this higher efficacy did not translate into a significantly improved overall survival, most likely because of the availability of active salvage therapies for both treatment arms, which blurred the effects of the first-line chemotherapy on overall survival in the trials. Of note, the median overall survival achieved with fluorouracil/LV/oxaliplatin was in the range of 17.5 to 20 months—the longest overall survival reported in phase III trials for advanced colorectal cancer at that time. Because no overall survival benefit was achieved in these first-line trials, in 2000 the FDA did not approve oxaliplatin for colorectal cancer. The FDA approval of oxaliplatin in combination with fluorouracil/LV in 2002 was based on the results of a second-line study that showed prolonged PFS and increased response rates compared with infusional fluorouracil/LV for patients who experienced disease progression while receiving IFL as first-line therapy.[279] It is notable that, in this trial, the arm with oxaliplatin as single agent, without 5-FU, did not show any relevant tumor activity, which highlights that oxaliplatin needs to be combined with another agent, preferably a fluoropyrimidine. The key side effect and dose-limiting toxicity of oxaliplatin is neurotoxicity, which comes in two distinct forms: an acute, cold-triggered sensory neuropathy, which is temporary, rapidly reversible, and does not appear to cause structural nerve damage; and a chronic cumulative sensory neurotoxicity, which is related to the cumulative dose of oxaliplatin administered over time and constitutes the dose-limiting side effect of oxaliplatin.[280] Preliminary data initially suggested that the infusion of calcium/magnesium salts before and after oxaliplatin can potentially reduce the incidence and

severity of chronic neurotoxicity,[281] but a larger, definitive trial unfortunately showed no neuroprotective effect of intravenous calcium/magnesium.[282]

Comparing Irinotecan- and Oxaliplatin-Based Regimens. With its FDA approval in 2000, the combination regimen IFL had emerged as standard first-line therapy for patients with advanced colorectal cancer in the United States. The encouraging results of trials conducted in Europe using oxaliplatin formed the rationale for the North Central Cancer Treatment Group (NCCTG)/Intergroup trial N9741.[283] This pivotal and practice-changing trial compared FOLFOX with the non–fluorouracil-containing combination of irinotecan/oxaliplatin (IROX), as well as with standard combination IFL. The results of N9741 clearly demonstrated the superiority of FOLFOX compared with IFL as first-line therapy for colorectal cancer with regard to response rate (45% vs. 31%, p = 0.002), PFS (8.7 months vs. 6.9 months, p = 0.0014), and overall survival (19.5 months vs. 15.0 months, p = 0.0001). The toxicity profile likewise favored FOLFOX compared with IFL, with only neurotoxicity being more prevalent for patients receiving the oxaliplatin-based combination. Results for IROX were in between the two other arms (response rate, 35%; PFS, 6.5 months; overall survival, 17.4 months), and, as such, FOLFOX emerged as new standard first-line therapy, with rapid and widespread adaptation in the United States. It should be emphasized that N9741 did not directly compare oxaliplatin and irinotecan; rather, it compared two different combination regimens with different fluorouracil and LV backbones. The higher efficacy and better tolerability observed with infusional fluorouracil and LV may have contributed to the differences in efficacy between IFL and FOLFOX. Two smaller trials comparing FOLFOX and FOLFIRI with the same fluorouracil and LV backbone failed to show significant differences in activity.[284,285] Although the small sample size of these trials might preclude wide-reaching conclusions, the choice between FOLFOX and FOLFIRI in the clinic should be based mainly on the expected side-effect pattern. Because the benefit of second-line therapy in colorectal cancer has been well established, patients should receive all active cytotoxic drugs in the course of their therapy in order to optimize outcome.[286] Combinations of 5-FU/LV/irinotecan/oxaliplatin (FOLFOXIRI) show high activity but also increased toxicity.[287] The use of this triplet combination should be reserved for specific situations, for instance, when substantial tumor shrinkage, as a prerequisite for a surgical approach toward borderline resectable liver metastases, is required.

Bevacizumab. Bevacizumab, a recombinant humanized monoclonal antibody to VEGF-A, has demonstrated clinical efficacy for the treatment of metastatic colorectal cancer. In a large phase III, placebo-controlled trial with 813 patients, irinotecan/bolus fluorouracil/LV (IFL protocol) was compared with IFL plus bevacizumab (5 mg/kg every 2 weeks) as first-line therapy for advanced colorectal cancer.[288] The addition of the anti-VEGF antibody led to a significantly increased response rate (45% vs. 35%, p = 0.0036), PFS (10.6 months vs. 6.2 months; HR, 0.54; p < 0.00001), and median overall survival (20.3 months vs. 15.6 months; HR, 0.66; p = 0.00004). This trial was the first phase III validation of an antiangiogenic agent as an effective treatment option in a human malignancy. Subsequently, bevacizumab also has been shown to enhance the efficacy of oxaliplatin-based regimens in first- and second-line treatments, as well as in combination with fluorouracil and LV alone or with irinotecan.[289-292] It is important to note that bevacizumab does not appear to have significant single-agent activity in metastatic colorectal cancer.[289] The main side effects observed with bevacizumab consist of hypertension (a class-effect of all agents targeting VEGF signaling), bleeding, gastrointestinal perforations (in 1.5 to 2% of patients), as well as arterial thrombotic events in approximately 4 to 5% of patients.[293] In addition to arterial thrombotic events, a meta-analysis identified a 33% higher incidence of venous thrombotic events in patients receiving bevacizumab compared with

the non-bevacizumab control arm in randomized trials,[294] although another, more recent analysis refuted this claim.[295] Based on its well-documented efficacy and relative moderate toxicity, bevacizumab has emerged as a standard component of first-line chemotherapy for advanced colorectal cancer.

Although most patients with metastatic colorectal cancer will tolerate and receive bevacizumab in the context of an irinotecan- or oxaliplatin-based combination regimen, it is unclear whether specific subgroups, in particular elderly patients, could benefit from a bevacizumab/fluoropyrimidine combination alone. This question was addressed in the pivotal and practice-informing AVEX phase III trial.[296] In this study, 280 patients age 70 or older (median age, 76), who were not deemed to be candidates for oxaliplatin- or irinotecan-based chemotherapy first-line regimens, were randomly selected to receive capecitabine (1000 mg/m^2 orally twice a day on days 1 to 14) alone or with bevacizumab (7.5 mg/kg intravenously on day 1), given every 3 weeks. PFS, the primary endpoint, was significantly longer with bevacizumab/capecitabine than with capecitabine alone (median, 9.1 months vs. 5.1 months; HR, 0.53; 95% CI; 0.41, 0.69; $p < 0.0001$). Although the study was underpowered to demonstrate a statistically significant improvement in overall survival, the median survival in the bevacizumab arm of 20.7 months (compared with 16.8 months for capecitabine alone) is remarkable given the age of the patient population and the limited postprogression therapies patients received. The combination of a fluoropyrimidine/bevacizumab can be considered as an acceptable standard of care for elderly patients who are not eligible for irinotecan or oxaliplatin but have no contraindication to receiving bevacizumab.

Initial reports suggested an over-additive activity when bevacizumab was combined with cetuximab in salvage therapy.[297] Subsequent larger, randomized first-line trials, however, suggested an antagonistic effect of the combination of EGFR antibodies with bevacizumab in the context of concurrent chemotherapy.[298,299] Thus, combinations of bevacizumab and EGFR antibodies should not be used in clinical practice outside of a clinical trial at this time.

It has been suggested that prolonged inhibition of the VEGF-mediated proangiogenic system is required to maximize treatment benefit for patients who are receiving anti-VEGF therapy, particularly since the mechanism and onset of secondary resistance could differ between chemotherapy and bevacizumab.[300] The efficacy of prolonged VEGF inhibition with bevacizumab added to chemotherapy was highlighted by several randomized trials. A prespecified analysis of a large phase III trial (NO16966) adding bevacizumab to an oxaliplatin-based first-line regimen demonstrated that improvements in PFS were much more profound in patients who received treatment until progression than in those who stopped therapy for other reasons.[297] Since the treatment-limiting toxicity of oxaliplatin-based first-line therapy is cumulative neurotoxicity, proactive strategies have to be employed to maximize treatment duration for patients who start palliative therapy with FOLFOX plus bevacizumab, the most commonly used first-line regimen in the United States. Therefore, induction-maintenance approaches with a limited number of oxaliplatin-containing treatment cycles up front and maintenance therapy with a fluoropyrimidine/bevacizumab combination can be considered a standard of care. This concept is supported by several prospective trials, most prominently by the recently presented Dutch CAIRO3 study.[301] In this trial, 558 patients who had achieved at least stable disease after an 18-week (six cycles) induction therapy of XELOX plus bevacizumab were randomly assigned to a complete chemotherapy-free interval or maintenance therapy with low-dose continuous capecitabine (625 mg/m^2 twice daily) plus bevacizumab (7.5 mg/kg every 3 weeks). All prospectively defined outcome parameters in this strategy trial were in favor of the maintenance therapy arm, even with a strong trend toward

improvement in overall survival. Toxicity associated with maintenance was mild and manageable. Thus, an induction-maintenance approach with a limited duration of oxaliplatin-based therapy and prolonged fluoropyrimidine/bevacizumab therapy may be considered an option to minimize toxicity in patients with advanced colorectal cancer.

Further evidence supporting the concept of prolonged VEGF inhibition as an optimized treatment approach in colorectal cancer comes from the so-called ML18147 (TML) phase III trial, which tested the efficacy of bevacizumab beyond progression (BBP) added to chemotherapy in metastatic colorectal cancer.[298] A total of 820 patients who had received first-line palliative therapy with a bevacizumab-based combination were randomly assigned at progression to either continue bevacizumab with another standard chemotherapy backbone or stop bevacizumab. The primary endpoint of the study, improvement in overall survival, was reached with an HR of 0.81 (95% CI; 0.69, 0.94) and a median improvement of 1.4 months (11.2 vs. 9.8 months, $p = 0.0062$). This effect was confirmed in all evaluated subgroups and supported by the results of PFS, which demonstrated superiority for the BBP arm (HR, 0.68; median 5.7 vs. 4.1 months, $p < 0.0001$). No increase in response rate was seen in the BBP group, and the response rates seen in both arms in second-line therapy were low, around 4 to 5%. No new or unexpected safety issues emerged for bevacizumab.

Ziv-aflibercept (VEGF-Trap) is a VEGF receptor decoy fusion protein that consists of extracellular-domain components of VEGFR1 and VEGFR2 fused with the Fc region of IgG1. VEGF-Trap binds to the VEGF-A, VEGF-B, and PGF (placental growth factor) ligands and prevents their interaction with VEGF receptors.[303] Aflibercept was tested in a second-line treatment trial among patients who had all failed oxaliplatin-based first-line chemotherapy.[304] About 1200 patients were randomly selected to receive FOLFIRI with aflibercept or placebo. The primary endpoint of improvement in overall survival was reached (13.5 vs. 12.1 months; HR, 0.82; $p = 0.0032$) and was mirrored by improvements in PFS (6.9 vs. 4.7 months; HR, 0.758; $p = 0.00007$) and response rate (19.8% vs. 11.1%, $p = 0.0001$). It is of note, though, that only 30% of patients in this trial had access to front-line bevacizumab, so the data are largely based on a VEGF inhibitor–naive population. The toxicity analysis demonstrated a surprisingly high rate of adverse events in the aflibercept arm, including side effects such as infections, asthenia, mucositis, and diarrhea not thought to be associated with a pure VEGF-inhibition mechanism. The FDA approved aflibercept in 2012 as a component of second-line therapy in combination with FOLFIRI.

Ramucirumab is a human monoclonal antibody directed against the VEGFR-2, the main mediator of VEGF-A signaling, located on the surface of endothelial cells. In a phase III, placebo-controlled trial of 1072 patients, the addition of ramucirumab to FOLFIRI as second-line therapy for patients pretreated with a fluoropyrimidine plus oxaliplatin and bevacizumab improved overall survival (median overall survival, 13.3 months vs. 11.7 months; HR, 0.8; 95% CI; 0.73, 0.98; $p = 0.022$) and PFS.[305] Observed adverse events fell within the range of expectations for a VEGF inhibitor, as discussed for bevacizumab. Ramucirumab, already approved for gastric cancer and non-small cell lung cancer, received FDA approval as a component of second-line therapy for advanced colorectal cancer in 2015. It is of note for clinical practice that single-agent use of the large-molecule VEGF inhibitors (bevacizumab, ziv-aflibercept, and ramucirumab) are not recommended in clinical practice.

Anti-EGFR Antibodies: Cetuximab and Panitumumab. Both monoclonal antibodies against the EGFR, cetuximab and panitumumab, have single-agent efficacy in advanced colorectal cancer. Two U.S. phase II trials confirmed the activity of cetuximab for the treatment of patients who had experienced disease progression on prior irinotecan-based therapy.[306] The single-agent

response rate of approximately 10% noted with cetuximab alone was in the same range as previously noted with FOLFOX in the same setting. A large international randomized, phase III trial comparing cetuximab with cetuximab/irinotecan confirmed the findings with almost identical results.[307] For patients who experienced progressive disease while receiving irinotecan-based therapy (with approximately two-thirds of their diseases also refractory to oxaliplatin), cetuximab monotherapy induced responses for approximately 11% of patients. When irinotecan was added, response rate and time to progression were significantly increased (HR, 0.54; 95% CI; 0.42, 0.71; $p < 0.001$). These data served as the basis for the initial approval of cetuximab as a treatment option for patients with metastatic colorectal cancer who were pretreated with irinotecan-based regimens. Single-agent panitumumab was tested against best supportive care in a large international phase III trial in an extensively pretreated population; crossover upon progression was optional.[308]

Panitumumab demonstrated similar single-agent activity to cetuximab, with an approximate 10% response rate when used as salvage therapy after failure of standard chemotherapy. In comparison with best supportive care, it significantly prolonged PFS (HR, 0.54; 95% CI; 0.44, 0.66; $p < 0.0001$). Overall survival was not increased, presumably because 75% of patients crossed over from best supportive care to the panitumumab arm. Based on these data, panitumumab was approved by the FDA as a single-agent salvage therapy option in the United States in 2006. A similar last-line trial comparing cetuximab with best supportive care (without crossover) showed almost identical results in terms of response rate and PFS but also with survival benefit for the cetuximab arm.[309] Both antibodies have been tested as components of first-line therapy in combination with modern chemotherapy regimens, such as FOLFOX and FOLFIRI, the results of which will be discussed further.[310-313] A phase III head-to-head comparison of both antibodies in salvage therapy for 999 patients recently confirmed the equivalent efficacy of both agents.[314] There are no data to support a switch from one EGFR antibody to the other in the case of tumor progression, but panitumumab can be considered for patients with allergic reactions to cetuximab.

The main toxic effects of anti-EGFR antibodies are skin rash, hypomagnesemia, diarrhea, and hypersensitivity reactions, which is particularly relevant for the chimeric antibody cetuximab.[293] Anaphylactic reactions to cetuximab have been correlated with the presence of preexisting serum immunoglobulin E antibodies to an oligosaccharide, galactose-alpha-1,3-galactose, which is present on the Fab portion of the cetuximab heavy chain.[315] These antibodies have been found in up to 21% of individuals from Tennessee who had never been exposed to cetuximab, compared with only 0.6% of individuals from the Boston metropolitan region.[315] The reason for these geographic differences are not known, but it is conceivable that environmental influences with exposure to sensitizing antigens play a role.

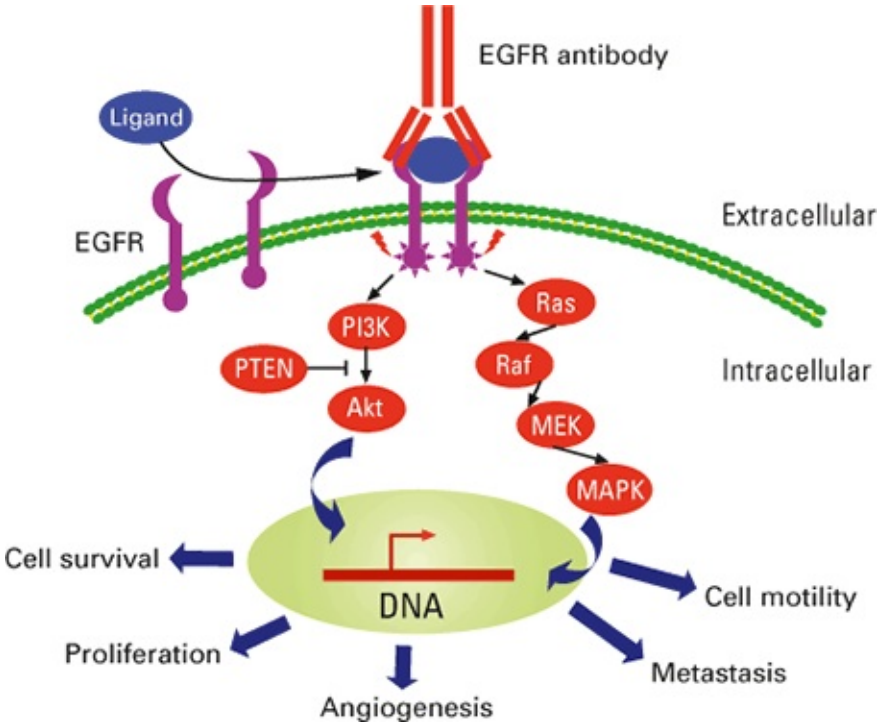

Fig. 10-4 EGFR-signaling pathway and predictive biomarkers for the efficacy of EGFR antibodies.

Data from various clinical trials and translational studies now have opened the door to individualized treatment approaches in colorectal cancer by identifying patients who are most likely to benefit from antibodies against EGFR, cetuximab, and panitumumab. It increasingly appears that patients with advanced colorectal cancer must have a tumor wild-type for both *KRAS* and *NRAS* for EGFR antibodies to be effective (Fig. 10-4).[311,313,316-321] *KRAS* is a phosphorylated signal transducer that self-inactivates via intrinsic guanosine triphosphatase (GTPase) activity.[322] It is a homolog of the transforming gene Kirsten rat sarcoma-2 virus. Several *KRAS* oncogene mutations—in colorectal cancer mainly in codons 12 and 13 (exon 2)—that result in the production of proteins with reduced guanosine triphosphatase (GTPase) activity have been identified. These *KRAS* mutations are among the most common oncogenic alterations in cancer. Four points are important to note with regard to *KRAS* mutations in colorectal cancer:

- *KRAS* mutations occur early in the adenoma–carcinoma sequence, leading to colorectal cancer and implying that the mutation can be found in all tumor cells derived from the initial malignant clone, in metastases as well as the primary tumor.[184,317]
- The determination of *KRAS* mutations is a yes/no binary decision; a tumor harbors either wild-type or mutated *KRAS.* No cutoff levels or subjective grades of expression levels have to be considered.
- The tests for *KRAS* mutation, whether mutation-specific polymerase chain reaction or next-generation gene sequencing is being used, are very robust, are high sensitivity and specificity, and can be obtained from formalin-fixed, paraffin-embedded tissue.
- The frequency of *KRAS* exon 2 mutations in colorectal cancer is about 40%.

In 2013, data emerged that beyond the currently routinely tested *KRAS* exon 2 mutations (codons 12 and 13), lower-frequency mutations in *KRAS* exons 3 and 4 and in *NRAS* also lead to resistance to EGFR monoclonal antibodies.[323,324] Thus, these mutations identify another 10 to 15% of patients beyond the 40% of patients identified with the conventional *KRAS* exon 2

mutations who have no benefit from cetuximab and panitumumab. In fact, results of the pivotal PRIME phase III trial in which patients were randomly assigned to first-line FOLFOX with or without panitumumab suggest that patients with tumors carrying these additional *RAS* mutations might actually experience a detrimental effect when treated with panitumumab.[323] A similar trend was observed for cetuximab added to FOLFIRI in the FIRE-3 trial, which will be discussed in detail in the following section.[324] NCCN guidelines now demand expanded *RAS* mutation testing before EGFR monoclonal antibodies are used for patients with colorectal cancer.

Further predictive biomarkers for the activity of EGFR antibodies in colorectal cancer have been identified in retrospective studies, in which the activity of cetuximab was correlated with the maintained expression of phosphatase and tensin (PTEN) homolog and higher levels of the EGFR ligands amphiregulin and epiregulin.[325-328] At this time, these biomarkers should not be used to exclude EGFR antibody therapy.

BRAF encodes a protein GTPase downstream of *RAS*. *BRAF* V600E mutations can be found in about 5 to 10% of patients with advanced colorectal cancer. They are mutually exclusive with *RAS* mutations[321] and have been consistently found to be associated with a very poor prognosis.[312,317,325] Even in the era of modern combination therapy, the median survival of patients with *BRAF*-mutated stage IV colorectal cancer is only 12 to 14 months.[312] More recent data, however, suggest that an aggressive first-line treatment approach using a triplet chemotherapy combination (FOLFOXIRI) plus bevacizumab might at least partially counteract the poor prognosis of patients with *BRAF*-mutated colorectal cancers.[330,331] More recently, in a random assignment phase II study including 106 patients, those with *BRAF* mutant colorectal cancer that had progressed on at least one line of therapy were randomly assigned to treatment with irinotecan/cetuximab with or without the *BRAF* V600E inhibitor vemurafenib.[328] Patients assigned to the three-drug regimen had significantly improved PFS, with median of 4.4 months versus 2.0 months with irinotecan and cetuximab alone (HR, 0.42; 95% CI; 0.26, 0.66; $p < 0.001$).[332] Thus, FOLFOXIRI/bevacizumab is recommended as first-line treatment for patients with *BRAF* mutations, and the combination of irinotecan/cetuximab/vemurafenib could emerge as the preferred second-line treatment option.

Whether activating *BRAF* mutations can be considered negative predictive markers for the activity of EGFR antibodies has long been unclear because of their strong negative prognostic effect and their low prevalence. Initial data suggested that cetuximab and panitumumab might still have some, albeit attenuated, activity in *BRAF*-mutated colorectal cancers.[312] A meta-analysis of nine phase III trials and one phase II trial, which all randomly assigned patients to treatment with or without an EGFR antibody, showed no benefit for the use of these antibodies with regard to PFS, overall survival, or response rate.[333] Thus, the use of EGFR antibodies for patients with tumors containing activating *BRAF* mutations should not be considered as first choice, if at all. Patients with *BRAF* mutations should preferably be enrolled in clinical trials using a rational combination of targeted agents with or without conventional chemotherapy. A subgroup of *BRAF* mutant colorectal cancer will be dMMR and, therefore, candidates for immunotherapy. Identification of this subset may be very important for patient care (discussed later).

With the proof of efficacy of two biologic therapeutic approaches in colorectal cancer—bevacizumab as VEGF-targeting agents and cetuximab/panitumumab as EGFR antibodies—it appears logical to try to further enhance the efficacy of therapy by combining the two approaches. Initial data for the combination of bevacizumab and cetuximab with or without irinotecan in salvage therapy were promising,[297] so that several subsequent clinical trials

investigated the combination of standard chemotherapy (FOLFOX, CAPOX, or FOLFIRI) plus bevacizumab with or without either cetuximab or panitumumab. The addition of an EGFR antibody to the bevacizumab-based combination therapy reduced PFS in the intention-to-treat populations, and not even the *KRAS* wild-type tumor population benefited from the intensified therapy.[298,299] In view of these findings, the combination of bevacizumab with EGFR antibodies should not be used outside of clinical trials.

Head-to-Head Comparison between EGFR Monoclonal Antibodies and Bevacizumab. Since EGFR antibodies and bevacizumab should not be combined in first-line therapy, a head-to-head comparison of these two biologic agents added to standard chemotherapy had been eagerly awaited. The FIRE-3 trial randomly selected 592 patients with conventionally assessed *KRAS* exon 2 wild-type colorectal cancer to receive FOLFIRI plus cetuximab or FOLFIRI plus bevacizumab.[334] The primary endpoint of the trial was investigator-assessed response rate, with an expected difference in the intention-to-treat analysis of 12%. The primary endpoint was not reached in the intention-to-treat analysis (cetuximab, 62%; bevacizumab, 58%; p = 0.18). In addition, no difference in PFS was noted (10.0 months vs. 10.3 months); in fact, the PFS curves were almost completely superimposable. Surprisingly, however, a statistically significant difference was found in overall survival, with a difference in median overall survival of 3.7 months (28.7 months vs. 25.0 months; HR, 0.77; p = 0.017) in favor of FOLFIRI/cetuximab. The survival curves appeared to split at 24 months—more than 12 months after the median PFS had been reached. An updated analysis, which accounted for additional mutations in *KRAS* exons 3 and 4 as well as *NRAS* mutations in exons 2, 3, and 4, demonstrated an even larger difference in median overall survival (33.1 months vs. 25.6 months; HR, 0.70; p = 0.011), again without a statistically significant difference in response rate and PFS.[324] As outlined above, for patients with tumors harboring the additional *KRAS* and *NRAS* mutations, cetuximab might have introduced a detrimental effect.

Data from the larger U.S. Intergroup study, CALGB/South-west Oncology Group (SWOG) 80405, were released in 2014.[335] This study compared chemotherapy (FOLFOX or FOLFIRI) with cetuximab with chemotherapy with bevacizumab as first-line therapy for 1137 patients with *KRAS* exon 2 wild-type metastatic colorectal cancer. In contrast to the FIRE-3 trial, no difference in overall survival was noted between the two treatment arms, not even when any *RAS*-mutated cancers were excluded. Both treatment arms showed long median overall survival —31.2 months for chemotherapy plus bevacizumab and 32.0 months for chemotherapy plus cetuximab (HR, 0.9; p = 0.40). Note that the outcome parameters of FIRE-3 and CALGB/SWOG 80405 were more alike than different, with the exception of the poor performance of the bevacizumab arm in FIRE-3. Table 10-9 details pertinent results of the two studies.

Table 10-9 **Comparison of Outcome Parameters of FIRE-3 and CALGB/SWOG 80405**

	FIRE 3 CT + Bev vs. CT + Cetux	CALGB/SWOG 80405 CT + Bev vs. CT + Cetux
Primary endpoint	Response rate	Overall survival
CT backbone	All FOLFIRI	FOLFOX 74%/FOLFIRI 26%
ITT (*KRAS* WT exon 2)	n = 295 vs. 297	n = 559 vs. 578
RR, %	58 vs. 62 (p = 0.183)	57.2 vs. 65.6 (p = 0.02)
PFS, months	10.3 vs. 10.0; HR, 1.06 (p = 0.547)	10.8 vs. 10.4; HR, 1.04 (p = 0.55)
Median OS, months	25.0 vs. 28.7 HR, 0.77 (p = 0.017)	29.0 vs. 29.9 HR, 0.92 (p = 0.34)
RAS WT	n = 201 vs. 199	n = 256 vs. 270
RR, %	58.7 vs. 65.3; OR, 1.33 (p = 0.18)	53.8 vs. 68.6; (p < 0.01)
PFS, months	10.2 vs. 10.3; HR, 0.97 (p = 0.77)	11.3 vs. 11.4; HR, 1.1 (p = 0.31)
OS, months	25.0 vs. 33.1 HR, 0.70 (p = 0.006)	31.2 vs. 32.0 HR, 0.9 (p = 0.40)

Abbreviations: Bev, bevacizumab; Cetux, cetuximab; CT, chemotherapy HR, hazard ratio; ITT, intention-to-treat; OR, odds ratio; OS, overall survival; PFS, progression-free survival; RR, recurrence rate; WT, wild-type.

Further analyses regarding duration of therapies and subsequent lines of treatment are underway to potentially discover reasons for the difference in overall survival outcomes, although an initial analysis of tumor location has been enlightening. Colon tumors present with substantial heterogeneity in molecular features, which is strongly associated with tumor location. Left-sided tumors often present with wild-type *BRAF* (*BRAF*-WT), *KRAS* point mutations (codons 12, 13, and 61; *KRAS*-mut), and extensive copy number alterations, as well as other structural genomic aberrations, including chromosomal instability and loss of heterozygosity (LOH). In contrast, right-sided tumors are enriched for *BRAF* V600E point mutations (*BRAF*-mut); are wild-type for *KRAS*; and have a diploid copy number, MSI, DNA hypermutation, and extensive DNA hypermethylation associated with CIMP. Based on these molecular differences, left- and right-sided colon tumors are now becoming increasingly recognized as two unique cancer types that may benefit from different therapeutic strategies. It appears that the difference in outcome between FIRE-3 and CALGB 80405 may have been the proportion of patients with left- and right-sided tumors in each study. Right-sided colorectal tumors are not sensitive to EGFR-antibody therapy,[336] and an imbalance of right- and left-sided

colon cancers likely explain the discordant results in these two studies.[337]

At this time, there does not appear to be a difference in outcome between first-line chemotherapy with bevacizumab or cetuximab, so the treatment approach can be adjusted based on patient and physician preference, goal of therapy, the side-effect profile associated with each regimen, and financial implications. Tumor sidedness (right or left), while intriguing, and potentially prognostic, has not yet been accepted as standard of care for choosing between a VEGF and EGFR antibody inhibitor.

Oral Agents in Salvage Therapy of Colorectal Cancer. Regorafenib, a small-molecule inhibitor of multiple cell-signaling kinases, has documented efficacy in salvage therapy in advanced colorectal cancer.[338] After preliminary data suggested a high disease control rate for patients with treatment-refractory colorectal cancer, regorafenib was investigated in a placebo-controlled, randomized, phase III trial in a salvage therapy setting. Efficacy results of the trial demonstrated a benefit in overall survival for patients receiving regorafenib compared with placebo (6.4 months vs. 5.0 months; HR, 0.77; $p = 0.0052$).[339] The activity of regorafenib was also reflected in an improvement of PFS (1.9 months vs. 1.7 months; HR, 0.49; $p < 0.000001$). The most common severe toxicities observed with regorafenib were hand–foot skin reaction, fatigue, diarrhea, and hypertension. Regorafenib is FDA-approved as a salvage therapy option in patients with advanced colorectal cancer who have previously been treated with a fluoropyrimidine, oxaliplatin, irinotecan, a VEGF inhibitor and, if *KRAS* wild-type, an EGFR monoclonal antibody

TAS-102 is a novel oral anticancer agent consisting of trifluorothymidine (FTD), as the antitumor component, and tipiracil hydrochloride, which prevents the degradation of FTD, at a molar ratio of 1:0.5. FTD, a thymidine analog, in its triphosphate form is incorporated and retained in the DNA of cancer cells.[340] This incorporation and its subsequent effects on DNA dysfunction appear to be the primary mechanism of sustained antitumor activity. Coadministration of tipiracil hydrochloride enables adequate and sustained serum levels of FTD, which would otherwise be immediately eliminated by thymidine phosphorylase in the human liver. After a randomized, phase II trial conducted in Japan showed promising activity of TAS-102 compared with best supportive care as salvage therapy for patients with metastatic colorectal cancer,[341] an international phase III study of 800 patients was launched in the same setting with a 2:1 randomization favoring TAS-102.[343] The primary endpoint of the trial was met, with an improvement of overall survival (median overall survival, 7.1 months vs. 5.3 months; HR, 0.68; 95% CI; 0.58, 0.81; $p < 0.001$). PFS was also improved, with an HR of 0.48. The most common grade 3/4 adverse event was neutropenia in about 40% of patients, with 4% having febrile neutropenia. TAS-102 received FDA approval in September 2015 for the treatment of patients with metastatic colorectal cancer who have previously been treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, an anti-VEGF biologic product, and an anti-EGFR monoclonal antibody, if *RAS* wild-type. This puts TAS-102 in the same clinical setting as regorafenib. It remains to be seen how these two agents will be sequenced in clinical practice. The two agents have distinctly different side-effect profiles (TAS-102: neutropenia; regorafenib: hand–foot skin reaction, fatigue) but very similar efficacy data.

An evidence–based treatment algorithm in the palliative management of colorectal cancer including biologic agents based on molecular testing for *RAS* and *BRAF* is outlined in Fig. 10-5. It highlights that in the salvage setting, regorafenib and TAS-102 can both be considered and could be sequenced in patients whose disease is considered appropriate for continued antitumor therapy.

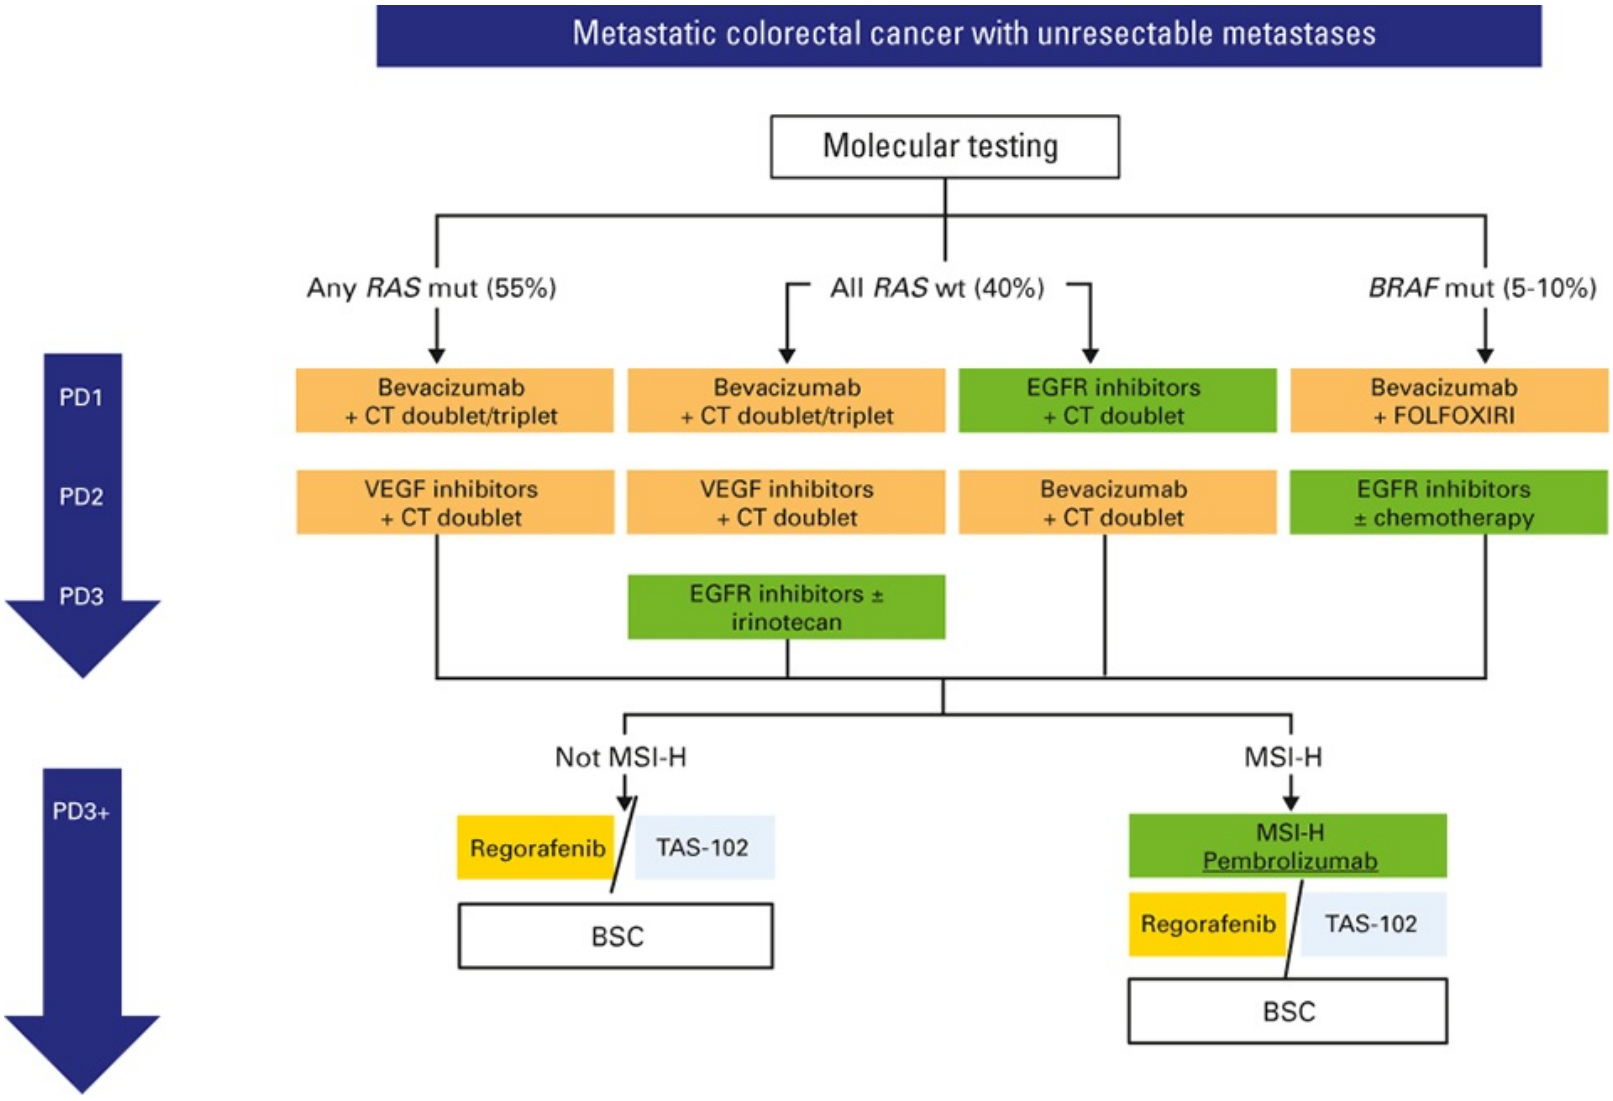

Fig. 10-5 Evidence-based treatment algorithm in the palliative management of colorectal cancer including biologic agents based on molecular testing for *RAS* and *BRAF*.

PD-1/PD-L1 Immune Checkpoint Inhibitors in Colorectal Cancer

Immune checkpoint inhibitors targeting the PD-1 pathway by binding to PD-1 or its ligand(s) (PD-L1/L2) have shown proof of efficacy in various malignancies since 2014, and several antibodies targeting this system have already received FDA approval in noncolorectal malignancies such as melanoma and non-small cell lung cancer.[343] PD-1/PD-L1 inhibitors allow the patient's immune system to recognize cancer cells by blocking immunosuppressive mechanisms generated by tumor cells, in particular, when these tumor cells carry a high DNA mutation burden with consecutive expression of a large number of neoantigens. It has long been known that MSI-H/dMMR colorectal cancers carry 10 to 100 times as many somatic mutations as MSS/pMMR tumors.[195] In addition, MSI-H/dMMR colon cancers are commonly characterized by dense lymphocytic infiltrates indicating a potential activation of the host's immune system.[344] Based on these observations, a pivotal pilot study was initiated that investigated the role of pembrolizumab, an antibody against PD-1, in heavily pretreated patients with advanced colorectal cancer with cohorts identified by their MSI status (MSI-H/dMMR vs. MSS/pMMR).[196] In addition, a cohort of MSI-H/dMMR noncolorectal cancer was included in the study. Single-agent pembrolizumab showed a remarkable activity only among patients with MSI-H/dMMR cancers independent of their histologic origin. In MSI-H/dMMR colorectal

cancers, patients experienced a more than 60% response rate and a more than 90% disease control rate with some experiencing durable response for more than a year. These findings have led to the initiation of several studies with PD-1/PD-L1 antibodies, which target the about 4 to 5% of patients with metastatic colorectal cancers characterized as MSI-H/dMMR. Furthermore, for the first time, the FDA granted approval of pembrolizumab for any dMMR solid tumor. For colorectal cancer, pembrolizumab is approved for MSI-H/dMMR tumors following prior treatment with a fluoropyrimidine, oxaliplatin, and irinotecan.

Limited Hepatic or Pulmonary Metastasis

For the subgroup of patients with recurrent metastatic colon cancer confined to the liver, the roles of hepatic-directed chemotherapy and hepatic resection have become better defined. There is only one multicenter evaluation of potentially resectable liver metastases; the results showed an improved survival for patients undergoing resection compared with those who either had unresectable disease or noncurative resection.[345] The survival advantage is clinically significant, with a near doubling of survival, to almost 37 months.[346] When pooling data for all patients who have a hepatic resection, the average 5-year survival rate is approximately 30%, with a less favorable prognosis for patients with multiple lesions, a short interval between the diagnosis of the primary tumor and recurrence, and the presence of stage III disease at the time of initial diagnosis.[347-349]

Preoperative chemotherapy can be used to downsize initially unresectable metastases to make them amenable for a surgical approach. It has been shown that the overall survival of patients who undergo successful neoadjuvant therapy with subsequent R0 resection of liver metastases approaches the survival of patients with initially resectable metastases.[346,347] Thus, the initial therapeutic approach for a patient with limited metastatic disease should always include consideration of a potentially curative option.

The role of chemotherapy in the potentially curative management of metastatic colorectal cancer can be classified in three different categories:

- **Neoadjuvant therapy**—For initially resectable metastases, mainly to obtain prognostic information, to treat potentially disseminated micrometastases as early as possible, and to test the chemosensitivity of the tumor;
- **Conversion therapy**—For initially unresectable or for borderline resectable metastases to allow for metastasectomy after tumor shrinkage; and
- **Adjuvant therapy**—After curative resection of metastases.

To date, no studies have been conducted to establish the value of neoadjuvant therapy (versus surgery alone or surgery plus postoperative therapy) for patients with resectable liver metastases. A European phase III trial in resectable, liver-limited metastatic colorectal cancer randomly assigned 364 patients to either proceed directly to surgery or to receive FOLFOX chemotherapy for 3 months followed by resection and then followed by 3 additional months of FOLFOX.[350] Patients meeting the eligibility criteria of the trial who received perioperative chemotherapy had a significant improvement in 3-year PFS compared with patients in the surgery-alone arm (36.2% vs. 28.1%; HR, 0.77; p = 0.041). The study was not able to determine whether all patients with resectable liver metastasis should receive neoadjuvant chemotherapy. Any beneficial effects of chemotherapy in this situation will have to be balanced against potential side effects of therapy and, in particular, against the observed higher surgical morbidity after neoadjuvant therapy.[350] After a median follow-up of 8.5 years, no difference in

overall survival was seen in this study; although it is important to realize that the trial was powered for PFS and not overall survival.[351]

The likelihood of conversion therapy to eventually lead to liver resection has been correlated with the overall response rate observed with a specific treatment regimen.[287,352]

The data on adjuvant therapy following resection of hepatic or pulmonary metastasis are limited. In one randomized clinical trial, half of the patients who had successful hepatic resection received both systemic and intrahepatic chemotherapy with floxuridine (FUDR); the other half received only systemic chemotherapy.[353] The results demonstrated a survival advantage at 2 years for patients who received the intrahepatic chemotherapy combination. This approach has not gained widespread use worldwide because of its difficult drug-delivery process and its associated hepatic toxicities and in view of the high activity of modern systemic combination chemotherapy. A pooled analysis of two small trials, with a combined 278 patients, that utilized adjuvant therapy after liver resection and a 5-FU/LV regimen demonstrated a strong trend toward improved outcome with systemic adjuvant chemotherapy in this setting (PFS, 27.9 months vs. 18.8 months; HR, 1.32; $p = 0.058$).[353]

The role of biologic agents (EGFR antibodies and VEGF inhibitors) in the context of pre- or perioperative therapy for potentially resectable liver metastases is unclear. Initial data suggest some benefit for the addition of cetuximab to chemotherapy (FOLFOX or FOLFIRI) in this setting,[354] but more recent results from a randomized trial conducted in the United Kingdom suggested an unexplained detrimental effect when cetuximab was added to chemotherapy in the perioperative setting.[355] No randomized trial exists that tests the role of bevacizumab in the context of liver resection. If bevacizumab is used in the preoperative setting, it needs to be discontinued about 6 weeks before planned surgery to reduce the risk of wound healing complications.[356]

It is important to note that there are substantial data to support disease resection outside of the liver, with the lung being the next most common site for secondary resection. In contrast, the role of aggressive surgical approaches toward peritoneal carcinomatosis, commonly conducted in the context of hyperthermic intraperitoneal chemotherapy, is controversial.[357]

KEY POINTS

- Screening for colorectal cancer, which can conceivably reduce the mortality of this disease, is underutilized. Screening endoscopy and FOBT/FIT testing have been shown to reduce colorectal cancer mortality long term.
- All individuals under age 70 should have their tumors evaluated for mismatch repair proteins or for MSI status. Patients younger than age 50 with colorectal cancer should be considered for formal genetic counseling.
- Adjuvant chemotherapy with an oxaliplatin-based regimen is the standard of care for stage III colon cancer; the role of adjuvant therapy in stage II colon cancer should involve shared decision-making given the marginal benefit in some subgroups.
- Patients with stage II colon cancer and MMR-D/MSI-H have an excellent prognosis and do not require adjuvant therapy.
- After completion of adjuvant therapy, lifestyle changes should be discussed with the patient, including diet, exercise, and use of anti-inflammatory agents.

- Patients with stage IV disease have a chance at cure if their metastases are amenable to complete surgical resection.
- Various conventional cytotoxic drugs (fluoropyrimidines, oxaliplatin, and irinotecan), as well as targeted agents (bevacizumab, aflibercept, regorafenib, as well as cetuximab and panitumumab in *RAS* wild-type cancers) have shown proof of efficacy for metastatic colorectal cancer.
- Expanded *RAS* mutation testing for mutations in *KRAS* and *NRAS* exons 2, 3, and 4 can be considered mandatory before the use of EGFR monoclonal antibodies.
- There is no single standard of care first-line regimen for the management of advanced colon cancer. The decision will involve molecular and histologic assessment of the tumor, goals of treatment, and shared decision-making based on anticipated toxicity.

NEOADJUVANT AND ADJUVANT THERAPY FOR RECTAL CANCER

Cancers arising in the rectum are associated with a higher overall risk of recurrence than that associated with similar stages of colon cancer. The reason for local recurrence in rectal cancer is believed to be the anatomic location of the rectum and the challenge this presents to the surgeon, particularly surgeons practicing in low-volume hospitals. However, pre- and postoperative therapy can help decrease differences in local recurrence rates between hospitals.[358] There is increasing evidence to suggest that local excision should be restricted to patients with T1 stage rectal cancer without high-risk factors.[359] For all other stages, total mesorectal excision (TME) has emerged as the preferred surgical technique. This technique honors natural tissue planes and decreases the chance for local seeding and for subsequent recurrence.[360] In combination with preoperative or postoperative chemoradiation, 5-year local recurrence rates of less than 10% can be achieved.[358,361-363]

The recognition of the significant morbidity and the potential mortality associated with local relapse led to the use of both preoperative and postoperative radiation therapy as additional regional treatment options designed to reduce local recurrence. Two different approaches have been used in this regard: short-term, high-dose radiation commonly delivered as 5 Gy daily for 5 days (5 × 5) immediately before surgery, or prolonged combined-modality therapy with radiosensitizing chemotherapy administered concurrently with radiation to a total dose of 50.4 Gy (45 + 5.4 Gy local boost) over 5 to 6 weeks, followed by a 3- to 4-week interval before curative surgery.[361,363,364] It is important to note that only the longer chemoradiation approach has repeatedly been demonstrated to be able to downstage tumors and cause tumor shrinkage, which might allow sphincter-preserving surgery. Both treatment approaches, however, have been associated with a decrease in local–regional failure. Prevention of local recurrence has not uniformly been associated with improved overall survival. However, the results of one Swedish trial, in which 1168 patients were randomly assigned to either 5 days of high-dose radiation therapy (to 25 Gy) in the week before surgery or to surgery alone, demonstrated a reduction in local recurrences (11% vs. 27%, $p < 0.001$) and a survival advantage at 5 years (58% vs. 48%, $p = 0.004$) for preoperative radiation therapy.[364] A subsequent Dutch trial, using the same radiation technique in combination with quality-controlled TME surgery, confirmed a low rate of local recurrence (at 2 years 2.4% vs. 8.4%, $p < 0.001$) but failed to demonstrate a survival benefit.[361] It is of note, however, that the local recurrence rate of tumors more than 10 cm from the anal verge was not significantly affected. Although the

shorter, high-dose preoperative radiation strategy is most commonly used in Scandinavia and other European countries, U.S. oncologists have historically preferred combined-modality therapy as preoperative or postoperative chemoradiation. Findings from two studies of postoperative adjuvant chemoradiation demonstrated that fluorouracil-based chemotherapy plus radiation was more effective than radiation or surgery alone in preventing both local and distant recurrence.[365,366] Results from another trial showed that prolonged infusion of fluorouracil was superior to bolus administration during radiation therapy, providing a 3-year DFS advantage.[367] This finding confirms that protracted delivery of chemosensitizing agents concomitantly with radiation is the best option for combined-modality therapy. In clinical practice, capecitabine administered twice daily parallel to radiation (common dose, 825 mg/m^2 twice daily on days of radiation) has become a widely used substitute for the continuous infusion of fluorouracil. Two phase III studies confirmed the noninferiority of capecitabine as a radiosensitizer compared with protracted infusion of 5-FU as neoadjuvant therapy in rectal cancer.[368,369]

The long-standing question about whether preoperative or postoperative chemoradiation results in improved outcomes was definitively answered by the results of a large German randomized trial that compared standard continuously infused fluorouracil plus radiation either before or after quality-controlled TME surgery.[363] Patients undergoing preoperative combined-modality therapy had a lower rate of local recurrence (6% vs. 13% at 5 years), a lower rate of acute and chronic toxicities, and a significantly higher rate of sphincter preservation compared with postoperative chemoradiation ($p = 0.006$). This trial established preoperative neoadjuvant radiochemotherapy with fluorouracil as a radiosensitizer as a new standard of care for stages II and III rectal cancers. Subsequent studies have tried to further improve the local control rate by incorporating additional radiosensitizing agents, such as oxaliplatin, and biologic agents into the preoperative treatment phase.[370-373] Data call into question the potential role of oxaliplatin as a radiosensitizer when added to fluoropyrimidines in the neoadjuvant radiochemotherapy of rectal cancer.[374-376] Consistent results from Italian, French, and U.S. phase III trials, found that the addition of oxaliplatin to fluoropyrimidine (5-FU or capecitabine) as a component of neoadjuvant radiochemotherapy did not increase the rate of pCR with the use of oxaliplatin, but it significantly increased toxic effects, mainly diarrhea. Only a German trial, which used a slightly different schedule of oxaliplatin administration, showed superiority of the oxaliplatin arm in terms of pathologic response.[377] However, the overwhelming body of evidence suggests that at this time, oxaliplatin should not be used as part of neoadjuvant radiochemotherapy for rectal cancer outside of clinical trials even if the results of long-term efficacy parameters, such as local recurrence rate, DFS, and overall survival, are still pending.

Two smaller phase III trials compared neoadjuvant chemoradiation therapy following the Sauer protocol to short-course radiation therapy (5 × 5 Gy) as neoadjuvant treatment for localized rectal cancer.[378,379] The two trials demonstrated that both treatment approaches are valid options in the preoperative setting of rectal cancer, with similar rates of local recurrence and overall survival.

The role of adjuvant therapy, particularly after neoadjuvant treatment, has been disputed by individual trials and by a meta-analysis of four studies.[380] The meta-analysis included subgroups of patients from trials, two of which were completed a decade ago. The trials utilized 5-FU-based adjuvant chemotherapies administered according to outdated regimens that are no longer considered standards of care, such as the Mayo Clinic regimen and its variations. Neoadjuvant therapy was heterogeneous and included chemoradiation therapy and radiation alone. The authors found no difference in distant relapse and overall survival associated with the use of adjuvant therapy. However, these results should not change the standard of care that

models the adjuvant approach in rectal cancer to strategies established in colon cancer. This concept has been validated by three randomized trials that used an adjuvant oxaliplatin-based treatment and that consistently found a DFS advantage mirroring the same findings in adjuvant colon cancer.[381-383] The design of these more current studies did not allow them to be included in meta-analyses. The similarity of treatment approaches between colon and rectal cancer is further supported by the results of the Cancer Genome Atlas project, which did not find major differences in the mutational and gene expression profile between rectal and colon cancers.[195] Thus, in agreement with current guidelines (NCCN, European Society for Medical Oncology), patients with rectal cancers should receive adjuvant therapy after resection, with the treatment intensity based on the initial clinical stage before neoadjuvant therapy.

Current studies seek to enhance the efficacy of preoperative therapy by adding biologic agents to a fluoropyrimidine backbone. In addition, studies are underway to compare systemic chemotherapy without radiation against standard chemoradiation for patients with cancers of the mid and upper rectum to spare them the short- and long-term toxicity of radiation therapy. Some studies have also examined the approach of increasing treatment, or even completing all treatment (e.g., total neoadjuvant treatment), prior to surgical resection. In this multicenter, randomized trial, 292 patients were randomly assigned to neoadjuvant fluorouracil-sensitized radiotherapy followed by zero, two, four, or six cycles of FOLFOX therapy prior to total mesorectal excision. Patients who received six cycles of FOLFOX therapy prior to surgery (e.g., total neoadjuvant therapy) experienced 38% pCR, significantly greater than the 18 to 25% pCR experienced with zero or twocycles of FOLFOX prior to resection ($p = 0.0036$).[384]

KEY POINTS

- Neoadjuvant chemoradiotherapy followed by total mesorectal excision is the standard treatment approach for stages II and III rectal cancer.
- Both a protracted course of radiotherapy (45 cGy in 25 fractions plus a 5.4-cGy boost) with chemosensitization or a short course of radiotherapy are acceptable neoadjuvant radiotherapy approaches.
- Capecitabine may be substituted for infusional 5-FU during a protracted course of radiotherapy.
- Adjuvant therapy (to a total course of approximately 4 months) is standard, based on the clinical stage prior to initiation of neoadjuvant chemoradiotherapy.

ANAL CANCERS

EPIDEMIOLOGY AND ETIOLOGY

Cancers of the anus are relatively uncommon in the United States; however, there is an increased incidence in certain populations, such as young men in whom genital viral infections have been implicated. The male-to-female ratio is approximately 2 to 3.5. The most clear causal relationship for anal cancer is infection with human papillomavirus (HPV) (mainly HPV-16). One large study found a strong positive correlation between the amount of sexual activity and the risk of anal cancer.[385] In addition, an association with venereal infection was noted in both men and women. Infection with HPV was presumed to be the etiologic cause. Although

earlier studies suggested that anal-receptive intercourse was directly linked to an increased risk of anal cancer, this finding has not been confirmed in more recent larger-scale trials. Cancers of the anal canal also have been associated with condylomata in both the general population and in gay men. In women with a history of genital warts, anal cancer was associated with seropositivity for herpes simplex virus type 1 and *Chlamydia trachomatis.* For men with no history of genital warts, there was an association with gonorrhea. The association between AIDS and anal cancer has been known for some time, but the exact etiologic relationship has not been elucidated. The incidence of anal cancer in patients infected with HIV is increased more than 40 times compared with the general population.[386] Further risk factors for anal cancers are smoking and chronic inflammation/fistulas in the context of inflammatory bowel disease.

The efficacy of a quadrivalent HPV vaccine (HPV-6, 11, 16, and 18) against anal intraepithelial neoplasia was prospectively investigated in a double-blind, randomized study of 602 healthy homosexual men, ages 16 to 26.[387] The rate of grade 2 or 3 anal intraepithelial neoplasia related to infection with HPV-6, 11, 16, or 18 was reduced by 54.2% (95% CI; 18.0, 75.3) in the intention-to-treat population and by 74.9% (95% CI; 8.8, 95.4) in the per-protocol efficacy population. These intriguing findings, which could lead to a decrease in the incidence of anal cancers through HPV vaccination, prompted the Advisory Committee on Immunization Practices to recommend, in October 2011, the routine use of the quadrivalent HPV vaccine in males ages 11 to 12.[388]

Most anal cancers are squamous cell cancers or cloacogenic cancers, with a few adenocarcinomas. In addition, melanoma accounts for a small percentage of cancers found in the anal canal. Tumors tend to spread by local extension but have the potential to metastasize. Involvement of the inguinal lymph nodes is found in as many as 63% of cases. The most important prognostic factors are the T stage (T1, < 2 cm; T2, 2–5 cm; T3, > 5 cm; T4, invasion into adjacent organs) and the lymph node status. In a pooled analysis of four randomized trials with a total of 644 patients, tumor diameter greater than 5 cm and lymph node involvement were associated with poorer 5-year DFS ($p < 0.0001$) and 5-year overall survival ($p = 0.0001$). In stratified analyses, lymph node involvement had more adverse influence on DFS and overall survival than did tumor diameter. Patients with greater than 5-cm tumor and lymph node metastases had the worst DFS (only 30% at 3 years compared with 74% for the best group; < 5 cm primary and N0) and overall survival (only 48% at 4 years compared with 81% for the best group; < 5 cm primary and N0). Men had worse DFS ($p = 0.02$) and overall survival ($p = 0.016$).[389]

TREATMENT

In the distant past, treatment for patients with anal cancers was surgical resection using an anterior–posterior approach. This treatment option was curative for only approximately 50% of patients and was associated with a high morbidity rate. Today, the standard approach to treatment of anal squamous cell cancers is combined-modality chemotherapy and radiation. Local excision is reserved for patients with small tumors that are well differentiated or are removed incidentally at the time of hemorrhoidectomy.

In initial chemoradiation trials, combinations of fluorouracil and mitomycin C with radiation yielded a high rate of response, including pCR.[386,390] Eventually, it was recognized that surgical resection was not necessary, and it is used today only as salvage therapy for patients with local recurrences following radiation. The expectation is that the CR rate with combined-

modality therapy will be between 70 and 80%, with an overall 5-year survival rate of more than 65%. However, a substantial number of patients will still experience either local relapse or metastatic disease. Treatment of disease in such patients is much more difficult. The addition of mitomycin C to fluorouracil as a radiation sensitizer improved colostomy-free and DFS compared with fluorouracil alone.[391] A phase III RTOG trial involving 682 patients with anal cancer, which compared the role of mitomycin C and fluorouracil with an intensified treatment approach consisting of induction chemotherapy with cisplatin/fluorouracil followed by cisplatin/fluorouracil during radiation therapy, did not show superiority of the experimental arm.[392] In fact, both the 5-year local–regional recurrence rate (25% vs. 33%) and the distant metastasis rates (15% vs. 19%) trended in favor of the mitomycin-based treatment. The cumulative rate of colostomy was significantly better for mitomycin-based than for cisplatin-based therapy (10% vs. 19%; p = 0.02). An updated analysis with long-term follow-up identified the standard mitomycin-based arm as significantly superior in overall survival.[393] Results of a more recent phase III comparison between fluorouracil combined with either mitomycin or cisplatin parallel to up-front radiation therapy did not find a significant difference in outcome,[394] so the inferior results of the RTOG trial for the cisplatin arm could be related to the delay in radiation because of its initial induction chemotherapy component.

Thus, in clinical practice, the well-established combined-modality approach using fluorouracil and mitomycin C plus radiation remains the standard of care. Cisplatin/fluorouracil can be used for patients with contraindications against mitomycin.

Intensity-modulated radiation therapy for anal cancer is currently being evaluated in an effort to reduce short- and long-term toxicity from radiotherapy.[395] Further trials are evaluating the role of cetuximab and bevacizumab as a component of multimodality therapy in local and also metastatic anal cancers. It is of note in this context that anal cancers have a very low rate of *KRAS* mutations.[396]

For patients in whom disease is present in the inguinal lymph nodes at the time of diagnosis or in whom disease develops in those nodes metachronously, additional radiation therapy or node dissection may be beneficial, although the latter is used less frequently. Salvage radiation therapy may result in a cure for up to 50% of patients who have an incomplete response to initial combined-modality therapy or for those who have a local relapse.[397] For patients who have metastatic disease, chemotherapy regimens used for other squamous cell cancers, such as fluorouracil, mitomycin C, cisplatin, paclitaxel, and others (e.g., EGFR antibodies) should be considered, but such treatment is palliative at best.

The treatment of anal cancer for patients with HIV is somewhat more complex. Standard aggressive combined-modality therapies should be used for patients with a CD4 count of more than 200×10^9 mm^3/L who have no signs or symptoms of other HIV-related diseases. For patients with more severe HIV-related problems, reduced doses of radiation, chemotherapy, or both should be considered to maintain local disease control.[398]

KEY POINTS

- Anal cancers are often cured by chemoradiotherapy.
- A quadrivalent HPV vaccine has shown to reduce the incidence of anal intraepithelial neoplasia.
- Mitomycin C plus fluorouracil with radiation remains the standard approach for localized

anal squamous cell cancers.

- At this time there is no role for induction chemotherapy which has not demonstrated benefit and may be associated with worse patient outcomes.

PANCREATIC ENDOCRINE TUMORS AND NEUROENDOCRINE TUMORS, INCLUDING CARCINOIDS

Pancreatic endocrine tumors are a group of uncommon neoplasms that histologically share several key cytochemical features with melanoma, pheochromocytoma, carcinoid tumors, and medullary thyroid cancers. All amine precursor uptake and decarboxylation neoplasms have the capacity to synthesize and secrete polypeptide products that have specific endocrine hormone activity. Most behave in a malignant fashion. The types of tumors are characterized by the hormones they secrete, including gastrinomas, insulinomas, vasoactive intestinal peptide tumors, glucagonomas, somatostatinomas, growth hormone–releasing factor tumors, and adrenocorticotropic hormone tumors. Pancreatic endocrine tumors and carcinoids are considered either functional (if associated with a clinical syndrome because of the production of hormones) or nonfunctional (if hormones are not a substantial element of the presentation). Thus, it is important to note that the absence of detectable hormone production does not rule out the presence of a neuroendocrine tumor. The nomenclature and classification of neuroendocrine tumors are summarized in Table 10-10.[399]

PANCREATIC NEUROENDOCRINE TUMORS

The diverse clinical presentation of pancreatic neuroendocrine (or islet cell) tumors and their frequently silent and relatively benign pathologic presence makes it difficult to accurately determine their true incidence. Many pancreatic neuroendocrine tumors remain asymptomatic and undiagnosed. Most of these tumors appear in sporadic cases without substantial personal or family history. However, certain patient groups have clear evidence of an inherited predisposition to multiple neoplasias of the endocrine system that is manifested in an autosomal-dominant fashion with mutations in the tumor suppressor gene *MEN1* that encodes the protein menin.[400] The syndrome first described (MEN1, Wermer syndrome) is characterized by the presence of tumors of the pituitary gland and parathyroid gland, as well as neuroendocrine tumors of the pancreas.[401] Multiple endocrine neoplasia type 2, associated with mutations in the *RET* gene, typically does not involve pancreatic neuroendocrine tumors; rather, it expresses tumors of the parathyroid, pheochromocytoma, and medullary thyroid cancer.[402] Table 10-11 lists common clinical, hormone-related symptoms associated with functional pancreatic neuroendocrine tumors.

CARCINOID TUMORS

About two-thirds of carcinoid tumors arise within the gastrointestinal system, with the appendix being the most common primary location.[403] However, carcinoid tumors may arise throughout the body, including in the chest. Carcinoid tumors are members of the neuroendocrine tumor family and share cytochemical features with melanomas, pheochromocytomas, medullary thyroid cancers, and pancreatic endocrine tumors. Some undifferentiated, and often nonfunctional, neuroendocrine tumors are characterized by a high mitotic rate (e.g., > 20/10 high-power fields [HPF]) and a high Ki-67 index (e.g., >20%). These high-grade tumors behave

like small cell cancers, have a much more aggressive clinical behavior than common carcinoids, and share characteristics with small cell lung cancers, including their chemo- and radiosensitivity.[404] The determination of cancer can be made only if invasion or distant metastasis is found. The disease is most commonly diagnosed during routine appendectomy. Carcinoid tumors synthesize bioactive amine and peptides, including neuron-specific enolase, 5-hydroxytryptamine, synaptophysin, chromogranin A, and other peptides such as insulin, growth hormone, neurotensin, corticotropin, gastrin, pancreatic polypeptide, and calcitonin. More than 80% of patients with resectable primary tumors are disease-free at 20 years, with similar overall survival rates for an age- and sex-matched cohort. Of those tumors with regional node metastasis, as many as 50% will recur more than 10 years after diagnosis. Typically, the prognosis for patients with resectable carcinoid tumors is favorable.[405] It is important to recognize the long disease-free interval that can occur, which requires patients to have a longer period of follow-up than patients with other tumor types. It is also important to note that appendectomy is inadequate if the carcinoid tumor is larger than 2 cm and/or if lymphovascular invasion or involvement of the mesoappendix is present. In these cases, right hemicolectomy is indicated as definitive oncologic surgery.[406]

Table 10-10 Nomenclature and Classification of Neuroendocrine Tumors

Differentiation and Grade	Mitotic Count (per 10 HPF)	Ki-67 Index (%)*	Traditional Classification	ENETS/WHO Classification
Well differentiated				
Low grade (grade 1)	< 2	< 2	Carcinoid, islet cell, pancreatic (neuro) endocrine tumor	Neuroendocrine tumor, grade 1
Intermediate grade (grade 2)	2–20	3–20	Carcinoid, atypical carcinoid,† islet cell, pancreatic (neuro) endocrine tumor	Neuroendocrine tumor, grade 2
Poorly differentiated				
High grade (grade 3)	> 20	> 20	Small-cell carcinoma	Neuroendocrine carcinoma, grade 3 small cell
			Large-cell neuroendocrine carcinoma	Neuroendocrine carcinoma, grade 3 large cell

Abbreviations: ENETS, European Neuroendocrine Tumor Society; HPF, high-power field (×40 magnification); WHO, World Health Organization.
*MIB1 antibody
†The term *atypical carcinoid* applies only to intermediate-grade neuroendocrine tumors of the lung.

Table 10-11 **Clinical Features of the Most Common Functional Pancreatic Neuroendocrine Tumors**

Tumor Type	Secreted Hormone	Clinical Symptoms	Comments
Gastrinoma	Gastrin	Peptic ulcers	Zollinger-Ellison syndrome (ZES)
		Diarrhea	
Insulinoma	Insulin, proinsulin, peptide C	Hypoglycemia	
Glucagonoma	Glucagon	Rash	
		Mucositis	
		Venous thrombosis	
		Hyperglycemia	
VIPoma	Vasoactive intestinal peptide (VIP)	Watery diarrhea	Watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome
		Dehydration	
		Hypokalemia	
		Achlorhydria	
Somatostatinoma	Somatostatin	Hyperglycemia	
		Achlorhydria	
		Cholelithiasis	
		Diarrhea	

Carcinoid Syndrome

As with pancreatic neuroendocrine tumors, carcinoid tumors can manifest with signs and symptoms of abnormal hormone production—namely, the malignant carcinoid syndrome. Flushing is the most common sign, followed by diarrhea, heart disease (valvular abnormalities), and bronchoconstriction. Diarrhea is not necessarily related to the flushing but appears to be caused by increased gastrointestinal motility as a direct consequence of hormone secretion. For intestinal carcinoids, the characteristic carcinoid syndrome appears only when liver metastases have been established and the biogenic amines can bypass the hepatic metabolic activity. When carcinoid syndrome is suspected, serologic testing should be done to measure 24-hour urine levels of 5-hydroxyindoleacetic acid (5-HIAA), serum serotonin levels, and/or serum chromogranin A. The cardiac disease associated with this condition typically involves abnormalities of the valves on the right side of the heart. Therefore, an echocardiogram is an important element in the evaluation of patients with prolonged disease courses. Novel imaging techniques, including octreotide scanning—a nuclear medicine test specifically designed for the detection of carcinoid tumors—have become more common. Individuals with positive findings on an octreotide scan are more likely to benefit from therapy with octreotide. The most common imaging techniques are CT and MRI, with the latter showing the greatest sensitivity for detection of intrahepatic metastases. PET scans commonly are ineffective because of the low proliferative and metabolic activity of differentiated carcinoids. Selective sampling of blood through venous catheterization sometimes can be helpful, but this technique is rarely used.

TREATMENT OF PANCREATIC NEUROENDOCRINE TUMORS AND CARCINOID TUMORS

Surgery is the main treatment for these tumors. Most tumors are easily resectable or are found

incidentally during surgery for other indications. Even when lymph nodes are involved, patients may live for long periods of time without apparent recurrence, but long-term follow-up typically shows continuing disease relapse over many years. In contrast to the situation for other tumor types, cytoreductive surgery (debulking) for palliative purposes (decreasing the amount of hormone-producing tissue) should be considered for these tumors. Such surgery includes hepatic resection or resection of other intra-abdominal and thoracic metastases. Surgical palliation of bowel obstruction from tumor masses or mesenteric fibrosis associated with carcinoid tumors may substantially improve quality of life. Hepatic surgery for liver metastasis may allow patients to remain disease-free for prolonged periods and may reduce hormone production.

Liver-directed therapy, such as (chemo)embolization, high-frequency radioablation, or surgical resection, commonly is used for these tumor types.[405] These techniques are particularly useful for reducing symptoms caused by local growth of the tumor or by hormone production and should be regarded as nonsurgical debulking. These procedures also are associated with a greater likelihood of prolonged tumor regression.

Octreotide and its analogs have been used for some time to control the secretion of 5-HIAA and other peptides.[407,408] More recently, the analogs have been assessed for their antitumor activity, despite their poor tumoricidal effect resulting in few regressions. There is substantial evidence from small phase II clinical studies that these agents have cytostatic effects and may prolong survival.[408] In a prospective, placebo-controlled, randomized trial of 85 patients with midgut neuroendocrine tumors (classic carcinoids) the PROMID study, the use of long-acting octreotide (30 mg IM monthly) was associated with significant delay in tumor progression and a trend toward improvement in overall survival.[409] Patients with carcinoid syndrome symptoms refractory to standard therapy with somatostatin analogs may benefit from telotristat etiprate, which targets an enzyme involved in excess serotonin production, tryptophan hydroxylase. In a phase III trial, patients with carcinoid syndrome uncontrolled on somatostatin analogs experienced a 35% reduction in the number of bowel movements with telotristat etiprate compared with placebo (17%; $p < 0.001$).[410] Patients in the telotristat etiprate arm also had a lower frequency of flushing episodes and less intense abdominal pain compared with placebo, although these differences were not statistically significant.

Another biologic agent that may have clinical benefit is interferon-alfa, which has been shown to decrease the tumor size for a few patients with metastatic disease. Similar to octreotide, interferon appears to have a tumoristatic effect rather than a tumoricidal one. Interferon has been investigated in combination with octreotide for patients with advanced carcinoid.[411] The addition of interferon did not improve PFS over octreotide alone. Given the apparent lack of substantial activity over octreotide, the role of interferon for the treatment of differentiated carcinoid tumors is still under debate.

An alternative long-acting somatostatin analog, lanreotide, was evaluated in advanced neuroendocrine tumors in the CLARINET trial.[412] In contrast to the aforementioned PROMID study, which included mainly patients with low-grade, midgut neuroendocrine tumors, CLARINET enrolled patients with neuroendocrine tumors from the pancreas, midgut, or hindgut or of an unknown origin that were well or moderately differentiated and had a Ki-67 index of less than 10%. A total of 204 patients were randomly assigned to lanreotide or placebo. PFS was not reached in the lanreotide arm compared with a PFS of 18 months in the placebo arm (HR, 0.47; 95% CI; 0.30, 0.73; $p < 0.001$). The 2-year PFS rates were 65.1% and 33.0% for the lanreotide and placebo arms, respectively. Overall survival was not different between the arms, likely because crossover was allowed on the study as well as potential differences in

subsequent treatments. Lanreotide was approved by the FDA in December 2014. Lanreotide's role in the management of advanced neuroendocrine tumors, in which another long-acting somatostatin analog (octreotide) is well established is uncertain, but given its broader indication, lanreotide may play a more of a role in the management of pancreatic neuroendocrine tumors (PNETs) and low-grade hindgut neuroendocrine tumors.

^{177}Lu-DOTA^{0}-Tyr^{3}-octreotate is a peptide receptor radionuclide therapy that has been available in Europe since 2000. This therapy was tested in the randomized, phase III trial NETTER-1, which randomly assigned patients with progressive, somatostatin receptor-positive midgut neuroendocrine tumors to receive four doses of ^{177}Lu-DOTA^{0}-Tyr^{3}-octreotate over 8 weeks along with 30 mg of octreotide every 28 days compared with octreotide alone 60 mg every 28 days.[413] The median PFS was not reached in the ^{177}Lu-DOTA^{0}-Tyr^{3}-octreotate plus octreotide arms and was 8.4 months in the octreotide arm (HR, 0.21; 95% CI; 0.13, 0.34; $p < 0.0001$). The promising results of the NETTER-1 trial will likely lead to an additional treatment option for patients with carcinoid tumors.

Traditional chemotherapy has been tested extensively for the treatment of patients with carcinoid cancers. Agents commonly used include fluorouracil and its oral analog capecitabine, streptozocin, and anthracyclines, such as doxorubicin and liposomal doxorubicin. Unfortunately, response rates for chemotherapeutic agents in combination regimens have been poor (typically < 20%). Therefore, for most patients, the use of systemic chemotherapy is either reserved for end-of-life care or should not be considered at all. It is important to recognize that the slow-growing nature of carcinoid tumors may allow patients to be followed for a long period of time without any considerable intervention. Patients should be monitored closely to determine whether the disease is slow-growing. If so, simple observation often is sufficient.

The outcome with systemic chemotherapy may be better for patients with noncarcinoid pancreas neuroendocrine tumors. One trial, in which streptozocin plus doxorubicin was compared with streptozocin plus fluorouracil, demonstrated that the doxorubicin-containing regimen was superior (response rate, 69% vs. 45%; $p = 0.05$; and overall survival, 2.2 years vs. 1.4 years; $p = 0.004$).[414] Several retrospective trials have evaluated the combination of capecitabine and temozolomide in advanced PNETs with encouraging results.[415] The observed overall response rate was 55% and the observed median PFS was more than 14 months. Thus, there is evidence that a combination temozolomide/capecitabine regimen has activity in this patient population.

For patients who have poorly differentiated gut neuroendocrine tumors, the selection of chemotherapy is similar to that for small cell lung cancer, with the most consistent regression observed using combination etoposide and cisplatin. This distinction is important and emphasizes the need for pathologic evaluation to distinguish between the small cell variant and the more slow-growing pancreatic neuroendocrine/carcinoid tumors.

Novel biologics—including VEGF inhibitors such as sunitinib and signal transduction inhibitors such as mammalian target of rapamycin (mTOR) inhibitors—have shown efficacy in PNETs.[416] Data from a placebo-controlled phase III trial with sunitinib (37.5 mg/day) versus best supportive care for 169 patients with advanced pancreatic neuroendocrine cancer, all of which had progressed in the past 12 months, have been released.[416] PFS increased from 5.5 months with placebo to 11.4 months in the sunitinib group (HR, 0.42; 95% CI; 0.26, 0.66; $p < 0.001$). Data on overall survival were not mature at the time of presentation, but a reduced death rate was noted in the sunitinib arm at the time of data cutoff (10% vs. 25%, $p = 0.02$). The most commonly reported grade 3/4 adverse events in the sunitinib group were neutropenia (12%),

hypertension (9%), abdominal pain (7%), diarrhea (97%), hypoglycemia (7%), and hand–foot syndrome (7%). In a parallel, placebo-controlled, phase III trial of 410 patients with advanced low- to intermediate-grade pancreatic neuroendocrine tumors, the mTOR inhibitor everolimus (10 mg daily) likewise improved median PFS from 4.6 months to 11.0 months (HR, 0.35; 95% CI; 0.27, 0.45; $p < 0.001$).[417] Overall survival data have been presented and they show a median overall survival of 44.0 months in the everolimus arm and 37.7 months in the placebo arm (HR, 0.94; 95% CI; 0.73, 1.20; $p = 0.300$).[418] Although the 6.3-month difference was clinically significant, it did not reach statistical significance, most likely because of the high (85%) crossover rate in the trial. Most common side effects of everolimus were (all grades) stomatitis (64%), rash (49%), diarrhea (34%), fatigue (31%), and infections (23%). Based on these positive trial results, in 2011 sunitinib and everolimus gained FDA approval for the treatment of pancreatic neuroendocrine tumors.

Although these positive results established a new medical standard of care in PNETs, the same treatment appears to be less effective in carcinoids. Everolimus added to octreotide initially demonstrated only modest activity for patients with carcinoids with only a borderline statistically significant improvement in PFS.[419] The RADIANT-4 study was a randomized, phase III trial of everolimus versus placebo for patients with advanced, progressive, well-differentiated, nonfunctional lung and gastrointestinal neuroendocrine tumors.[420] Patients in the everolimus arm had a median PFS of 11.0 months compared with 3.9 months with placebo ($p < 0.001$). There were very few partial responses (2% and 1% for everolimus and placebo, respectively). An interim analysis did show a trend for overall survival benefit with everolimus (HR, 0.64; 95% CI; 0.40, 1.05; $p = 0.037$). This study demonstrated that the activity of everolimus extends to well-differentiated neuroendocrine tumors regardless of origin.

A phase II study of everolimus plus bevacizumab versus everolimus alone for metastatic PNETs showed an improved response rate (31% vs. 12%; $p = 0.005$) but no significant difference in PFS or overall survival.[421]

In summary, though, these results can be regarded as proof of principle for the role of multitargeted kinase inhibitors in neuroendocrine cancers. Ongoing studies are currently investigating the activity of combinations of targeted agents (e.g., VEGF plus mTOR inhibition) in neuroendocrine malignancies.[215]

KEY POINTS

- Pancreatic neuroendocrine tumors are a heterogeneous group of rare tumors that have a variable course of illness depending on the histologic grade, mitosis rate, and Ki-67 index.
- Surgery is the primary treatment for tumors amenable to resection, and there is a role for cytoreductive surgery as well.
- Octreotide and its analogues (e.g., lanreotide) are standard options for most well or moderately differentiated neuroendocrine cancers with a low Ki-67 index.
- Everolimus and sunitinib are standard of care options in pancreatic neuroendocrine tumors following progression on hormonal therapy.

GENITOURINARY CANCERS

Matthew I. Milowsky, MD

Recent Updates

Bladder Cancer

- Checkpoint inhibitors including anti-PD-1 and anti-PD-L1 antibodies have changed the landscape for the management of patients with locally advanced or metastatic urothelial cancer with an improvement in survival for patients who have progressed after platinum-based chemotherapy and promising activity in those unfit for cisplatin in the first-line setting. (Rosenberg JE, *Lancet* 2016; Massard C, *J Clin Oncol* 2016; Balar AV, *Lancet* 2017; Sharma P, *Lancet Oncol* 2017; Bellmunt J, *N Engl J Med* 2017; Apolo AB, *J Clin Oncol* 2017; Balar AV, *Lancet Oncol* 2017)

Renal Cancer

- Cabozantinib, an oral small molecule inhibitor of VEGFRs, MET, and AXL, improves survival as compared to everolimus in patients with metastatic clear cell renal cell carcinoma (RCC) who have received prior antiangiogenic therapy and improves progression-free survival (PFS) as initial targeted therapy compared to sunitinib in patients with intermediate/poor risk disease. (Choueiri TK, *Lancet Oncol* 2016; Choueiri TK, *J Clin Oncol* 2017)
- In treatment-naïve patients with advanced or metastatic clear cell RCC, the combination of nivolumab plus ipilimumab demonstrated an improvement in overall response rate (ORR), PFS, and overall survival (OS) as compared to sunitinib in patients with intermediate/poor risk disease. (Escudier B, ESMO, 2017)
- The S-TRAC trial of adjuvant sunitinib compared with placebo in patients with high-risk RCC after nephrectomy demonstrated a diesase-free survival (DFS) benefit for sunitinib; however, in another adjuvant trial, ASSURE, no significant differences in DFS or OS were seen with either sunitinib or sorafenib, and in both studies sunitinib-related toxicity was significant. (Ravaud A, *N Engl J Med* 2016; Haas NB, *Lancet* 2016)

Prostate Cancer

- There is a high frequency of DNA damage repair germline mutations in men with metastatic prostate cancer. DNA repair gene mutations are associated with responses to PARP inhibitors in men with metastatic prostate cancer. (Pritchard CC, *N Engl J Med* 2016; Mateo J, *N Engl J Med* 2015)
- Two prospective randomized clinical trials, LATITUDE and STAMPEDE, have shown an OS benefit for the addition of abiraterone (with prednisone or prednisolone) to androgen deprivation therapy in men with noncastrate metastatic prostate cancer. (Fizazi K, *N Engl J Med* 2017; James ND, *N Engl J Med* 2017)

OVERVIEW

Genitourinary cancers accounted for 20% of new cancer cases and 10% of cancer-related deaths, with an estimated 335,000 cases and 58,000 deaths in the United States for the year 2016.[1] Aside from arising in genitourinary organs and requiring a multidisciplinary approach to management, each cancer type is unique with respect to its biology, natural history, and treatment options. The medical oncologist must understand the following: the use of a risk-

adapted approach including surveillance, surgery, radiation therapy, and chemotherapy in patients with germ cell tumors; the integration of chemotherapy and immunotherapy in the treatment of muscle-invasive and metastatic urothelial cancer; the use of targeted therapy and immunotherapy in advanced kidney cancer; and the role for androgen-deprivation therapy, chemotherapy, immunotherapy, radiopharmaceuticals, and antiresorptive bone therapies in the treatment of localized and advanced prostate cancer. The medical oncologist also has a key role in survivorship issues that accompany each disease. Although recent advances have led to novel treatment options that are associated with an improvement in outcome, a cure remains elusive for the majority of patients with advanced genitourinary cancers, and continued research is needed.

GERM CELL TUMORS

Germ cell tumors are the most common malignancies among men between ages 15 and 35. It is estimated that 8720 cases and 380 deaths occurred in the United States in 2016.[1] Germ cell tumors most frequently originate in the gonads (testis or ovary) and less commonly in the retroperitoneum and mediastinum. (For a discussion of germ cell tumors in women, see Chapter 12: Gynecologic Cancers.) Retroperitoneal tumors are often associated with an invasive tumor or carcinoma in situ within the testis, even in the absence of a palpable testicular mass. Primary mediastinal germ cell tumors are not associated with testicular involvement. Primary extragonadal germ cell neoplasms also arise rarely in the sacrum, pineal gland, paranasal sinuses, and liver. Regardless of the stage or extent of disease, the therapeutic objective is cure, which requires an integrated multidisciplinary approach.

EPIDEMIOLOGY

Germ cell tumors are primarily seen in white patients. Risk factors include both abdominal and inguinal cryptorchidism, spermatic or testicular dysgenesis, and a family history that confers a 4- to 10-fold increase in risk.[2] Orchiopexy or surgical correction of abdominal cryptorchidism results in an improved ability to monitor the testis; and treatment of an undescended testis before puberty decreases the risk of testicular cancer as compared to correction after puberty.[3] Factors associated with increased testicular cancer mortality include age older than 40, nonwhite race, and lower socioeconomic status.[4] Testicular seminoma occurs more frequently in men with HIV, and the treatment by stage is the same as for the HIV-negative population.[5] Klinefelter syndrome is a risk factor for the development of mediastinal germ cell tumors. Carcinoma in situ (intratubular germ cell neoplasia) is found in virtually all cases of testicular germ cell tumors. Men in whom in situ disease is identified during a testicular biopsy as part of an infertility evaluation have a 50% risk of an invasive tumor within a 5-year period. A metachronous or synchronous testicular primary germ cell tumor occurs in 2% of patients, with seminoma as the most common histology.[6] Regular self-examination of the remaining testis is recommended.

BIOLOGY

Germ cell tumors are derived from the malignant transformation of premeiotic germ cells. To create a pluripotential tumor, these transformed germ cells must be able to differentiate in a manner similar to the totipotential zygote without the reciprocal genetic information that results from fertilization.[7] An isochromosome of the short arm of chromosome 12—i(12p)—is present

in 80% of all histologic subtypes, including carcinoma in situ and extragonadal tumors. The remaining 20% of cases have excess 12p genetic material as an increase in copy number, tandem duplication, or transposition, which indicates that one or more genes on 12p are involved in malignant transformation. Although the 12p target genes have not been clearly defined, several candidate genes include *CCND2* at 12p13, as well as *SOX5, JAW1,* and *KRAS* mapped to an amplified region at 12p11.2-12.1.[8] Most germ cell tumors are hyperdiploid, often triploid or tetraploid, implying that endoreduplication is important in the early steps of malignant transformation. Based on several studies identifying genetic loci associated with a predisposition to testicular cancer, aberrant KITLG-KIT signaling may be involved in the development of intratubular germ cell neoplasia.[9] Epigenetic regulation including DNA methylation may then have a role in the development of the different histologic subtypes.[10] An integrated analysis of genomewide messenger (mRNA) and micro RNA (miRNA) expression profiles in testicular cancer demonstrated alterations in gene sets implicated in processes related to male reproductive function.[11] Several single-nucleotide polymorphisms (SNPs) within genes involved in gonocyte development have been identified that increase the risk of a germ cell tumor diagnosis.

DIAGNOSIS

A painless testicular mass is highly suggestive of a testicular tumor; however, the majority of patients present with diffuse testicular swelling, hardness, pain, or some combination of these findings. For patients who present with pain, the initial therapy prescribed is often antibiotics for presumed infectious epididymitis or orchitis. Scrotal ultrasonography should be performed when there is any concern about the possibility of a testicular tumor. If the ultrasound is abnormal and a testicular tumor is suspected, a radical inguinal orchiectomy with removal of the testis and ligation of the spermatic cord at the level of the internal ring is performed. Because the testes originate in the genital ridge and migrate through the abdomen and inguinal canal into the scrotum, the vascular and lymphatic drainage of the testes is to the renal or great vessels and the retroperitoneal nodes, respectively. A testicular biopsy or transscrotal orchiectomy is contraindicated because the normal vascular and lymphatic drainage is disturbed. Levels of alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG), and lactate dehydrogenase (LDH) also should be determined. Less common presentations include gynecomastia (as a result of elevated levels of HCG), back pain related to retroperitoneal nodal disease, superior vena cava syndrome from primary mediastinal tumors, and hemoptysis from extensive pulmonary metastases.

PATHOLOGY

Germ cell tumors are classified histologically into seminomas and nonseminomas. Seminomas, which account for approximately half of testicular germ cell tumors, retain totipotentiality and are exquisitely sensitive to radiation and chemotherapy. Nonseminomas are composed of the following cell types: embryonal carcinoma, teratoma, choriocarcinoma, and yolk sac tumors.[12,13]

Table 11-1 shows the World Health Organization (WHO) Classification for Germ Cell Tumors.[14] Embryonal carcinoma is the most undifferentiated, with totipotential capacity to differentiate into extraembryonic malignant cell types, such as yolk sac tumors and choriocarcinoma, and somatic cell types, such as teratoma. Teratoma is composed of somatic cells from two or more germ cell layers (i.e., ectoderm, mesoderm, or endoderm), and thus can differentiate into tissue types such as cartilage, muscle, mucinous glandular epithelium, and

others. The presence of any component of nonseminoma with seminoma is treated as a nonseminomatous germ cell tumor. In addition, an abnormal serum AFP level is not seen in seminoma and indicates a nonseminomatous germ cell tumor. Most nonseminomas show mixed histologies, including embryonal carcinoma, yolk sac tumors, teratoma, and choriocarcinoma. When reporting histology, all subtypes present must be noted, starting with the most prevalent and ending with the least common component.

Table 11-1 Classification of Germ Cell Tumors

Germ cell tumors derived from germ cell neoplasia in situ
Noninvasive germ cell neoplasia
• Germ cell neoplasia in situ
• Specific forms of intratubular germ cell neoplasia
Tumors of a single histologic type (pure forms)
• Seminoma
• Seminoma with synctiotrophoblast cells
• Nonseminomatous germ cell tumours
• Embryonal carcinoma
• Yolk sac tumor, postpubertal-type
• Trophoblastic tumours
◦ Choriocarcinoma
◦ Nonchoriocarcinomatous trophoblastic tumours
◦ Placental site trophoblastic tumour
◦ Epithelioid trophoblastic tumour
◦ Cystic trophoblastic tumour
• Teratoma, postpubertal-type
• Teratoma with somatic-type malignancy
Nonseminomatous germ cell tumors of more than one histologic type
• Mixed germ cell tumours
Germ cell tumors of unknown type
• Regressed germ cell tumours
Germ cell tumors unrelated to germ cell neoplasia in situ
• Spermatocytic tumor
• Teratoma, prepubertal-type
◦ Dermoid cyst
◦ Epidermoid cyst
◦ Well-differentiated neuroendocrine tumour (monodermal teratoma)
• Mixed teratoma and yolk sac tumor, prepubertal-type
• Yolk sac tumor, prepubertal-type

Adapted from 2016 WHO Classification of Tumours of the Urinary System and Male Genital Organs-Part A: Renal, Penile, and Testicular Tumours. Eur Urol. 2016 Jul; 70(1): 93-105 with permission from Elsevier.

Seminomas are positive for placental alkaline phosphatase (PLAP), CD117 (c-kit), OCT-4, and SALL-4. They are negative for cytokeratins and CD30. Embryonal carcinoma, however, almost universally expresses cytokeratins, epithelial membrane antigen (EMA), CD30, OCT-4, and SALL-4; approximately 50% express PLAP. Yolk sac tumors are positive for cytokeratins,

AFP, and SALL-4, but negative for CD117 and CD30. Immunohistochemical analysis and testing for i(12p) may be useful in the evaluation of patients with midline tumors of uncertain histogenesis.

PATTERNS OF SPREAD

The primary lymphatic drainage for testicular germ cell tumors is to the retroperitoneal lymph nodes (primary landing zones). The right testicular artery originates from the aorta, and the right testicular vein drains into the inferior vena cava. The left testicular artery originates near the left renal artery, and the left testicular vein terminates in the left renal vein. Right-sided tumors spread to the interaortocaval lymph nodes immediately below the renal blood vessels, and left-sided tumors spread to the para-aortic lymph nodes immediately below the left renal artery and vein. Cross-metastases are more commonly seen from right to left. Invasion of the epididymis or spermatic cord may be associated with iliac nodal involvement, and inguinal metastases may be seen with scrotal invasion or if there has been disturbance of the normal lymphatic drainage related to prior surgery. Additional metastatic sites include retrocrural, mediastinal, and supraclavicular lymph nodes; the lungs; and, less commonly, the liver, central nervous system, and bone.

STAGING

Pretreatment Evaluation

The extent of disease evaluation for patients with newly diagnosed germ cell tumors includes a chest x-ray, computed tomography (CT) of the abdomen and pelvis, and tumor markers. Indications for a CT scan of the chest include an abnormal chest x-ray, known mediastinal disease, and risk for pulmonary metastases. A bone scan and magnetic resonance imaging (MRI) of the brain are indicated only if related symptoms are present. Measurement of tumor markers, including AFP, HCG, and LDH, is used to establish the diagnosis and may assist in determining histologic subtype. Sperm banking should be performed before treatment is pursued.

Stage Groupings

A tumor–node–metastasis (TNM) staging classification system was developed by the American Joint Committee on Cancer (AJCC) and incorporates serum tumor markers, including AFP, HCG, and LDH (Table 11-2).[15] Adverse factors include mediastinal primary site; degree of elevation of AFP, HCG, and LDH; and presence of nonpulmonary visceral metastases. Based on these findings, advanced germ cell tumors are risk-stratified as follows: good risk, accounting for 60% of germ cell tumors and resulting in a 5-year survival rate of 91%; intermediate risk, accounting for 26% of germ cell tumors and a 5-year survival rate of 79%; and poor risk, accounting for 14% of germ cell tumors and a 5-year survival rate of 48%. All seminomas are either good or intermediate risk (Table 11-3).[16] Regardless of the initial risk stratification, patients with advanced germ cell tumors who survive and remain without disease more than 2 years after their diagnosis have an excellent chance of remaining disease-free in subsequent years.[17]

TUMOR MARKERS

Tumor markers are measured before, during, and after treatment. An initial rise in tumor

markers may occur with chemotherapy, particularly in the setting of bulky advanced disease. The serum half-lives of AFP and HCG are 5 to 7 days and 30 hours, respectively, and a slow marker decline after orchiectomy or during chemotherapy implies residual active disease. Elevated or rising AFP and/or HCG levels that occur without radiologic or clinical findings imply active disease and must be managed accordingly. Other conditions associated with elevated AFP levels include hepatocellular carcinoma, liver damage, and other gastrointestinal malignancies. HCG elevations may occur as a result of treatment-related hypogonadism or cross-reactivity with pituitary hormones, including luteinizing hormone. This cross-reactivity is generally less of an issue with current assays specific for the beta subunit of HCG. Hyperthyroidism may be associated with elevated levels of HCG related to cross-reactivity of HCG with the thyroid-stimulating (TSH) receptor. A spurious elevation in HCG also has been associated with marijuana use.[18] With these exceptions, increased levels of AFP are pathognomonic of a nonseminoma and not seen in seminoma, whereas elevated levels of HCG may be seen in both seminoma and nonseminoma. LDH levels can increase for patients with advanced seminoma or nonseminoma and are used for staging and assessment of outcome. Elevations in any one marker or combination are found in approximately 20% of patients with stage I disease, 40% of patients with stage II disease, and 60% or more of patients with stage III disease.

SEMINOMA

Approximately 70% of patients with seminoma have stage I disease. After radical inguinal orchiectomy, standard treatment options include surveillance, adjuvant infradiaphragmatic radiotherapy to include the para-aortic nodes, and single-agent carboplatin, recognizing that approximately 80% of these patients will not have required treatment and that the long-term survival is nearly 100% regardless of the initial option chosen. Observational studies of patients with clinical stage I seminoma indicate a 15 to 20% likelihood of disease relapse, mostly in the retroperitoneum; however, the median time to relapse is 14 months, which is twice as long as for clinical stage I nonseminomatous tumors, and late relapses at greater than 5 years may occur.[19] Based on the excellent outcome for patients with stage I seminoma and the potential for long-term radiation-related toxicity, including secondary malignancies, surveillance represents a preferred strategy for the management of patients with clinical stage I disease.[20-23] Radiation therapy is to be avoided in the setting of inflammatory bowel disease or a horseshoe kidney. Radiotherapy using a para-aortic field as compared with a dogleg field is associated with reduced toxicity and a low rate of recurrence.[24] A randomized trial comparing radiotherapy with single-dose carboplatin in the adjuvant treatment of stage I seminoma has shown a noninferior relapse-free rate for single-dose carboplatin (AUC 7), with a reduced risk of a second primary germ cell tumor in the carboplatin arm.[25,26] Although chemotherapy represents a potential strategy for the management of clinical stage I disease, concerns have been raised based on the relatively short follow-up period (median, 6.5 years) to evaluate for late relapse and late toxicity.[27,28] In a retrospective report on patients who experienced a relapse after adjuvant carboplatin, 15% of the relapses occurred > 3 years after adjuvant treatment.[29]

Patients with stage IIA and nonbulky IIB disease are treated with 30 to 36 Gy of radiation to the para-aortic and ipsilateral iliac lymph nodes. Chemotherapy is preferred for patients with clinical stage IIB seminoma with bulkier disease. Chemotherapy will cure more than 90% of the patients who experience disease relapse after radiotherapy; approximately 99% of patients

with early-stage seminoma are cured.

Advanced Seminoma

Approximately 10% of patients with seminoma require chemotherapy. Fifteen to 20% of patients with advanced seminoma present with an elevated HCG. An elevated AFP indicates a nonseminomatous tumor, and the patient should be treated accordingly. Patients with retroperitoneal masses larger than 5 cm (stage IIC), supradiaphragmatic lymphadenopathy, visceral disease, bulky retroperitoneal tumors, tumor-related back pain, and mediastinal extragonadal presentations are treated with primary chemotherapy. Approximately 90% of patients with advanced seminoma will be classified as having a good prognosis and receive treatment with good-risk chemotherapy, with an 86% 5-year survival, whereas only 10% of patients have intermediate risk disease. Pure seminomas are never classified as poor risk (see section on Management of Advanced Germ Cell Tumors by Risk Classification).[16]

Table 11-2 **Staging of Testicular Germ Cell Tumors**	
Primary Tumor (T)	
Clinical T (cT)	Note: Except for Tis confirmed by biopsy and T4, the extent of the primary tumor is classified by radical orchiectomy
cTX	Primary tumor cannot be assessed
cT0	No evidence of primary tumor
cTis	Germ cell neoplasia *in situ*
cT4	Tumor invades scrotum with or without vascular/lymphatic invasion
Pathological T (pT)	
pTX	Primary tumor cannot be assessed
pT0	No evidence of primary tumor
pTis	Germ cell neoplasia in situ
pT1	Tumor limited to testis (including rete testis invasion) without lymphovascular invasion (subclassification only applies to pure seminoma)
pT1a	Tumor < 3 cm
pT1b	Tumor ≥ 3 cm
pT2	Tumor limited to testis (including rete tesis invasion) with lymphovascular invasion;
	OR Tumor invading hilar soft tissue or epididymis or penetrating visceral mesothelial layer covering the external surface of tunica albuginea with or without lymphovascular invasion
pT3	Tumor invades the spermatic cord with or without lymphovascular invasion
pT4	Tumor invades the scrotum with or without lymphovascular invasion
Regional Lymph Nodes (N) Clinical	
cNX	Regional lymph nodes cannot be assessed
cN0	No regional lymph node metastasis
cN1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension;
	OR Multiple lymph nodes, none > 2 cm in greatest dimension
cN2	Metastasis with a lymph node mass > 2 cm but not > 5 cm in greatest dimension;
	OR Multiple lymph nodes, any one mass > 2 cm but not > 5 cm in greatest dimension
cN3	Metastasis with a lymph node mass > 5 cm in greatest dimension
Pathologic (pN)	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension and ≤ 5 nodes positive, none > 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass > 2 cm but not > 5 cm in greatest dimension;
	OR > 5 nodes positive, none > 5 cm in greatest dimension; or evidence of extranodal extension of tumor

Pathologic (pN)	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension and ≤ 5 nodes positive, none > 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass > 2 cm but not > 5 cm in greatest dimension;
